# CHAPTER 3 - AFFECTED ENVIRONMENT AND ENVIRONMENTAL CONSEQUENCES

## 3.1 INTRODUCTION AND BACKGROUND

This chapter presents both the affected environment and environmental consequences, as required by the National Environmental Policy Act (NEPA). It is organized by resource topic, with the status of the affected environment described first, followed by the impacts of each alternative described within each resource section. Each resource has defined the area of analysis consistent with where that resource may experience effects.

The affected environment sections provide a description of different aspects of the human environment that may be affected by the No Action Alternative and four Multiple Objective Alternatives (MOs). The environmental consequences sections provide a description of the impact assessment methodologies, and potential direct and indirect effects. Many natural resources are of importance both currently and historically to Native American tribes. As such, effects to these resources, and relationships to tribal interests, are discussed within each applicable resource section as well as in sections such as Indian Trust Assets, Tribal Perspective and Tribal Interests, and Cultural Resources.

Effects can be short-term or long-term, and beneficial or adverse. The analysis focuses only on those resources of the human and natural environment which are likely to be affected by the alternatives under consideration. The time scale used for the comparative analysis of the four MOs to the No Action Alternative is a 25-year period from 2020 to 2045. For the purposes of conducting the economic analysis, a 50-year period of analysis is used to better capture the full array of changing costs and investments, and represent the total costs, benefits, and tradeoffs being evaluated in each of the MOs. This economic analysis also would be able to distinguish between short-term impacts that may occur during the implementation of alternatives, with initial investments, versus the long-term effects that would occur after implementation is completed. For comparing effects of each alternative, the assumption for analysis in the environmental impact statement (EIS) is that any alternative would be implemented immediately after the Records of Decision (RODs) are signed, recognizing certain structural and mitigation measures may take time to implement. This side-by-side temporal evaluation provides a better point of comparison of effects to resources to inform the analysis and agencies' decisions.

There are other factors that influence the effects to resources, and could change the significance determinations of effects. The influence of climate variability could exacerbate effects of an alternative on a resource when cumulatively considered. This is presented in Chapter 4, Climate. The mitigation development process, and proposed mitigation to avoid, minimize, or replace resources, is presented in Chapter 5, Mitigation. Described separately from direct and indirect effects, cumulative effects further considers the effects of each MO in the context of reasonable foreseeable future actions and climate change. This analysis is included in Chapter 6, Cumulative Effects.

Consistent with the Council on Environmental Quality's Implementing Regulations for NEPA (40 Code of Federal Regulations [C.F.R.] § 1502.16), adverse environmental effects that cannot be avoided, the relationship between short-term uses of the environment and the maintenance and enhancement of long-term productivity, and any irreversible or irretrievable commitments of resources involved in implementation, are presented in separate sections at the end of this chapter.

The Council on Environmental Quality (CEQ) regulations for implementing NEPA (40 C.F.R. § 1508.8) define the following impact categories:

- **Direct Effects**: caused by an action included in an alternative and occurring at the same time and place.
- **Indirect Effects**: caused by an action included in an alternative but would occur later in time or farther removed in distance.
- **Cumulative Effects**: caused from incremental impact of an action added to other past, present, and reasonably foreseeable future actions.

Effects are described as either *beneficial* or *adverse*. Beneficial effects or impacts result in a positive change in the condition of the resource when compared to the No Action Alternative. Adverse effects or impacts result in a negative change in the condition of the resource when compared to the No Action Alternative. Impacts are also described in terms of duration. *Temporary* or *short-term effects* would not persist for the duration of the management action or would only occur for a limited time after implementation of the action (or both). Temporary impacts can be reoccurring such as in the case of flow actions that occur at different intervals over time. *Long-term effects* would be permanent or continuous over the period of analysis.

Finally, impacts are described in relation to their significance. The CEQ regulations require consideration of both context and intensity when determining the significance of an effect on a resource. Context means considering the extent of the effect such as in a national, regional, or local setting (see 40 C.F.R. § 1508.27(a)).

The following factors can be considered in determining the intensity or severity of an effect (40 C.F.R. § 1508.27):

- Impacts that may be both beneficial and adverse. A significant effect may exist even if the Federal agency believes that on balance the effect will be beneficial.
- The degree to which the proposed action affects public health or safety.
- Unique characteristics of the geographic area, such as proximity to historic or cultural resources, park lands, prime farmlands, wetlands, wild and scenic rivers, or ecologically critical areas.
- The degree to which possible effects on the human environment are uncertain or involve unique or unknown risks.
- The degree to which the action may establish a precedent for future actions with significant effects or represents a decision in principle about a future consideration.
- Whether the action is related to other actions with individually insignificant but cumulatively significant impacts. Significance exists if it is reasonable to anticipate a

cumulatively significant impact on the environment. Significance cannot be avoided by terming an action temporary or by breaking it down into small component parts.

- The degree to which the action may adversely affect districts, sites, highways, structures, or objects listed in or eligible for listing in the National Register of Historic Places (NRHP) or may cause loss or destruction of important scientific, cultural, or historic resources.
- The degree to which the action may adversely affect an endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act (ESA).
- Whether the action threatens a violation of Federal, state, or local law or requirements imposed for the protection of the environment.

The following descriptors are used in the body of this chapter to describe the level of effect to the various resources affected by the MOs, as compared to the No Action Alternative:

- **No Effect**: The action would result in no effect as compared to the No Action Alternative.
- **Negligible Effect**: The effect would not change the resource character in a perceptible way. Negligible is defined as of such little consequences as to not require additional consideration or mitigation.
- **Minor Effect**: The effect to the resource would be perceptible; however, it may result in a small overall change in resource character.
- **Moderate Effect**: The effect to the resource would be perceptible and may result in an overall change in resource character.
- **Major Effect**: The effect to the resource would likely result in a large overall change in resource character.

The rationale for why an impact is considered to fall under one of the preceding intensity descriptors is included in each resource section. Statements of significance are supported by text describing the context and intensity of the impact.

This section also provides information relevant to the decision process for selecting the Preferred Alternative, described in Chapter 7. The analysis investigates the potential for activities associated with the four MOs to affect the various resources and provides a comparative assessment of each alternative's expected effect on the environment. The assessment of environmental effects is based on a comparison of the No Action Alternative and related MOs; in this case, the four MOs that were brought forward from the alternative development process (Chapter 2) are compared to the No Action Alternative.

The analysis considers the following factors to determine whether effects are negligible, minor, moderate, or major:

- **Context:** The geographic scope of the effect or size of the population affected, for example whether effects are localized to a project site or would occur broadly across the region.
- **Intensity:** Relative magnitude of the effect as compared with the No Action Alternative.

- **Duration:** Persistence of the effect over time. The analysis considers whether effects are short term (such as those limited to a construction period) or long term.

### 3.1.1 Assumptions

The effects analysis of each resource is based on best available existing information including, but not limited to, the following: quantitative modeling, studies, and reports relevant to the project area, and co-lead agency expertise.

Estimated condition under the No Action Alternative and MO conditions is based on extrapolation of current trends and consistent with current laws, regulation, and policies.

For purposes of comparing MOs and developing preliminary costs, the EIS assumes that (1) operations under the MOs, including the measures in MO3 that include lower Snake River projects embankment breach, would be initiated at the signing of the RODs and (2) the construction period for these structural measures would occur over 2 consecutive years.

The analysis considers the following assumptions for implementation of dam breach:

- Lower Granite and Little Goose Dams would be breached in year 1, followed by Lower Monumental and Ice Harbor Dams in year 2.
- Drawdown rate of 2 feet per day maximum evacuation rate for safety purposes and to prevent damage to infrastructure adjacent to each reservoir.
- Construction (demolition) to begin in August (low water) and last through January to reduce safety risks and minimize impacts to ESA-listed fish.
- Embankment excavation duration ranges from 28 to 60 days, depending upon site conditions at each location.
- Modifications at the dams could begin prior to start of excavation.

Given the uncertainty over if, or when, Congress might authorize dam breach in MO3, these assumptions were necessary to establish a reference condition to evaluate the likely effects of MO3.

### 3.1.2 Resources Screened from Further Analysis

Consistent with 40 C.F.R. § 15017(a)(3), land use was screened from further analysis because it was not identified as a significant issue during the scoping process, was not anticipated to have adverse or beneficial changes with implementation of any MO, and thus was not analyzed as a stand-alone resource. Where direct and indirect land-use impacts surfaced during the analysis of impacts to other resources, such as for water supply (Section 3.12), potential changes in land use are described in that section.

### 3.1.3 Summary of Environmental Consequences

Table 3-1 summarizes the expected effects on resources analyzed for each of the MOs, as compared to the No Action Alternative. The remainder of this section discusses the evaluations that resulted in these expectations.

**Table 3-1. Summary of Expected Effects by Multiple Objective Alternative**

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
| --- | --- | --- | --- | --- | --- |
| Hydrology and Hydraulics | Same or similar to affected environment. All CRS projects are modeled to represent the current 2016 operating rules and constraints. | Moderate changes in reservoir levels can occur seasonally at Libby, Hungry Horse, Grand Coulee, and Dworshak Dams, with major differences from the NAA occurring in some high and low forecast years. The largest changes typically occur in winter and spring months, with the exception of at Dworshak Dam where the changes occur in the summer. Minor changes in operating levels occur at the four lower Snake River projects and the four lower Columbia River projects. There are no changes in minimum and maximum reservoir levels at any of the reservoirs.<br>Moderate changes in river flow can occur on the Kootenai River downstream of Libby Dam in the winter and early spring, and minor changes occur on the Flathead River below Hungry Horse Dam in the winter, early spring, and late summer. Moderate to major flow changes can occur immediately downstream of Dworshak Dam and on the Clearwater River in August and September, leading to minor to moderate changes through the lower Snake River and negligible to minor changes through the lower Columbia River. Changes to seasonal storage result in relatively large flow changes below Grand Coulee Dam, but the percent change in total flow is negligible to moderate. | Moderate changes in reservoir levels occur at Libby, Hungry Horse, Grand Coulee, and Dworshak Dams, with major change occurring during some high and low forecast years at Libby and Dworshak. The largest changes typically occur in late winter through the spring months. Lower Snake dams and John Day can be operated at slightly higher pools in the spring through summer months. There are no changes in minimum and maximum reservoir levels.<br>Moderate changes in river flow can occur in the Kootenai River below Libby, with a notable increase in November and December and decreases in January and May. On the Flathead River below Hungry Horse Dam and the Clearwater River below Dworshak Dam, major flow increase can occur in January followed by minor decreases in flow through the spring. These changes are diluted to minor or moderate changes in the rivers downstream (e.g., the Pend Oreille River, lower Snake River, and lower Columbia River). Minor increases in flow can occur below Grand Coulee in the winter, followed by negligible decreases in the spring and summer. | Moderate changes in reservoir levels occur at Libby and Hungry Horse Dams, with major change occurring during some high and low forecast years at Libby Dam. There are negligible changes to Lake Roosevelt water levels and no changes at Dworshak Dam. John Day Dam has a minor increase in water levels in the spring, otherwise no changes. There are no changes in minimum and maximum reservoir levels at any of the storage projects, but water levels in the four lower Snake River dams are dramatically lowered as the step-reservoir system is converted to a free-flowing river reach.<br>Moderate changes in river flow can occur in the Kootenai River below Libby, with notable increase in November and December and decreases in January and May. Minor changes in flow occur on the Flathead River below Hungry Horse Dam in the winter, early spring, and late summer. Below Grand Coulee Dam, there are minor increases in November and December river flow, and minor decreases later in the year, particularly in dry years. These translate to very minor to negligible decreases further downstream below McNary Dam.<br>On the lower Snake River, changes to flow amounts would be minor since the four lower Snake River dams are run-of-river projects, not storage projects. However, without the reservoirs, the water particle travel time through the reach could be reduced by an order of magnitude. | Moderate changes in reservoir levels can occur seasonally at Libby, Hungry Horse, and Grand Coulee Dams, in high and low forecast years. Major changes are in the summer during low water years at Grand Coulee, Hungry Horse, Albeni Falls, and Libby Dams to support McNary Dam augmentation. Minor changes occur in the lower Snake River projects and the four lower Columbia River dams, respectively, in the spring-summer months.<br>Moderate changes in river flow can occur in the Kootenai River in the winter and spring months. Minor changes in flow occur on the Flathead River below Hungry Horse Dam in the winter, early spring, and late summer. In low water years, moderate flow changes occur below Libby and Hungry Horse Dams in the summer, and at Albeni Falls Dam in June and September. Below Grand Coulee Dam, flow changes are typically negligible but minor changes are common in lower flow years. Minor flow changes can occur through the lower Columbia River in lower water years, especially in May through July. |

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| River Mechanics | Negligible change | Minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream into Lake Roosevelt, although available deposit volume is limited.<br>Minor decrease in the amount of sediment passing the Clearwater River at the confluence of the Snake and Clearwater Rivers.<br>Minor amount of coarsening of bed sediment at the head of Lake Roosevelt.<br>Minor (less than 1% change) in average annual volume of sediment depositing in the Snake River FNC and LCR FNC.<br>For the other metrics, the effects would be negligible. | Minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream into Dworshak Reservoir.<br>Minor amount of coarsening of bed sediment at the head of Lake Roosevelt.<br>Minor (less than 1% change) in average annual volume of sediment depositing in the Snake River FNC and LCR FNC.<br>For the other metrics, the effects would be negligible. | Due to the Breach Snake Embankments measure, four run-of-river reservoirs would be drawn down and converted to a riverine environment. The current reservoirs contain fine sediment deposits that would partially erode leaving margin sediment on high terraces behind. The new river bottom after breaching would initially become finer and gradually coarsen over the long term. The change in the overall geomorphic character would occur on the Snake and Clearwater Rivers within the backwater extents of Lower Granite Reservoir downstream to the confluence with the Columbia River.<br>Potential for a major increase in the amount of sediment passing downstream of the Snake River into the Columbia River above McNary.<br>Potential for major increase in amount of material depositing in McNary Reservoir.<br>Dredging would stop in the lower Snake River. Minor increase in average annual volume of sediment passing into the lower Columbia below McNary.<br>Effects at the remaining storage project would be negligible. | Minor change in depositional patterns in the Columbia River and Spokane River entering Lake Roosevelt. Minor change in head of reservoir sediment mobilization with deposits becoming coarser in John Day Reservoir.<br>Minor change in shoreline exposure at Hungry Horse Reservoir. Minor amount of bed sediment coarsening in Lake Roosevelt and reaches upstream to the U.S.-Canada border. Minor amount of bed sediment coarsening in Snake River downstream of Ice Harbor Dam. Minor amount of bed sediment coarsening in Columbia River from the Snake River confluence to Wallula, Washington.<br>Minor amount of bed sediment coarsening in Columbia River at the upstream end of John Day Pool. Minor amount of coarsening in Columbia River between John Day Dam and Skamania, Washington.<br>Minor amount of coarsening of bed sediment at the head of Lake Roosevelt. Minor (less than 1% change) in average annual volume of sediment depositing in the Snake River navigation Channel and LCR FNC. |

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| Water Quality | Same or similar to affected environment. | Minor increase in spill and associated TDG levels at Libby Dam due to the project's draft and refill operations.<br>Overall negligible water quality effects in Regions A, B, and D, with the exception of major reductions in TDG below Grand Coulee Dam in Region B.<br>In Region C, moderate adverse effects to water temperature and negligible effects to TDG and other water quality parameters would occur. | In Region A, negligible to minor improvements to water quality would occur. In Region B, negligible water quality effects would occur, with the exception of major reductions in TDG below Grand Coulee Dam. In Regions C and D, negligible effect to water temperatures would occur. In Regions C and D, frequency of exceeding state TDG water quality standards would decrease. | Overall minor effect on water quality in Region A.<br>Negligible to minor overall water quality effect in Region B, with the exception of major reductions in TDG below Grand Coulee Dam.<br>Major short-term adverse effect on water quality due to the mobilization of sediment during dam breaching.<br>Long-term beneficial effect on water quality in Region C, including major reductions in TDG and spring and fall water temperatures, while there would be warmer water temperatures in the summer.<br>Moderate short-term adverse effect on water quality, particularly in McNary Reservoir due to the mobilization of sediment during dam breaching. Long-term negligible to minor beneficial effect on water quality in Region D. | Negligible to minor adverse water quality effects in Regions A and B, with the exception of major reductions in TDG below Grand Coulee Dam. Negligible to major increase in TDG levels in Regions C and D, depending on project. Minor to negligible effects to water temperature in Regions C and D. |
| Anadromous Fish | Same or similar to affected environment | Models predict that returns of salmon and steelhead would be similar to the NAA or higher. Elevated temperatures during summer months would have a negligible to minor adverse effect on Snake River sockeye, fall Chinook and steelhead. In addition, MO1 could have minor adverse effects to chum, and minor beneficial effects for lamprey. These effects on anadromous fish are generally expected to be beneficial with negligible to minor changes as compared to the NAA. | Lower spill would, generally, increase travel time, transportation, and the number of powerhouse encounters for juvenile outmigrants. Modeled species show two separate results. CSS modeling predicts major decreases in survival and adult returns, and major increases in travel time, and powerhouse passage, which would lead to major adverse effects relative to the NAA. By contrast, NOAA modeling predicts minor decreases in survival, and minor increases in travel time and powerhouse passage, but increases in transport result in minor increases in adult returns. Minor beneficial effects for lamprey. These modeled changes under MO2 range from minor beneficial effects to a major adverse effect depending on species and latent mortality assumptions. | In general, anadromous species not migrating to or from the Snake River may see minor changes in passage through the lower Columbia River, while effects to Snake River anadromous species are expected to be a major beneficial effect after short-term major adverse effects associated with dam removal stabilize. Minor beneficial effects for lamprey are expected. | The degree to which the alternative affects anadromous fish varies widely between to the two models used to evaluate benefits. The CSS model predicts the potential for large increases in anadromous salmon and steelhead returns, but the Life Cycle Model predicts that unless latent mortality effects are reduced by more than 10%, the net impact to Snake River Chinook salmon is estimated to be negative. This potential negative effect is also possible for Snake River steelhead based on recent observations of beneficial effects of transport. Snake River sockeye may benefit from reduced levels of transport. Minor beneficial effects for lamprey are expected. Overall, predicted effects from this MO range from moderately negative to major beneficial effect and also vary widely by species. |
| Resident Fish | Same or similar to affected environment. | While MO1 results in both beneficial and adverse effects on resident fish, overall, these effects are expected to be negligible, minor, or in some cases localized moderate as compared to the NAA. | MO2 has minor to major adverse effects in some localized areas due to change in water elevation and flows. Effects in the lower Columbia River would be minor. | Breaching of the lower Snake River projects would have major long-term beneficial effects to resident fish in the Snake River; however, during the breaching, major short-term adverse effects would occur. Effects outside of the Snake River would be similar to MO1. | MO4 has effects ranging from minor to major adverse for resident fish. Changes in upper Basin flow levels and reservoir elevations, particularly in low-flow years are particularly impactful. Region B would also see moderate to major effects, particularly in dry years when Lake Roosevelt would be drawn down deeper and summer outflows would increase. In Regions C and D, resident fish would be affected by increased TDG. |

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| Vegetation, Wetlands, Wildlife, and Floodplains | Same or similar to affected environment | Minor effect to wildlife, vegetation, and wetlands associated with operation of Libby Dam. and negligible effect for other areas in Region A.<br>Minor adverse effect to wildlife habitat and wetland vegetation for Lake Roosevelt. Negligible effects to other areas in Region B.<br>Minor (Dworshak) and negligible change (lower Snake River) to habitat, vegetation, and wildlife in Region C.<br>Negligible effect to habitat, vegetation, and wildlife in Region D.<br>Negligible effects on floodplains in Regions B and C, with minor effects in Region A and D below Bonneville Dam.<br>For special status species, there would be negligible effects. | Moderate effects to Region A.<br>Minor effect to vegetation, wetlands, habitat, and wildlife in Lake Roosevelt. Negligible effect in other locations in Region B.<br>Negligible effects in Regions C. Minor effects in Region D.<br>Minor effects on floodplains in Regions A and B. Negligible in Region C, with minor effects in Region D below Bonneville Dam.<br>For special status species, there would be negligible effects. | Moderate adverse effect on wetlands, vegetation, habitat, and wildlife in Region A.<br>Negligible effects in Region B.<br>In Region C, vegetation, habitat, and wildlife along the existing shorelines would either be lost or change how wildlife utilize the area. However, new vegetation and habitat types along new shoreline would be added associated with dam breaching, resulting in negligible beneficial effects and major negative effects.<br>Negligible effects in Region D.<br>Negligible effects on floodplains in Regions A, B, and D, with major beneficial effects in Region C below Dworshak Dam.<br>For special status species, there would be negligible effects to all except California sea lion and Steller sea lion where they may increase their activity at Bonneville and The Dalles Dam. | Moderate adverse effect on wetlands, vegetation, habitat, and wildlife in Region A and D.<br>Minor effect in Regions B.<br>Negligible effects on wildlife and habitats in Region C.<br>Moderate effects on floodplains in Regions B and C, with minor effects in Region D below John Day Dam.<br>For special status species, there would be negligible effects. |
| Power Generation and Transmissio n | Same or similar to affected environment. Power rates may change over time if there are reductions in regional fossil fuel generation as many coal plants in the region are slated for retirement. | Long-term, moderate, adverse effects on power costs and rates. Hydropower generation from the CRS projects would decrease by 130 aMW (roughly enough to power 100,000 households annually). The FCRPS, which includes the CRS would lose 290 aMW of firm power available for long-term, firm power sales to preference customers under critical water conditions. The reduction in generation would reduce power system reliability, requiring replacement power resources that could cost up to $160 million per year. Bonneville's PPF wholesale power rates would experience upward rate pressure from 6.0% to 8.6%. (Cost uncertainties could cause upward pressure on the PF rate by up to 14%.) Regional average residential retail rates for power would experience upward rate pressure from between +0.62% and +0.74% depending on the applicable scenario, but the effect would be larger for public power customers and range up to +3.4% in some counties. These effects could be greater if fossil fuel generation is reduced under the NAA. | Long-term, moderate beneficial effects on system reliability. Hydropower generation from the CRS projects would increase by 450 aMW (roughly enough to power 360,000 households annually), and the FCRPS would gain 370 aMW of firm power available for long-term firm power sales. This would improve power system reliability and reduce electricity costs. Bonneville's PF wholesale power rates would decrease about 0.8%. (Cost could cause upward pressure on the PF rate by up to 2.7%.) Retail electricity rates would remain similar to the NAA. (If collecting fish for transport at McNary Dam were accomplished with a more cost-effective measure instead of with a powerhouse surface passage structure, Bonneville's wholesale PF rate would experience downward rate pressure by about 4% and retail rates would also experience downward pressure.) The reliability benefits of MO2 would be greater if fossil fuel generation is reduced under the NAA. | Long-term, major, adverse effects on power costs and rates. Hydropower generation from the CRS projects would decrease by 13%, or 1,100 aMW (roughly enough to power 900,000 households annually). The FCRPS would lose 730 MW of firm power available for long-term firm power sales. Bonneville's PF wholesale power rates would experience upward rate pressure by 10% to 19%. (Cost uncertainties could cause upward pressure on the PF rate by up to 50%.) The loss of hydropower generation at Ice Harbor would require that a transmission reinforcement project be in place prior to breaching of the dams, which would cost about $94 million. Regional average residential retail rates for power would experience upward rate pressure between +1.6% and +3.6%, depending on the applicable scenario, but the effect would be larger for public power customers and range up to +8.1% in some counties. These effects would be greater if fossil fuel generation is reduced under the NAA. | Long-term, major, adverse effects on power costs and rates. Hydropower generation from the CRS projects would decrease by 16%, or 1,300 aMW (roughly enough to power 1 million households annually). The FCRPS would lose 870 MW of firm power available for long-term firm power sales. Bonneville's PF wholesale power rates would experience upward rate pressure by 15% to 25%. (Cost uncertainties could cause upward pressure on the PF rate by up to 41%.) The reduction in generation would reduce power system reliability, requiring replacement power resources that would cost up to $580 million per year. Regional average residential retail rates for power would experience upward rate pressure between +2.8% and +3.2%, depending on the applicable scenario, but the effect would be larger for public power customers and range up to +11% in some counties. Effects could be greater if fossil fuel generation is reduced under the NAA. |

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| Air Quality and Greenhouse Gases | Air quality would most likely improve and GHG emissions be reduced over time due to current trends in decarbonization. | Negligible to potentially minor, long-term effects on air quality and GHG emissions. Effects could be adverse or beneficial depending on whether fossil fuel or renewable resources replace reduction in hydropower generation. Short-term minor adverse effects in Region D from localized construction activities. | Minor beneficial air quality and GHG emissions effects from increased hydropower generation. | Long-term, moderate, adverse effects on air quality and GHG emissions from increased fossil fuel power generation, particularly in Region D and in Montana and Wyoming, even assuming resources replacing hydropower are renewables. Minor increases in emissions in Regions C and D from increased commercial truck and rail transport to replace barges.<br>Short-term moderate adverse effects from localized construction activities in Region C. | Long-term, moderate, adverse effects on air quality and GHG emissions from increased fossil fuel power generation, particularly in Montana and Wyoming, even assuming resources replacing hydropower are renewables. Short-term, minor, adverse effects from localized construction activities in Regions A, C, and D. |
| Flood Risk Managemen t | Same or similar to affected environment | No increases in flood risk are anticipated as a result of MO1. Minor decreases in flood risk are possible in some areas, especially due to winter events in Region D. | No increases in flood risk are anticipated as a result of MO2. Minor decreases in flood risk are possible in some areas, especially due to winter events in Region D. | No increases in flood risk are anticipated as a result of MO3. Under MO3, the draining of Lower Granite Reservoir and breaching of the lower Snake River dams would result in no anticipated change in flood risk. | Minor to negligible changes in flood risk are anticipated as a result of MO4. Minor decreases in flood risk are possible in some areas, especially due to winter events in Region D. |
| Navigation and Transportati on | Same or similar to affected environment | MO1 would result in negligible increases in average annual costs for deep draft navigation and shallow draft navigation. Negligible effects to the cruise line industry. Moderate effects would occur to the Inchelium-Gifford Ferry at Lake Roosevelt in wet years. | MO2 would result in negligible increases in average annual costs for deep draft navigation and a minor decrease in costs for shallow draft navigation. Negligible effects to the cruise line industry. Moderate effects would occur to the Inchelium-Gifford Ferry at Lake Roosevelt in wet years. | MO3 would result in major adverse effects related to elimination of commercial navigation on the lower Snake River. Costs of shipping would increase 10% to 33% on average region-wide. Investments in infrastructure may be required. Cruise ship transit to the lower Snake River would not be possible. Additional dredging would be required in the McNary pool to access port facilities for 2 to 7 years. Reductions in regional economic benefits to port cities where cruise line expenditures would have occurred; redistribution of regional demands for material handlers. Adverse effects to accident rates; increased highway traffic and congestion. Minor effects would occur to the Inchelium-Gifford Ferry at Lake Roosevelt in wet years. | MO4 would result in minor increases in average annual costs for deep draft navigation and minor decreases in average annual costs for shallow draft navigation. Negligible effects to the cruise line industry. Moderate effects would occur to the Inchelium-Gifford Ferry in wet years. |
| Recreation | Same or similar to affected environment | Negligible to minor effects on water-based recreation with the exception of localized, moderate adverse effects to recreation fishing along the Clearwater River in August and September. Overall, however, effects to quality of recreation experience related to fishing, hunting, wildlife viewing, swimming, and water sports at river recreation sites would be negligible. | Negligible to minor effects on water-based recreation. Adverse short- and long-term effects of MO2 on recreation would be minor. Minor adverse effects to quality of recreation experience for fishing, hunting, wildlife viewing, swimming, and water sports associated with changing river conditions in river segments below reservoirs. | Negligible to minor effects to water-based recreation visitation and quality in Region A, B, and most of C. Major adverse effects to water-based recreation at the four lower Snake River projects in Region D, as well as water-based recreation on left bank of Lake Wallula (Region C). Some of the adverse effects to reservoir recreation may be replaced to some extent over time, by increased river recreation activities, higher quality recreational experience for fishing, hunting, wildlife viewing, and river-based recreation activities. | Minor to major localized adverse effects to water-based recreation. At Lake Roosevelt minor effects are expected during a typical year, and major localized water-based recreation access effects during dry water year. Major adverse effects could occur in low water years at Lake Pend Oreille due to accessibility issues at private docks and marinas. Changes in the quality of recreational experience are anticipated to be potentially adverse as well as beneficial. |
| Water Supply | Same or similar to affected environment | MO1 does not have any measures that would affect the ability to deliver water to meet current water supply. | MO2 does not have any measures that would affect the ability to deliver water to meet current water supply. | Measures implemented under MO3 could affect delivery of current water supply in Region C, and are expected to result in major effects. Measures implemented under MO3 are expected to have minor effects in Region D. | Overall, MO4 is expected to result in minor effects to water supply in Region D. |

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| Visual | Short-term minor and moderate visual quality effects associated with operational measures. The effects to the casual observer would be minimal; however, sensitive viewers would experience moderate effects. Impacts from structural measures would have a minor effect. | The operational measures under MO1 would have a similar effect as the NAA. There would be a moderate effect to visual quality from new fish passage structures and minor effect from modifications of existing structures in Region D and the lower Snake River projects in Region C. | Same as MO1. | Operational measures would have a similar effect on the view shed and to viewers as the NAA. Modifications to lower Snake River projects would result in a major visual quality effect. Effects to viewers depend on their perspective of these changes, which would be either beneficial or adverse. | The operational measures under MO4 would have a major effect on Lake Koocanusa, Hungry Horse Reservoir, Lake Pend Oreille, and Lake Roosevelt. For all other reservoirs, the visual quality effect, and effect to all viewer groups would be similar to NAA. Structural measures would have the same effect as MO1 |
| Noise | Same or similar to affected environment | Negligible to minor noise effects from structural and operational measures. | Same as MO1. | In Regions A, B, and D, noise effects would be similar to those in MO1. In Region C, breaching of the dams would result in temporary moderate noise effects from construction activities. | Negligible to minor noise effects from structural and operational measures. |
| Cultural Resources | Same or similar to affected environment | Ongoing major effects to cultural resources and tribal interests. Additional major effects to cultural resources at Hungry Horse, Lake Roosevelt, and Dworshak reservoirs. There is the potential for major effects to the sacred site, Kettle Falls, if changes in reservoir elevations result in increased looting. | Ongoing major effects to cultural resources and tribal interests. Additional major effects to cultural resources at Dworshak and Lake Roosevelt. There is the potential for major effects to the sacred site, Kettle Falls, if changes in reservoir elevations result in increased looting. | Ongoing major effects to cultural resources and tribal interests. Potential for additional major adverse effects to cultural resources compared to the NAA in the lower Snake River due to potential exposure of 14,000 acres currently inundated. The exposure of the traditional cultural properties would allow for some traditional uses that have not been possible since the dams were built. There is also the potential for additional major adverse effects to cultural resources at Hungry Horse Reservoir. | Ongoing major effects to cultural resources and tribal interests. Additional major effects to cultural resources at Lake Roosevelt, John Day, and Hungry Horse. Additional moderate effects at the remaining lower Columbia River projects due to additional drawdown. There is the potential for major effects to Kettle Falls (sacred sites) if changes in reservoir elevations cause increased looting. Changes in reservoir elevation at Albeni Falls may result in a decrease of access to Bear Paw Rock, which may result in less tribal visitation or access to the site. |
| Indian Trust Assets, Tribal Perspectives, and Tribal Interests | Same or similar to affected environment | Negligible to minor beneficial effects to tribal interests and resources (anadromous and resident fish) with some localized minor to moderate negative effects to resident fish. No direct or indirect effects to ITAs. | Minor to major negative effects to tribal interests and resources, especially anadromous fish and associated harvest rights. No direct or indirect effects to ITAs. | Major beneficial effects to tribal interests and resources for lower river and Snake River Basin tribes. Dam breaching and restoring free flowing sections of river is discussed favorably in many tribal perspectives submittals. Negligible to minor effects for upper basin tribal interests and resources. No direct or indirect effects to ITAs. | Uncertain effects to key tribal interests and resources, specifically anadromous fish, and moderate to major adverse effects to upper basin tribal resources such as resident fish, wildlife, wetlands, and vegetation. No direct or indirect effects to ITAs. |

| Resource | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| Environmental Justice | Same or similar to affected environment | Through analysis considering effects detailed in Chapter 3, Affected Environment and Environmental Consequences; Chapter 4, Climate; Chapter 5, Mitigation; and Chapter 6, Cumulative Effects, there would not likely be a disproportionately high and adverse effect on environmental justice populations for MO1. | Through analysis considering effects detailed in Chapter 3, Affected Environment and Environmental Consequences; Chapter 4, Climate; Chapter 5, Mitigation; and Chapter 6, Cumulative Effects, there would not likely be a disproportionately high and adverse effect on environmental justice populations for MO2. | Through analysis considering effects detailed in Chapter 3, Affected Environment and Environmental Consequences; Chapter 4, Climate; Chapter 5, Mitigation; and Chapter 6, Cumulative Effects there would not likely be a disproportionately high and adverse effect on environmental justice populations for MO3. | Through analysis considering effects detailed in Chapter 3, Affected Environment and Environmental Consequences; Chapter 4, Climate; Chapter 5, Mitigation; and Chapter 6, Cumulative Effects there, would not likely be a disproportionately high and adverse effect on environmental justice populations for MO4. |
| Total Annual-Equivalent Costs for the Alternatives (2019 $) | $1,055 million | $1,076 million | Low estimate = $1,108 million<br>High estimate = $1,161 million | Low estimate = $897 million<br>High estimate = $1,002 million | Low estimate = $1,000 million<br>High estimate = $1,105 million |

## 3.2 HYDROLOGY AND HYDRAULICS

### 3.2.1 Introduction and Background

The term hydrology and hydraulics (H&H) is commonly used in a general manner to discuss the quantity, movement, or behavior of water. The hydrologic and hydraulic characteristics discussed in this H&H Affected Environment and Environmental Consequences sections relate to surface water conditions: flow rates in rivers, and water levels in reservoirs and rivers.

The section describes the climate of the CRS, the characteristics of the river system organized in four separate regions, how reservoirs in the CRS are operated together, and water level characteristics on a reach-by-reach basis.

#### *3.2.1.1 Columbia River Basin Description*

The Columbia River drains approximately 258,000 square miles. The drainage area comprises most of Washington, Oregon, and Idaho; the western quarter of Montana; the southeastern corner of British Columbia; and small portions of Wyoming, Nevada, and Utah. Although only 15 percent of the river's basin lies in Canada, 38 percent of the average annual flow volume (as measured at The Dalles, Oregon) originates in Canada. In addition, up to 50 percent of the peak flood waters in the lower Columbia River between Oregon and Washington originate in Canada and result from snowmelt in the upper Columbia River Basin. Its average annual runoff is 198 million acre-feet (Maf), as measured at the river's mouth.

The Columbia River originates in British Columbia, Canada, and flows 1,204 miles through Canada and the United States to the Pacific Ocean (456 miles in British Columbia and 748 miles in the United States)[1] (Figure 3-1). The river begins in Columbia Lake on the west slope of the Rocky Mountain Range in British Columbia and enters the United States in the northeastern corner of the state of Washington. The river then flows south and west, then southeasterly to its confluence with the Snake River near Richland, Washington. It turns westward for 320 miles, forming the Washington-Oregon border before flowing into the Pacific Ocean near Astoria, Oregon. Its largest tributary, the Snake River, travels 1,038 miles from its source in Yellowstone National Park in Wyoming before joining the Columbia River.

Major tributaries of the Columbia River include the following:

- The Kootenai River, which originates in British Columbia, Canada, and flows through Montana and Idaho before joining the Columbia River in British Columbia.
- The Flathead River, which originates in British Columbia and Montana and flows through Montana, draining into the Clark Fork River, which flows into Lake Pend Oreille.
- The Pend Oreille River, which originates at the outlet of Lake Pend Oreille and flows through Idaho and Washington before joining the Columbia River in British Columbia.
- The Yakima, Spokane, Okanogan, Wenatchee, and Methow Rivers in Washington.

[1] River miles and reach lengths from the Corps' Columbia River Basin modeling schematic.

- The Snake River, which originates in Wyoming and flows primarily through Idaho. Tributaries of the Snake River include the Clearwater River and the Salmon River.
- The John Day River and Deschutes River in Oregon, which join the Columbia River upstream of John Day Dam and The Dalles Dam, respectively.
- The Willamette River in Oregon; the MOs do not include any specific actions that would require the Willamette projects (in most subsequent cases in this chapter, "project" is used to collectively refer to a dam and its associated reservoir) to operate outside their normal ranges.

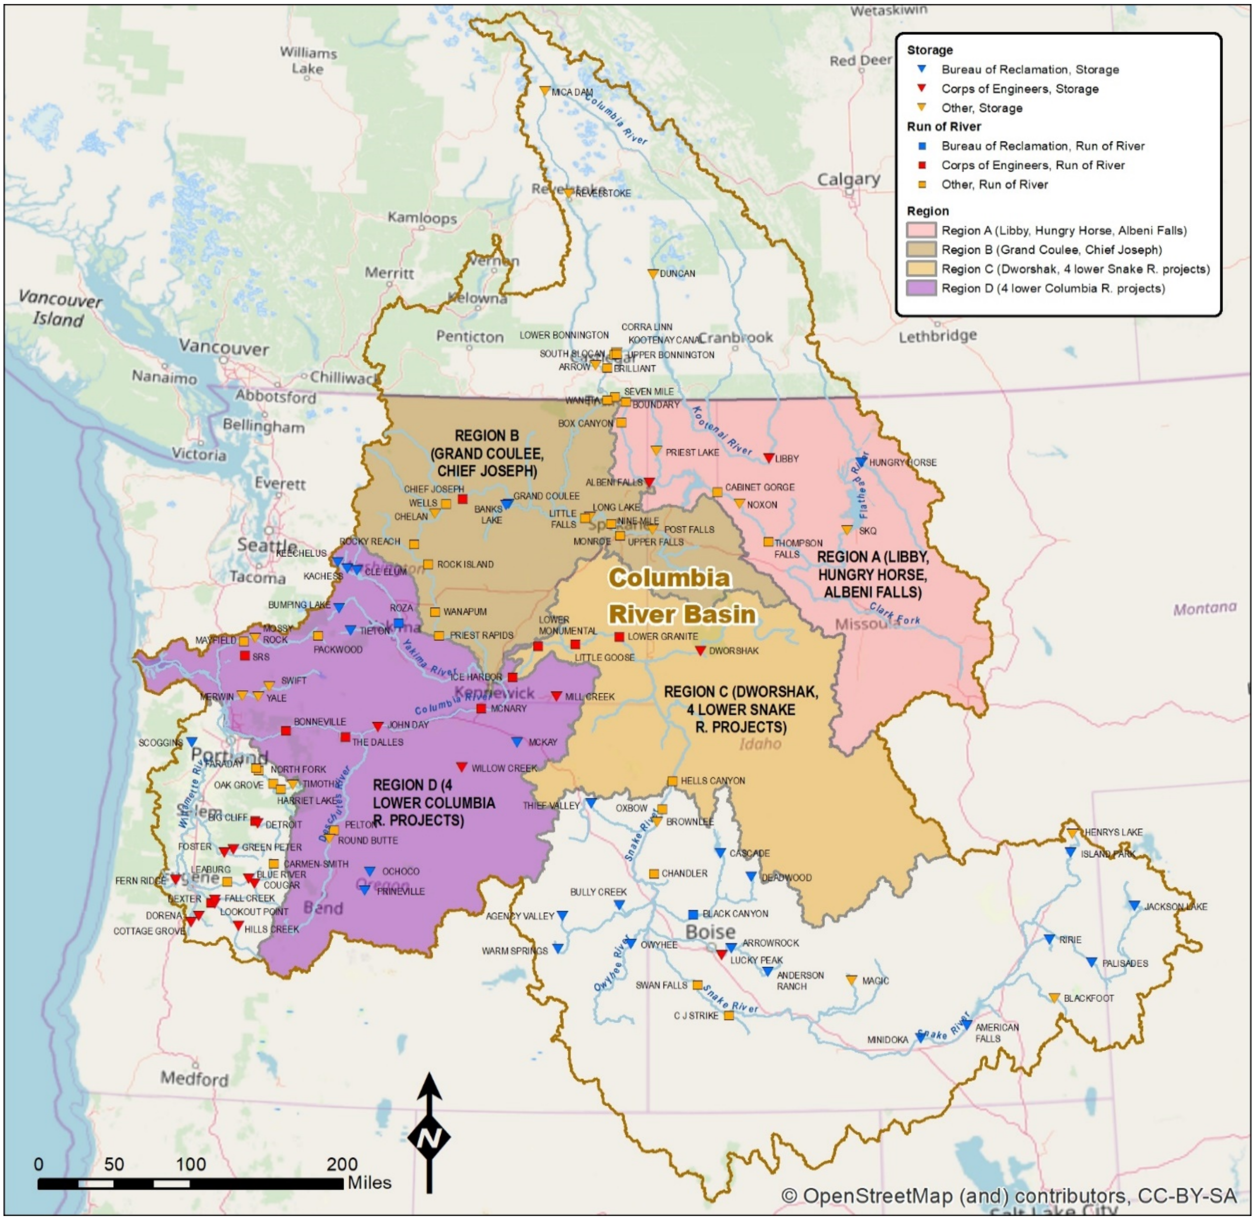

**Figure 3-1. Columbia River Basin**

Note: Many dams besides the 14 CRS projects are shown here to illustrate the complex system of dams in the Columbia River Basin.

Where the river meets the coast, saltwater intrusion from the Pacific Ocean extends approximately 23 river miles upstream from the mouth; tidal effects can be experienced on the Columbia River up to Bonneville Dam, located 146 river miles inland.

#### *3.2.1.2 Columbia River Basin Climate*

The climate in the Columbia River Basin ranges from a moist, mild maritime condition near the mouth of the river to a relatively cool desert climate in some of the inland valleys of eastern Oregon and southern Idaho. The Columbia River Basin is influenced by a modified west coast marine and continental climate, which varies with elevation and proximity to mountain ranges.

In the mountainous regions, most of the precipitation falls during the late fall and winter months, though there can also be wet springs and early summers as heavy rains and occasionally severe thunderstorms affect the region. The headwaters of the Columbia River and its major tributaries are in high-elevation and snow-dominant watersheds. Snow-dominant watersheds are sufficiently cold in the winter to allow for precipitation to fall in the form of snow and for that snow to accumulate and remain until temperatures rise in the spring and summer. High-elevation summers tend to be short and cool, while the lower-elevation interior regions are subject to greater temperature variability.

The north-south Cascade Range, the Blue and Wallowa Mountains of northeast Oregon, and the Rocky Mountains at the eastern and northern boundaries of the basin strongly influence climate in the Columbia River Basin. The basin has dramatic elevation changes ranging from sea level to more than 10,000 feet in the high mountains. The Cascade Range separates the coast from the interior of the basin and has a strong influence on the climate of both areas. The basin is generally cooler and wetter on the western side of the Cascades and warmer and drier to the east toward the Rocky Mountains. The two important runoff patterns in the basin are the snowmelt runoff in the interior east of the Cascade Range and the rainfall runoff of the coastal drainages west of the Cascades. Marine influences are strongest during the winter and cause most of the winter snowfall when warm moist air from the Pacific Ocean is cooled as it is forced to ascend over mountainous terrain in the upper basin or when there is frontal contact with Arctic air masses.

Most of the annual precipitation in the basin occurs in the fall through early spring, with the largest share falling as snow in the mountains. This moisture, stored during the winter as snowpack, is released as snowmelt in the spring and early summer. Stream flow in the Columbia River typically begins to rise in mid-April, reaching a peak flow during May or early June. About 60 percent of the natural runoff in the basin occurs during May, June, and July. The Columbia River has an average annual runoff volume at its mouth of about 198 Maf and an average annual flow of 273,500 cubic feet per second (cfs).

Chapter 4 provides an overview of projected changes in future regional climate and assesses how these projected changes may impact resources and the effectiveness of the MOs. Refer to Section 4.1.2 for projected changes in climate compared to the historical period for the Columbia River Basin including air temperature, precipitation, snowpack, and streamflow.

### 3.2.2 Area of Analysis

The area considered in this hydrology and hydraulics evaluation is the CRS reservoirs and the river reaches downstream. The modeling of the system for this analysis is described in the H&H Appendix (Appendix B) and the Hydroregulation Appendix (Appendix I). The order of discussion goes from upstream locations to downstream locations, and is organized by the physiographic NEPA regions shown in Figure 3-2.

#### *3.2.2.1 Columbia River Basin Region Descriptions*

The CRS consists of subbasins, each having distinct topographic, meteorological, and/or hydrologic characteristics. These subbasins are grouped into four regions, Regions A to D, that are referred to throughout this EIS. The 14 Federal projects in the CRS and their locations are shown in Figure 3-2.

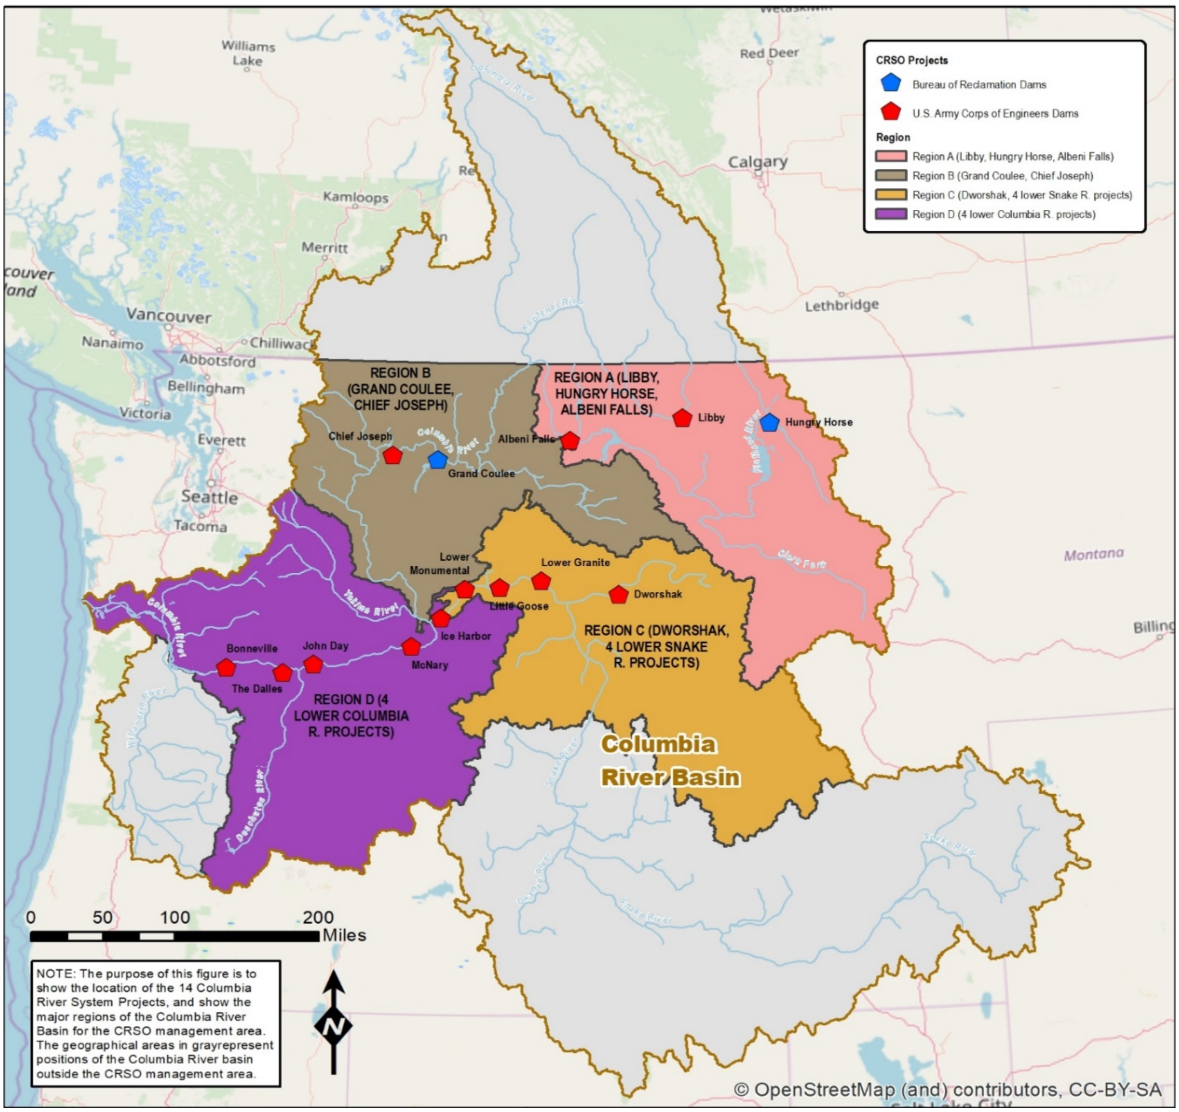

**Figure 3-2. Columbia River Basin Regions (Regions A, B, C, and D)**

**REGION A**

This region includes the portions of the Kootenai and Pend Oreille River Systems that are within the United States. The majority of the Kootenai River System and the Pend Oreille River System region is mountainous, with the Continental Divide forming much of the eastern boundary; the Selkirk Mountains, the north and western boundary; and the Selway-Bitterroot Mountains, the southern boundary. The Cabinet and Purcell Mountains are located in the region. The elevation ranges over 9,000 feet between the mountain peaks and the valley floors scattered throughout the region.

The Kootenai(y) River System is an international system that begins in the Rocky Mountains in British Columbia. From the headwaters, the river flows 173 miles to the U.S.-Canada border, where it flows another 163 miles through Montana and Idaho and loops back to the U.S.-Canada border. From the U.S.-Canada border, the Kootenay River (Canadian spelling) flows another 105 miles in Canada before entering the Columbia River near Castlegar, British Columbia. The Kootenai(y) River has five major tributaries, including the Fisher and Yaak Rivers in the United States; Goat and Duncan Rivers in British Columbia; and the Moyie River, which begins in Canada and enters the Kootenai River near Moyie Springs, Idaho.

The following dams are located within the Kootenai River System: Libby, on the Kootenai River in Montana; Goat on the Goat River in British Columbia; Kootenay Canal Plant, Corra Linn, Upper Bonnington, Lower Bonnington, Slocan, and Brilliant on the Kootenay River in British Columbia; and Duncan Dam on the Duncan River in British Columbia.

The Pend Oreille River System includes over 1,000 miles of river among the North Fork, Middle Fork, South Fork, and mainstem Flathead Rivers, as well as the Clark Fork, Thompson, Pend Oreille, and Priest Rivers. The North, Middle, and South Fork Flathead Rivers join to form the Flathead River, which flows into the Clark Fork River after passing through Flathead Lake. Flathead Lake is a natural lake, but its elevation is mainly controlled by Seli’š Ksanka Qlispe’ (SKQ; formerly known as Kerr) Dam. The Clark Fork River is joined by Thompson River before flowing into Lake Pend Oreille, which flows into the Pend Oreille River. The Pend Oreille River is joined by the Priest River and then turns north, flows into British Columbia where it is called the Pend-d’Oreille (Canadian spelling), and empties into the Columbia River.

There are nine dams in the Pend Oreille River System in the United States: Hungry Horse, on the South Fork Flathead River; SKQ Dam on the Flathead River; Thompson Falls, Noxon Rapids, and Cabinet George on the Clark Fork River; Priest Lake on Priest River; and Albeni Falls, Box Canyon, and Boundary on the Pend Oreille River. On the Pend-d’Oreille River in Canada, there are two: Waneta and Seven Mile.

There are three CRS dams in Region A: Libby Dam, Hungry Horse Dam, and Albeni Falls Dam.

**REGION B**

Region B includes the Spokane River System and the middle Columbia River in the United States. The region is bounded on the north and west by the Cascade Range and borders the

Pend Oreille basin on the east; the Columbia River Plateau dominates the southern landscape in the region. The highest point in the region is in the Cascade Range at approximately 9,500 feet, and the lowest elevation occurs along the Columbia River near Priest Rapids Dam at approximately 400 feet.

The Spokane River System includes the Spokane (140 river miles), St. Joe (44 river miles), and Coeur d'Alene (33 river miles) Rivers. The St. Joe and Coeur d'Alene Rivers flow into Lake Coeur d'Alene, located in northern Idaho, and outflow from the lake forms the Spokane River. Lake Coeur d'Alene is a natural lake, but its elevation is mainly controlled by Post Falls Dam, which is located approximately 8.5 miles downstream from the lake's outlet. There are six dams on the Spokane River below Lake Coeur d'Alene: Post Falls, Upper Falls, Monroe Street, Nine Mile, Long Lake, and Little Falls Dams.

The middle Columbia River has seven major tributaries: the Wenatchee, Chelan, Methow, Okanogan, Sanpoil, Spokane, and Kettle Rivers. There is a diversion from the Columbia River into Banks Lake in this region. Several non-Federal dams are in Region B. On the Columbia River these dams are Priest Rapids Dam, Wanapum Dam, Rock Island Dam, Rocky Reach Dam, and Wells Dam.

There are two CRS dams in Region B: Grand Coulee Dam and Chief Joseph Dam.

**REGION C**

Region C begins just downstream of Ice Harbor Dam, located approximately 9 miles upstream from the confluence of the Snake and Columbia Rivers, and continues upstream along the Snake River to Hells Canyon Dam, located along the Idaho-Oregon border. The region includes the Clearwater River and its tributaries, with Dworshak Dam located on the North Fork Clearwater River. The region is bounded on the east by the Idaho-Montana border, where the Bitterroot and Rocky Mountains dominate the landscape, and on the southwest by the Wallowa and Blue Mountains. The rolling hills and prairies of the Columbia River Plateau dominate the northwest portion of the region. Region C has a mostly semi-arid or desert climate.

The major Snake River tributaries in Region C include the Clearwater, Grande Ronde, Imnaha, and Salmon Rivers.

There are five CRS dams in Region C: Dworshak Dam, Lower Granite Dam, Little Goose Dam, Lower Monumental Dam, and Ice Harbor Dam.

**REGION D**

Region D contains portions of the lower Columbia River Basin, with the furthest downstream dam on the Columbia River being Bonneville Dam. Upstream of Bonneville Dam, the Columbia River is not influenced by tides; downstream of Bonneville Dam, it is.

The reach of the Columbia River from Priest Rapids Dam to Bonneville Dam, most of which is in Region D, is approximately 250 river miles long. The contributing drainage area to the reach is approximately 38,150 square miles. The landscape is diverse, with the Cascade Range on the west; the Blue, Wallowa, and Ochoco Mountains along the south and east; and the Columbia River Plateau defining the middle and northern portion of the drainage area. Five major tributaries join this reach: the Deschutes River, Snake River, John Day River, Umatilla River, and Yakima River.

The reach that is tidally influenced extends from Bonneville Dam (the most downstream dam on the Columbia River) to the mouth of the Columbia River, where it empties into the Pacific Ocean. This reach is approximately 150 river miles long. Excluding the Willamette Region, the contributing drainage area to the reach is 7,340 square miles. It is bounded by the Cascade Range on the north and east, the Willamette River Valley on the south, and the Pacific Ocean on the west.

The principal tributaries joining the Columbia River downstream of Bonneville Dam are the Willamette River, Lewis River, and Cowlitz River. High flows on these three tributaries generally occur during winter storms, from November to March, and account for most of the local runoff below Bonneville Dam.

There are four CRS dams in Region D: McNary Dam, John Day Dam, The Dalles Dam, and Bonneville Dam.

### 3.2.3 Affected Environment

#### *3.2.3.1 Reservoir System*

Since the 1880s, numerous dams—both Federal and non-Federal—have been authorized and built in the basin for flood control, hydropower, fish and wildlife conservation, navigation, recreation, irrigation, municipal and industrial water supply, and water quality.

A figure depicting the range of flows at The Dalles is provided in Figure 3-3, with an overlay of unregulated and observed (regulated) flows from water year 2017. The average annual flow volume at The Dalles is 134 Maf, and the average annual flow is approximately 185,000 cfs[2]. The term “unregulated” is used to describe what the runoff in the river would be without dams[3]. From the figure depicting the range of flows at The Dalles, an annual recurring pattern can be seen, with peak flows occurring in late spring. The figure also shows that during the late spring and early summer, the range of flows between the minimum and maximum lines is greater than any other time of year. This means that there is more variability in natural flows in the system during this time of year than at any other time. The overlay of observed flows for water year 2017 shows the effect of regulation by storage dams in the system. Water year 2017 had a higher than average annual runoff volume of 164 Maf. Despite having a higher than average

[2] The most recent 30-year period is from 1981 to 2010; these averages are updated decennially and the next update will occur in 2021 for the 1991 to 2020 period.
[3] Unregulated streamflow is calculated by removing the effects of reservoir regulation from observed timeseries. This systematic reconstruction of unregulated historical flow has been developed for 1928 to 2008 in the 2010 Modified Flows dataset. See the Appendix B, Part 4, *Hydrologic Data Development,* for further detail.

runoff volume, it is still a typical depiction of how the timing of streamflow on the Lower Columbia Reach is affected by upstream storage dams.

The water levels behind storage dams are lowered during the winter months through early spring to make room to prepare to capture high spring runoff; during this period day to day reservoir discharge is also managed to support other purposes. During the winter, reservoirs are also sometimes drafted to maintain minimum flow or stage requirements downstream of each reservoir or in the lower Columbia River. In the late spring through early summer, flows begin to increase and reservoirs are operated to manage flood risk downstream of each reservoir, as well as in the lower Columbia River, and to refill. During the summer and into early fall, reservoirs are drafted to provide additional flow for fish.

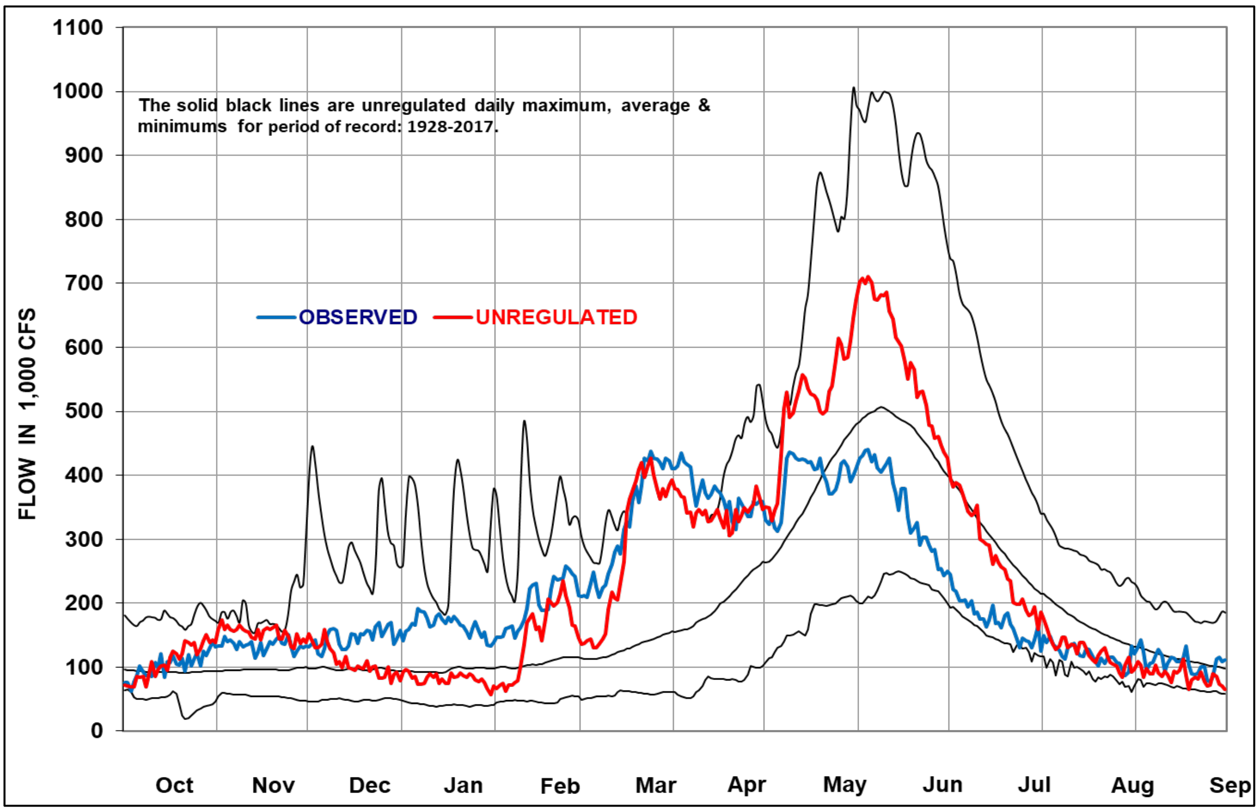

**Figure 3-3. Columbia River Stream Flows as Measured at The Dalles, Oregon, October 2016–September 2017**

Note: Figure source is U.S. Entity and Canadian Entity (2017), simplified by the Corps for clarity.

#### *3.2.3.2 Water Levels Between Projects*

Water levels throughout this system are strongly influenced by the many dams, to the extent that the water surface profile throughout the study area can largely be described as a series of reservoirs. There are only a handful of relatively steep stretches of river that are above the influence of a downstream dam and/or reservoir. Figure 3-4 shows water surface profiles for most of the major rivers evaluated in this study for changes in water levels. The rivers are divided into hydraulic reaches, each of which has an assigned reach number, and they are shown here to introduce the reader to the numbering convention and geographic extent of each reach. Several technical teams involved with CRSO EIS environmental consequences evaluations use this reach numbering system to describe effects that would be associated with the various MOs.

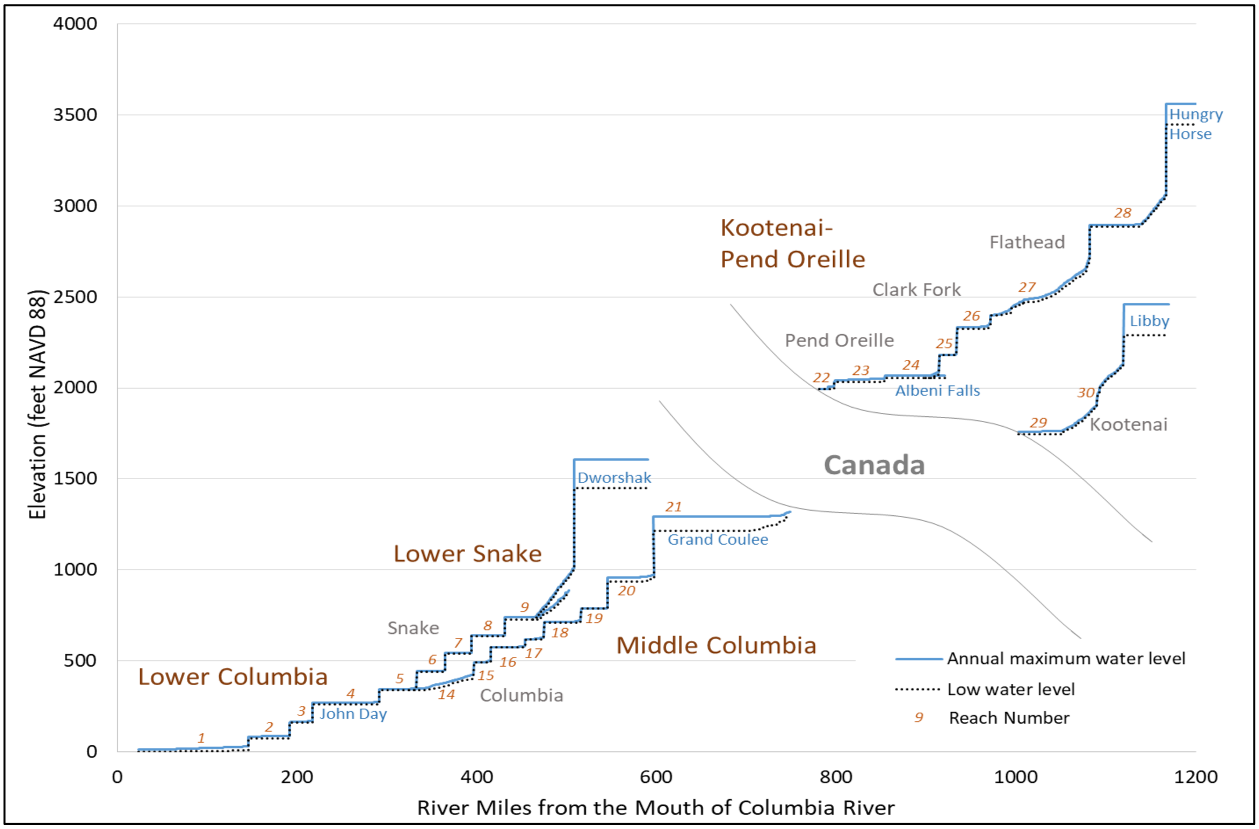

**Figure 3-4. Water Surface Profiles for the Columbia River System Hydraulic Model Reaches**

Water levels at a given location will fluctuate seasonally with the hydrologic cycle, typically dominated by high flows during the spring and early summer, also called the "freshet," and dam operations which are typically lower in the winter months and higher following the freshet. Depending on the location within a given reach, the changes in water level will be influenced by either changes in the forebay elevation held at the downstream dam, changes in the outflow from the upstream project, or a combination of the two. To facilitate discussion of impacts to water levels from changes in reservoir operations, three profile types are established: flat pool, free-flowing, and transitional. These are depicted in Figure 3-5 and described below:

- A reservoir may be considered "flat," for practical purposes, where the water level is influenced solely by and, in most cases, is equal to the forebay elevation. The extent of the reservoir that is "flat" is related to the size of the dam, the shape and slope of the river channel, and the flow through the reach.
- The upstream portions of some reaches are considered to be "free-flowing." In these zones, water levels are outside the influence of the downstream reservoir operations but change

with changes in the flowrate in the channel, which is typically dominated by outflow from the upstream dam. Note, the use of the term "free-flowing" is not to be confused with other interpretations related to natural or unregulated rivers.

- Most reaches will have a zone between the flat pool and free-flowing zones where the water level can be influenced by both the water level held in the forebay at the downstream project and the amount of flow coming into the reservoir. For this study, this part of the profile is called the "transitional" zone.

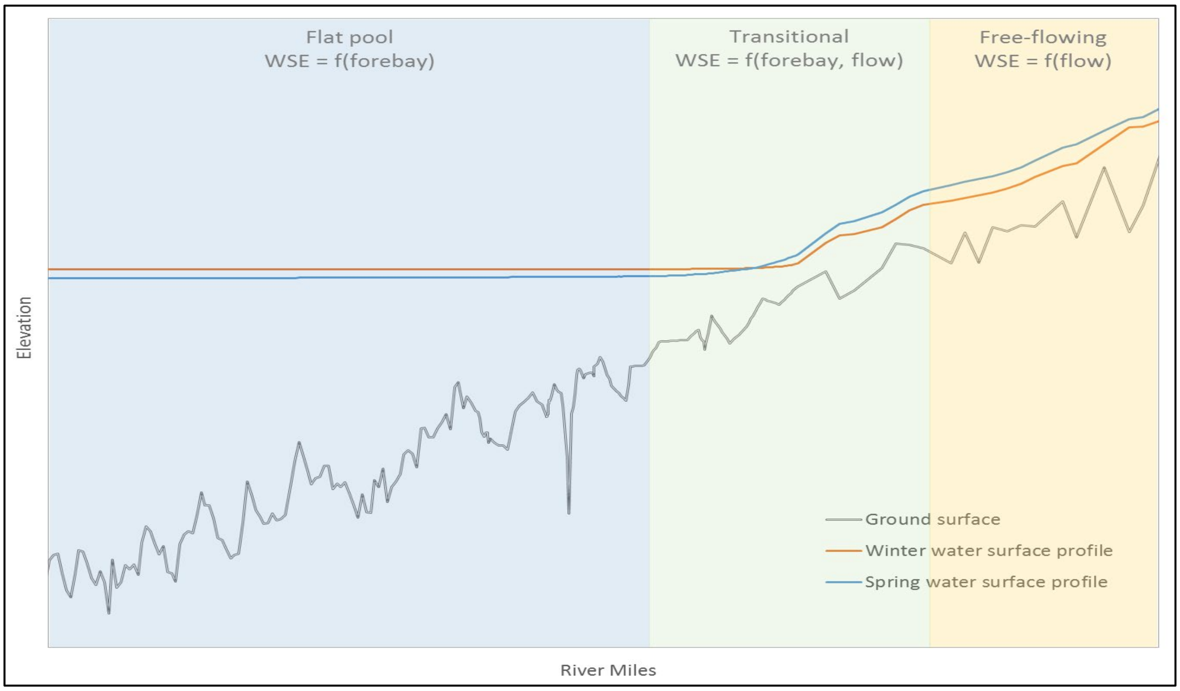

**Figure 3-5. Water Surface and Ground Surface Profiles of Typical Hydraulic Reach, and the Three Zones of Influence**

Each of the hydraulic reaches has a unique water surface profile. The water surface profile is made from the calculated water surface at various locations throughout a reach. The water surface elevation at any given location is related to the downstream boundary, such as dam forebay elevations, the channel geometry (bed slope, roughness, conveyance area, etc.), and the given flow condition. More detailed discussion of the H&H conditions in each reach is provided in the H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*), but Table 3-2 summarizes the key elements related to the water surface profile for each reach. Figure 3-6 is provided to show the location of reaches.[4]

[4] It should be noted that definitive boundaries of these zones for a given reach are not provided as it depends on the precision of a given analysis and metric of interest; however, general zone extents are provided to help describe the shape of a given reach's water surface profile and where changes in flow and water level will likely impact water levels. Also, most of the apparently flat reaches are actually slightly sensitive to discharge during high flow conditions, particularly if they coincide with low pool conditions, and should therefore be considered transitional.

**Table 3-2. Reach-by-Reach Profile Summaries**

| CRSO Region | Reach | Reach Extents | Profile Description (e.g., flat pool, free-flowing sections, constrictions) |
|---|---|---|---|
| A. Kootenai, Flathead, Clark Fork, Pend Oreille | R30[1/] | Libby Dam to Crossport, Idaho<br>Kootenai RM 157 to 219 | Entire reach is free-flowing, i.e., above influence of Kootenay Lake downstream.<br>Includes Kootenai Falls (Kootenai RM 191) |
| | R29 | Crossport, Idaho, to U.S.-Canada Border<br>Kootenai RM 103 to 157 | Water levels influenced by Kootenay Lake, especially below Bonners Ferry, Idaho (RM 150). |
| | R28 | Hungry Horse to SKQ<br>Flathead RM to 79 to 158 includes Whitefish River | Reach begins at bottom of Flathead Lake (RM 79.437) above constriction above SKQ Dam.<br>The upper end of Flathead Lake is at roughly RM 110 and the estuary extends for another 20 meandering miles upstream on the Flathead River.<br>Free-flowing reaches exist above roughly RM 133 on the Flathead River and RM 3 on the Whitefish River. |
| | R27 | SKQ to Thompson Falls<br>Clark Fork RM 72 to 110 and Flathead RM 0 to 74 | Thompson Falls is a run-of-river dam.<br>Free-flowing reach along both Clark Fork and Flathead reaches. |
| | R26 | Thompson Falls to Noxon<br>Clark Fork RM 35 to 72 | Flat pool may occur during low-flow periods. |
| | R25 | Noxon to Cabinet Gorge<br>Clark Fork RM 15 to 34 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R24 | Lake Pend Oreille | Lake Pend Oreille is not modeled via detailed methods. Transitional reaches exist from Albeni Falls Dam to Sandpoint, Idaho, and along from the Clark Fork River confluence to Cabinet Gorge Dam. A flat pool is assumed for the reservoir above Sandpoint, Idaho, to the Clark Fork confluence. |
| | R23 | Albeni Falls to Box Canyon<br>Pend Oreille RM 33 to 89 | This run-of-river reservoir extends the length of the reach, but a major constriction at RM 33.7, a half-mile above the Box Canyon Dam, can produce a relatively sharp jump in water surface elevations during high-flow conditions. |
| | R22 | Box Canyon to Boundary Dam<br>Pend Oreille RM 16 to 33 | A flat pool can be assumed for only first mile of the reach, but almost the entire length of the reach can be flat during low-flow conditions.<br>There is a major constriction around RM 25.8 that can produce a relatively sharp jump in water surface elevations during high-flow conditions. |

| CRSO Region | Reach | Reach Extents | Profile Description (e.g., flat pool, free-flowing sections, constrictions) |
|---|---|---|---|
| B. Middle Columbia | R21 | U.S.-Canada Border to Grand Coulee<br>Columbia RM 597 to 748 | Roosevelt Lake operation can change pool levels by 50 to 80 feet annually.<br>Flat pool can be assumed for 100 to 130 miles above the dam, depending on the season. |
| | R20 | Grand Coulee to Chief Joseph<br>Columbia RM 546 to 597 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R19 | Chief Joseph to Wells<br>Columbia RM 516 to 546 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R18 | Wells to Rocky Reach<br>Columbia RM 475 to 515 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R17 | Rocky Reach to Rock Island<br>Columbia RM 454 to 475 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R16 | Rock Island to Wanapum<br>Columbia RM 415 to 453 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R15 | Wanapum to Priest Rapids<br>Columbia RM 397 to 415 | This run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R14[2/] | Priest Rapids to Richland, Washington<br>Columbia RM 335 to 397 | Sometimes referred to as the “Hanford Reach,” this reach is mostly free-flowing.<br>The lower few miles can be influenced by Lake Wallula above McNary Dam. |

| CRSO Region | Reach | Reach Extents | Profile Description (e.g., flat pool, free-flowing sections, constrictions) |
|---|---|---|---|
| C. Lower Snake | R09 | Dworshak to Lower Granite Snake RM 107 to 178 and Clearwater RM 0 to 45 | Lower Granite Lake extends almost 40 miles to Lewiston, Idaho, and the Snake confluence with the Clearwater.<br>Reservoir levels can influence Snake River water levels as far RM 145, 10 miles upstream of the confluence with the Clearwater.<br>Free-flowing reach on the Clearwater River starts about 5 miles above confluence with Snake River. |
| | R08 | Lower Granite to Little Goose<br>Snake RM 70 to 106 | This mostly run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R07 | Little Goose to Lower Monumental<br>Snake RM 41 to 69 | This mostly run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R06 | Lower Monumental to Ice Harbor<br>Snake RM 9 to 40 | This mostly run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| D. Lower Columbia | R05 | Richland, Washington, and Ice Harbor to McNary Columbia RM 291 to 335 and Snake RM 0 to 8 | Lake Wallula extends approximately 27 miles past Pasco, Washington.<br>Includes Snake and Yakima River reaches for a short distance above their confluences with the Columbia.<br>A flat pool can extend from the dam for 20 to 40 miles depending on flow conditions. |
| | R04 | McNary to John Day<br>Columbia RM 217 to 291 | Reservoir mostly run-of-river but pool can fluctuate over 10 feet.<br>The lower 25 miles can be assumed flat year-round, and flat pool may extend the entire reach during low-flow periods. |
| | R03 | John Day to The Dalles<br>Columbia RM 192 to 217 | Mostly run-of-river reservoir extends the length of the reach.<br>Flat pool may occur during low-flow periods. |
| | R02 | The Dalles to Bonneville<br>Columbia RM 146 to 191 | Mostly run-of-river reservoir extends the length of the reach.<br>Reach is relatively channelized with a notable constriction a couple of miles above dam (~RM 147). |
| | R01 | Below Bonneville<br>Columbia RM 30 to 146 | Free-flowing reach from Bonneville Dam (RM 146) to RM 30 near Tongue Point, Oregon.<br>Includes Willamette River below Oregon City Falls (RM 26), Cowlitz River below Castle Rock, Washington (RM 19) and other smaller tributaries.<br>Tidal influence extends all the way to Bonneville Dam and partially up the major tributaries. |

Note: RM = river mile.
1/ Reach 30 is combined with Reach 29 in hydraulic model “R29_30” or just “R29”.
2/ Reach 14 is combined with Reach 5 in hydraulic model “R5_14” or just “R05”.

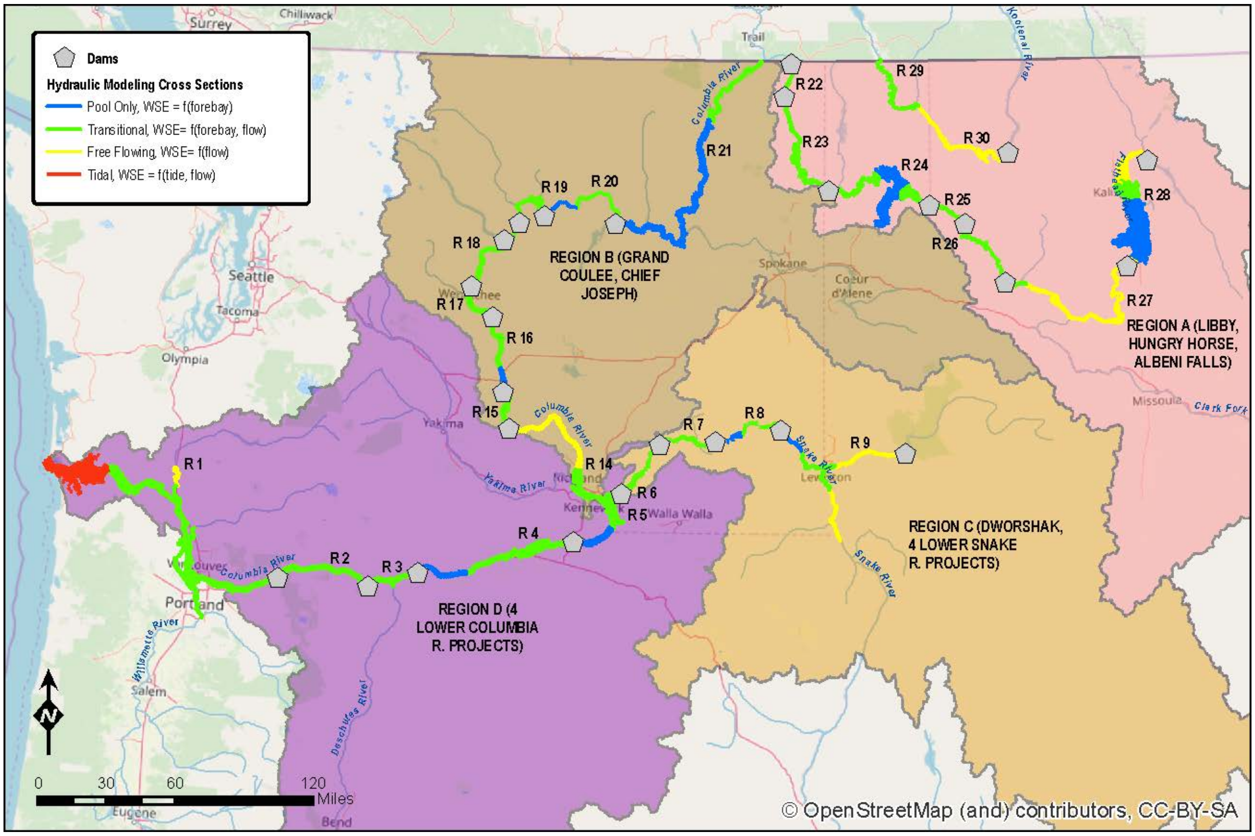

**Figure 3-6. Map of Hydraulic Reaches Showing the Zones of Influence**

Note: WSE = water surface elevation. Flat pool (blue); free-flowing (yellow); transitional (green); Reach 1, which is tidally influenced, is shown in red.

### 3.2.4 Environmental Consequences

#### *3.2.4.1 Methods*

The term H&H is used in a general manner to discuss the quantity, movement, or behavior of water. Hydroregulation is the process water managers use to make decisions about routing water through a series of dams in a river system. Computer hydroregulation modeling, also called reservoir operations modeling, was used to simulate operations for the system of dams in the Columbia River Basin.

Two hydroregulation models were used to simulate operations in the basin in support of the H&H analysis: Hydro System Simulator (HydSim) and Hydrologic Engineering Center Reservoir System Simulation (ResSim) software (U.S. Army Corps of Engineers [Corps] 2013). The models mesh together through multiple steps to simulate operations in the Columbia River Basin.

The ResSim model provided FRM constraints as inputs to the HYDSIM model. Conversely, the HYDSIM model provided the Columbia River Treaty operation for the Canadian projects to ResSim. In addition, HYDSIM modeling provided the lack-of-market information that was layered on the ResSim output to provide daily spill flow. Since both models produced flows and elevations for the CRS projects, their outputs were compared to verify that they were providing similar results. Details of how the models worked together are described in Appendix I, *Hydroregulation Appendix*. The CRS ResSim Model is the last modeling step from which daily flow and reservoir elevations are taken for analysis and use by other technical teams. While operations important for determining water conditions on a seasonal and even daily basis are generally modeled, certain operations such as load shaping or turbine preference are not captured in the model.

The ResSim model for the CRS is a model that simulates reservoir releases and river flows over a wide variety of hydrologic conditions. River and reservoir levels in the system are sensitive to forecasted water supply volume each year, and this uncertainty is reflected in the hydroregulation modeling approach used for the MOs. Details on the hydroregulation modeling approach are provided in the H&H Appendix (Appendix B, Part 3, *HEC-ResSim/WAT Documentation*).

The inputs used to drive the model include hydrologic datasets based on the historically observed 80-year period of record (1929 to 2008), as well as synthetic hydrologic datasets to represent extreme winter and spring flood events. Details on the input hydrology and runoff volume forecasts used to drive the model are provided in the H&H Appendix (Appendix B, Part 4, *Hydrologic Data Development*).

The modeling process used 80 years of historical hydrology plus 26 larger synthetic years to test reservoir operations. Because seasonal water supply forecasts are the biggest factor in reservoir operations, each year of hydrology was run multiple times, each time with a different sequence of seasonal water supply forecasts. For example, the hydrology for the year 1994 gets simulated many times, but the seasonal runoff volume forecast used in the simulation is unique each time that 1994 is run. Sampling of volume is done because the runoff volume forecast is a driver for many reservoir operations, playing a major role in the resultant river flows over the operational water year.

Computer hydroregulation modeling is conducted for planning studies in which operational scenarios, or rules, are tested over many years of data. Each alternative has a fixed rule set, so that when the model is computed each event is handled with the same rule conditions without human interference to prefer different conditions. Real-world reservoir operation is complex; different information is available to the water manager for decision making, and decisions are shaped by an individual water manager's experience and risk tolerance. Water managers also adapt operations, as possible within constraints, to an operation that meets the goals of system users given the specific conditions of that particular water year[5]. Operation changes of this nature are not possible to represent in a planning model, nor are they desirable, as they would make comparing different MOs substantially more challenging and likely skew the results towards the personal/professional opinions of what should happen.

[5] Examples of real-time operation flexibility can include how the system may operate for fish (e.g., chum salmon spawning and incubation by changing Bonneville Dam downstream stage levels), or other purposes (e.g., summer drawdown patterns at Libby Dam for habitat restoration work downstream of the dam on the Kootenai River).

The hydroregulation modeling produces regulated streamflows and reservoir elevations, which are used to develop summary figures and tables to describe water conditions at locations of interest. Figures include summary flow hydrographs, summary elevation hydrographs, and elevation duration plots. Key results are presented and described in the effects sections. The H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*) contains a more comprehensive set of figures and tables, including an in-depth discussion of what they show.

With each alternative, there are several measures that were not included in the hydroregulation modeling, either because the measures are not operational in nature or because the reservoir operations model is not configured to simulate a given measure. For example, the hydroregulation modeling results presented here do not incorporate hourly, daily, or weekly load shaping which may occur at some dams. Load shaping increases project power generation during peak power demand and decreases power generation during low demand while passing the necessary water through the dams for the day and month flow and elevation objectives. Load shaping causes outflow from a dam to generally be higher during the weekdays and lower on the weekends. Load shaping within a day causes dam outflows to generally be higher during the morning and evening during peak power demand, and lower during the overnight period. The extent to which load shaping occurs, including sometimes not at all, depends on the project and the time of year. Effects on power generation and transmission are discussed in Section 3.7.3.

Water surface profiles and mid-reach water levels (between projects) were produced for the study area. Details on the procedures used to develop these results are contained in the H&H Appendix (Appendix B, Part 6, *Flow-Stage Relationship*, and Appendix B, Part 1, *H&H Data Analysis*). The reservoir elevations, regulated streamflows, water surface profiles, and mid-reach water levels produced for the MOs support the effects analyses for other resource areas described throughout the EIS.

Summary hydrographs were also produced for the study area. A hydrograph is a graph showing an indicator of water flow (such as stage or discharge) over time. One time span commonly used for hydrographs, when there is need to see how water conditions change through all seasons of a year, is the water year. A water year runs from October 1 through September 30. A summary hydrograph is an especially useful way to display information because it shows the expected range and likelihood of water levels (or flow) at a given location for each day of the water year. The curves on a summary hydrograph do not represent a single water year. Rather, each curve represents the percentage chance of exceeding the corresponding water level (or flow) on a given day. Five exceedance levels are shown: 1 percent, 25 percent, 50 percent, 75 percent, and 99 percent.[6] Select summary hydrographs are presented here in Chapter 3, and a more comprehensive set of summary hydrographs and other figures, with accompanying discussion, is provided in the H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*).

[6] As an example, if the 25 percent curve on a summary hydrograph says the flow on May 1 is 10 thousand cubic feet per second (kcfs), that means that flow on May 1 has a 75 percent chance of being lower than 10 kcfs and a 25 percent chance of being higher than 10 kcfs.

In addition to the summary hydrographs described above, a different figure is also used to show how each alternative would affect water conditions in different types of water years. For this purpose, figures showing median hydrographs based on water year type are used to describe effects at Libby, Hungry Horse, Albeni Falls, Grand Coulee, Dworshak, and McNary Dams. The plots group water years into “dry,” “average,” and “wet” years based on the April to August water supply issued on May 1, then take the median flow or elevation for each day within the group. Water years are categorized with respect to the forecasted seasonal runoff volume percentile: dry years represent the lowest 20 percent, average years represent forecasts between 20 percent and 80 percent, and wet years represent forecasts greater than 80 percent (same as the highest 20 percent). The figures for Libby, Hungry Horse, and Dworshak Dams use their own local basin forecast volumes for the water year categorization. The figures for Albeni Falls, Grand Coulee, and McNary Dams use The Dalles Dam forecast volumes for the water year categorization.

The range of forecast volumes for each category, derived from the 5,000 water years of runoff volume forecasts that were simulated, is shown in Table 3-3 below.

**Table 3-3. Water Year Type by Seasonal Forecast Volume**

| Category | Probability Range (%) | Dworshak (kaf) | Hungry Horse (kaf) | Libby (kaf) | The Dalles (kaf) |
|---|---|---|---|---|---|
| Dry | p ≤ 20 | ≤1,931 | ≤1,433 | ≤5,096 | ≤71,462 |
| Average | 20 < p ≤ 80 | 1,932–3,349 | 1,433–2,305 | 5,101–7,647 | 71,466–102,298 |
| Wet | p > 80 | >3,349 | >2,306 | >7,647 | >102,336 |

Note: kaf = thousand acre-feet; p = probability

While median hydrographs of dry, average, and wet years look similar to summary hydrographs, they provide different, useful information. Summary hydrographs analyze a single day over all years together, and so provide the probability of a specific occurrence, on a specific day, over all modeled hydrologic events. In contrast, the median hydrographs of dry, average, and wet years, group years by the May forecast value and then calculate the median value for each day. Thus, they can give an indication of how a measure or combination of measures would affect different types of years.

Figure 3-7 summarizes major groupings of operational measures for the No Action Alternative at five CRS storage projects and is a useful reference for what types of operations occur at these dams throughout the year. For further reading on the implementation of these operational measures in hydroregulation modeling, refer to the H&H Appendix (Appendix B, Part 3, *HEC-ResSim/WAT Documentation*).

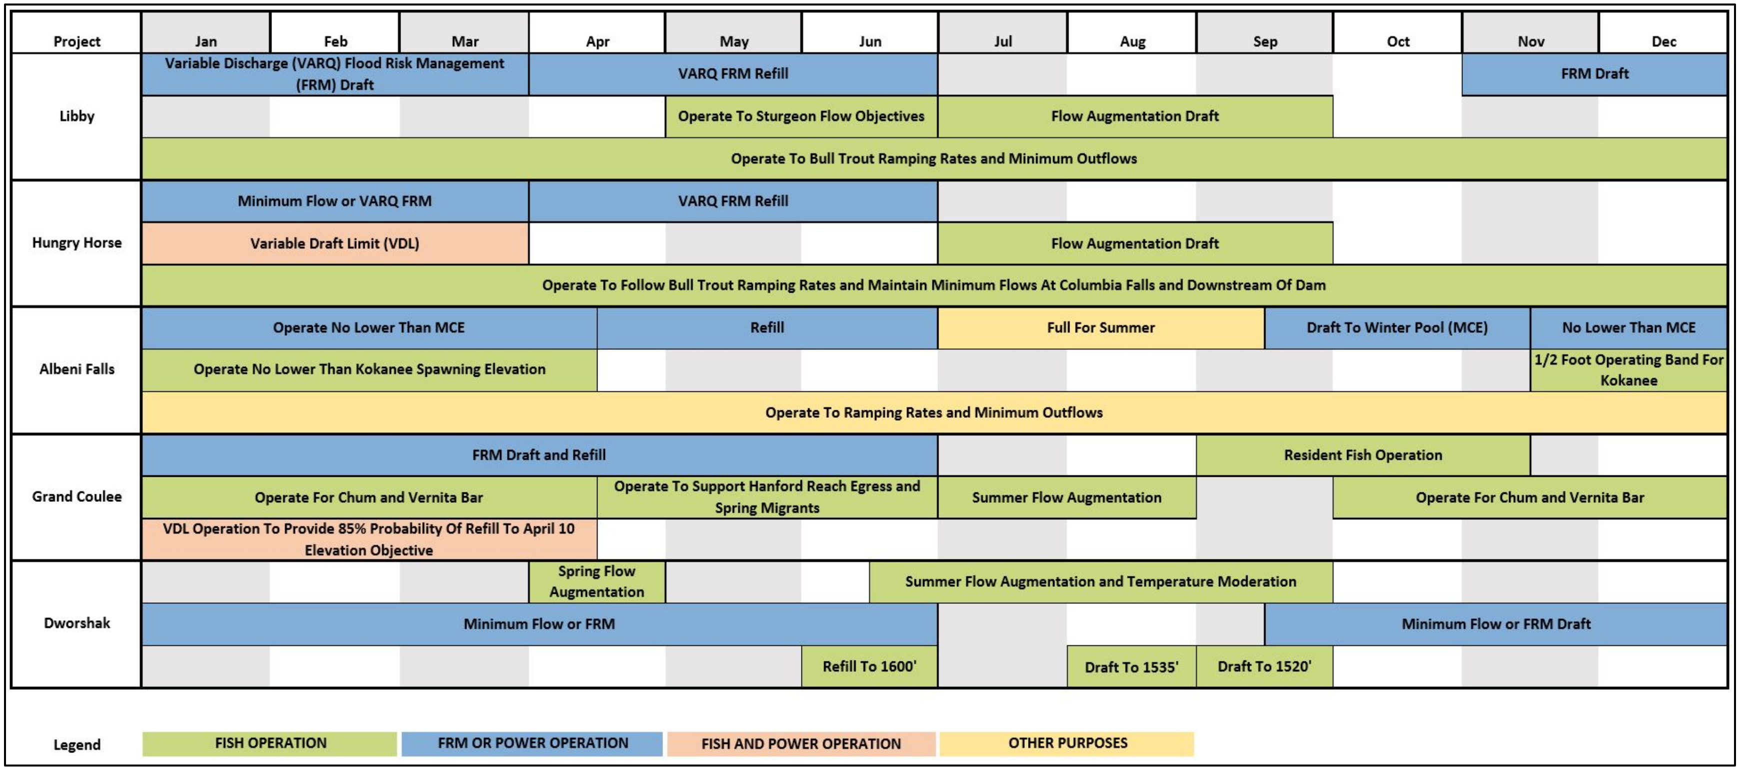

**Figure 3-7. Seasonal Operations at Major Columbia River System Storage Dams**

Throughout this EIS, reservoir water levels at the CRS dams are expressed in the National Geodetic Vertical Datum of 1929 (NGVD29).[7] River flows are expressed as volumetric flow rate in kcfs. Mid-reach water levels are expressed as a stage in feet above a specified datum, typically NAVD88. River miles and reach lengths are from the Corps' Columbia River Basin modeling schematic.

#### *3.2.4.2 Effects (Summary)*

Table 3-4 provides a high-level summary of the effects the MOs would have on hydrologic conditions in the study area, based on hydroregulation modeling. The key indicators used to describe hydrologic conditions are reservoir elevations and regulated streamflows. Bold font is used to call out indicators where there is a difference from the No Action Alternative.

Though it is not strictly a hydrologic effect, the effect the MOs would have on the ability to conduct drum gate maintenance at Grand Coulee Dam is also presented in this section, as the drum gate maintenance is directly tied to the water level of Lake Roosevelt, the reservoir behind Grand Coulee Dam. Drum gate maintenance is planned to occur annually during March, April, and May but is not conducted in all years. The reservoir must be at or below elevation 1,255 feet NGVD29 for 8 weeks to complete drum gate maintenance. The key indicator for this metric is the percentage of years when drum gate maintenance would be possible. Drum gate maintenance at Grand Coulee would be possible in 65 percent of years under the No Action Alternative, and would not be affected by any of the MOs.

[7] Notes on the NGVD29 and North American Vertical Datum of 1988 (NAVD88) datums: The Corps Engineering Regulation 1110-2-8160, Policies for Referencing Project Elevation Grades to Nationwide Vertical Datums, dated March 1, 2009, establishes the Corps policy for referencing project elevation grades to the current nationwide vertical datums, which at this time is NAVD88. Many of the CRS projects were constructed based on the mean sea level datum which is equivalent to NGVD29, the same datum used by all of the Corps projects in the Columbia River System. Individuals involved with the CRS rely heavily on this datum for all operations, and the datum is considered a legacy datum. The Engineering Regulation recognizes that the use of a legacy datum is critical to long-term H&H analyses, flood maps, and operations manuals, but that the relationship between the legacy and current datums should be documented and kept current. For the purpose of this EIS main report, the NGVD29 datum is used unless otherwise noted. As of 2019, the NGVD29 datum is lower than the NAVD88 datum by the amounts listed in Table 6-1, Vertical Datum Adjustment, located in the H&H Appendix (Appendix B, Part 3, *HEC-ResSim/WAT Documentation*).

**Table 3-4. Summary of Effects of Multiple Objective Alternatives Based on Hydroregulation Modeling**

| Indicator | NAA | MO1 | MO2 | MO3 | MO4 |
|---|---|---|---|---|---|
| Lake Koocanusa (Libby Dam Reservoir) | Dec 31 elevation generally between 2,426.7 feet and 2,411 feet<br>April 10 elevation between 2,410 and 2,325 feet in the middle 50% of years<br>Median elevation for Jul, Aug, and Sep: 2,448, 2,452, and 2,450 feet, respectively | Dec 31 elevation generally at 2,420 feet (**higher than NAA for most years**)<br>April 10 elevation between 2,407 and 2,332 feet in the middle 50% of years (**narrower band than NAA**)<br>Median elevation for Jul, Aug, and Sep: 2,450, 2,453, and 2,451 feet, respectively (**about 1–2 feet higher than NAA**) | Dec 31 elevation generally at 2,400 feet (**lower than NAA**)<br>April 10 elevation between 2,392 and 2,333 feet in the middle 50% of years (**narrower band than NAA**)<br>Median elevation for Jul, Aug, and Sep: 2,448, 2,453, and 2,451 feet, respectively (**about 0–1 foot higher than NAA**) | Dec 31 elevation generally at 2,400 feet (**lower than NAA**)<br>April 10 elevation between 2,392 and 2,333 feet in the middle 50% of years (**narrower band than NAA**)<br>Median elevation for Jul, Aug, and Sep: 2,448, 2,453, and 2,451 feet, respectively (**about 0–1 foot higher than NAA**) | Dec 31 elevation generally at 2,420 feet (**higher than NAA for most years**)<br>April 10 elevation between 2,408 and 2,332 feet in the middle 50% of years (**narrower band than NAA and about the same as MO1**)<br>Median elevation for Jul, Aug, and Sep: 2,446, 2,448, and 2,445 feet, respectively (**about 2–5 feet lower than NAA**) |
| Libby Dam outflow | Median monthly outflow for Nov, Dec, Jan, and Feb is 14, 18, 9, and 6 kcfs, respectively<br>Median monthly outflow for Jul, Aug, and Sep is 11, 10, and 8 kcfs, respectively | Median monthly outflow for Nov, Dec, Jan, and Feb is 15, 13, 11, and 10 kcfs, respectively (**higher than NAA in Nov, Jan, and Feb; lower than NAA in Dec**)<br>Median monthly outflow for Jul, Aug, and Sep is 11, 10, and 8 kcfs, respectively (about the same as NAA) | Median monthly outflow for Nov, Dec, Jan, and Feb is 19, 20, 5, and 5 kcfs, respectively (**higher than NAA in Nov and Dec; lower than NAA in Jan and Feb**)<br>Median monthly outflow for Jul, Aug, and Sep is 10, 9, and 7 kcfs, respectively (**lower than NAA**) | Median monthly outflow for Nov, Dec, Jan, and Feb is 19, 20, 5, and 5 kcfs, respectively (**higher than NAA in Nov to Dec; lower than NAA in Jan to Feb**)<br>Median monthly outflow for Jul, Aug, and Sep is 11, 9, and 7 kcfs, respectively (**lower than NAA for Aug to Sep**) | Median monthly outflow for Nov, Dec, Jan, and Feb is 11, 13, 10, and 10 kcfs, respectively (**lower than NAA in Nov to Dec; higher than NAA in Jan to Feb**)<br>Median monthly outflow for Jul, Aug, and Sep is 14, 10, and 8 kcfs, respectively (**higher than NAA for Jul**) |

Note: FRM = flood risk management; MIP = minimum irrigation pool; MOP = minimum operating pool.

1/ When MO1 and MO3 were modeled, the initial Hungry Horse Reservoir levels at the start of each water year were erroneously set lower than intended. The expected elevations from October through May would actually be 1 to 3 feet higher than shown in this table for those two MOs.

2/ The typical summer elevation range for Lake Pend Oreille is 2,062.0 to 2,062.5 feet NVGD29. It is represented as 2,062.25 feet NGVD29 in the HEC-ResSim model, so appears as 2,062.3 feet NGVD29 in this table.

3/ MO1, MO2, and MO4 changes are not reflected in ResSim modeling.

4/ MO2 and MO3 changes are not reflected in ResSim modeling.

Other dam maintenance activities affected by water levels (including discussion of the metrics/indicators for ability to conduct maintenance) are discussed in the H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*) and/or the Water Quality Appendix (Appendix D). These include maintenance of the 57-inch butterfly drum gate intake valves at Grand Coulee Dam, maintenance of the selective withdrawal structure at Hungry Horse Dam, and general power plant maintenance activities.

The amount of water spilled at each project was modeled using a spill allocation methodology described in the H&H Appendix (Appendix B, Part 2, *Spill*). Table 3-5 summarizes the spill operations for the MOs. Further details and modeling results from the extended year dataset (water years 2008 through 2016) are presented and discussed in the H&H Appendix (Appendix B, Part 2, *Spill Analysis*).

1/ Under MO3, the four lower Snake River projects (Ice Harbor, Lower Monumental, Little Goose, and Lower Granite) would be breached; therefore, no spill operations exist for these projects.

2/ These dams on the middle Columbia River are not CRS projects, but are included in this table for completeness in describing fish spill operations.

The effects associated with each MO are discussed in the subsequent H&H Environmental Consequences sections (Sections 3.2.4.4 through 3.2.4.7). The effects associated with the No Action Alternative are discussed in Section 3.2.4.3, with additional detail on the No Action Alternative also included in Sections 3.2.4.4 through 3.2.4.7 where each MO is discussed. As MO1, MO2, MO3, and MO4 are each discussed, the operational measure (or measures) which would result in changes from the No Action Alternative are identified to the extent possible. For a comparison of model results from the various alternatives, see the H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*) for additional discussion and a comprehensive set of tables and plots.

#### *3.2.4.3 No Action Alternative*

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Lake Koocanusa (Libby Dam Reservoir) Elevation**

The reservoir behind Libby Dam is called Lake Koocanusa. The summary hydrograph showing Lake Koocanusa elevations for the No Action Alternative is shown in Figure 3-8. In this and other summary hydrographs presented for reservoirs, the 1 percent exceedance level represents the highest elevations; 99 percent represents the lowest. For instance, looking at the figure below, one can see that on June 1, the 99 percent exceedance level curve corresponds to an elevation of about 2,330 feet NGVD29. That means there is a 99 percent chance the reservoir will be higher than 2,330 feet NGVD29 on June 1, and 1 percent chance it will be lower than 2,330 feet NGVD29 on June 1.

There would not be much variability in water levels in October and November. In December, the range of the reservoir water level begins to spread, as the end of December FRM elevation for Libby Dam is based on a seasonal water supply forecast that is issued at the beginning of December. The range of possible reservoir elevations widens further in the subsequent winter months, lasting into the early spring. The drawdown of the reservoir level that occurs in the winter and early spring months is guided by variable discharge storage regulation procedure (VarQ) FRM requirements, and also by minimum outflow requirements. The reservoir usually begins refilling by April or May and reaches its peak elevation in July. Libby Dam releases water and drafts over the summer to help meet flow objectives in the lower Columbia River for juvenile anadromous fish migration. The elevation objective at the end of September is either elevation 2,449 feet NGVD29 or elevation 2,439 feet NGVD29. The elevation objective of 2,439 feet NGVD29 applies in the driest 20 percent of years,[8] based on the May issued April to August water supply forecast at The Dalles. In all other years, the elevation objective of 2,449 feet NGVD29 applies.

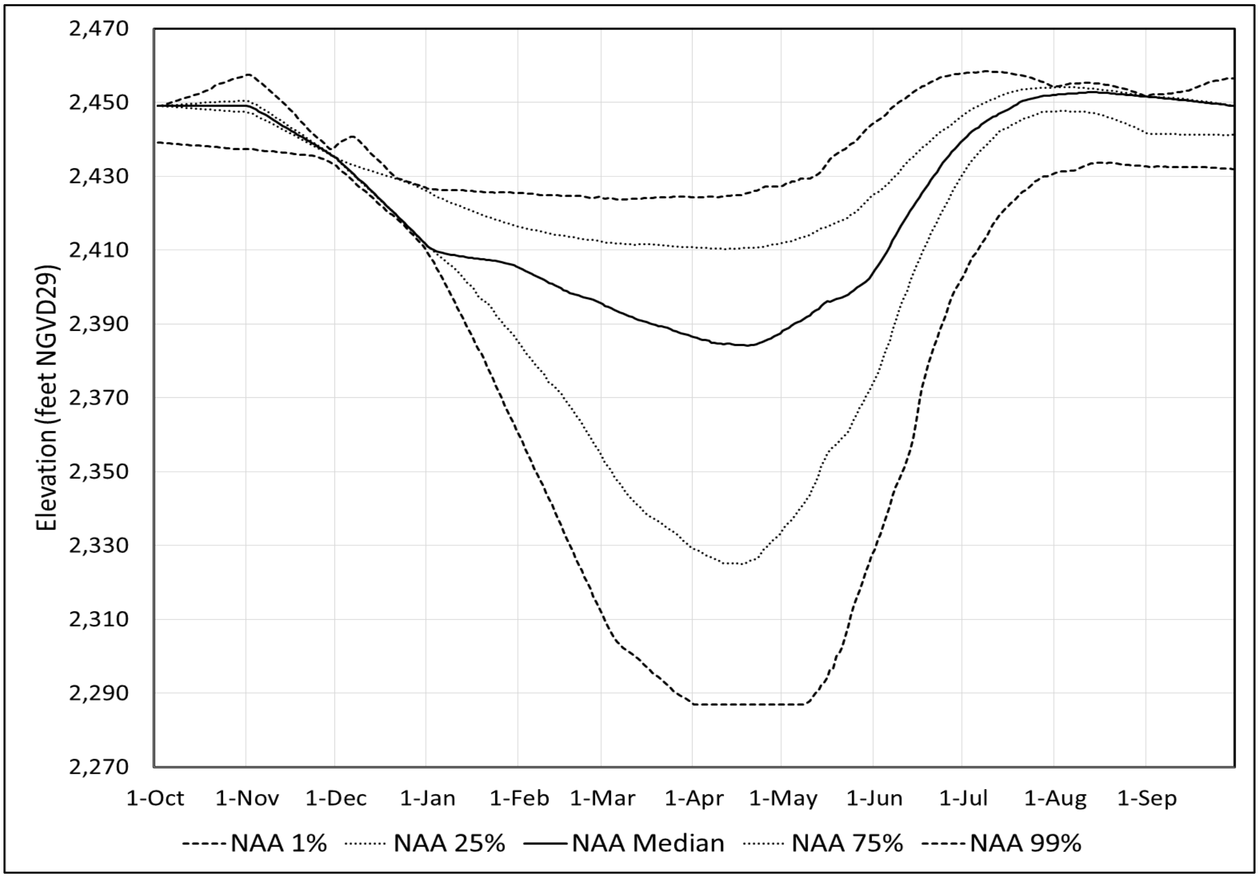

**Figure 3-8. Lake Koocanusa Summary Hydrograph for No Action Alternative**

### Libby Dam Outflow

A summary hydrograph showing outflow from Libby Dam for the No Action Alternative is shown in Figure 3-9.

Outflow in October is typically less than 5 kcfs. It increases in November and usually increases again in December, though not always. From January through March, the range of outflow from Libby Dam can be quite wide, as seen in the difference between the 25th percentile and 75th percentile lines on the Figure 3-9 summary hydrograph. By about mid-May, there is usually a pronounced increase in Libby Dam outflow for several weeks to provide flows for Kootenai River white sturgeon. Following the pronounced increase, the outflow gradually decreases over the remaining months of the water year. In addition to outflows for Kootenai River white sturgeon in the late spring, operations are also guided by meeting minimum bull trout flow

[8] This driest 20 percent of years is based off the most recent 30-year period statistics developed by the National Oceanic and Atmospheric Administration (NOAA).

requirements from May 15 through September 30, and also the end of September reservoir elevation objective for anadromous fish migration on the lower Columbia River.

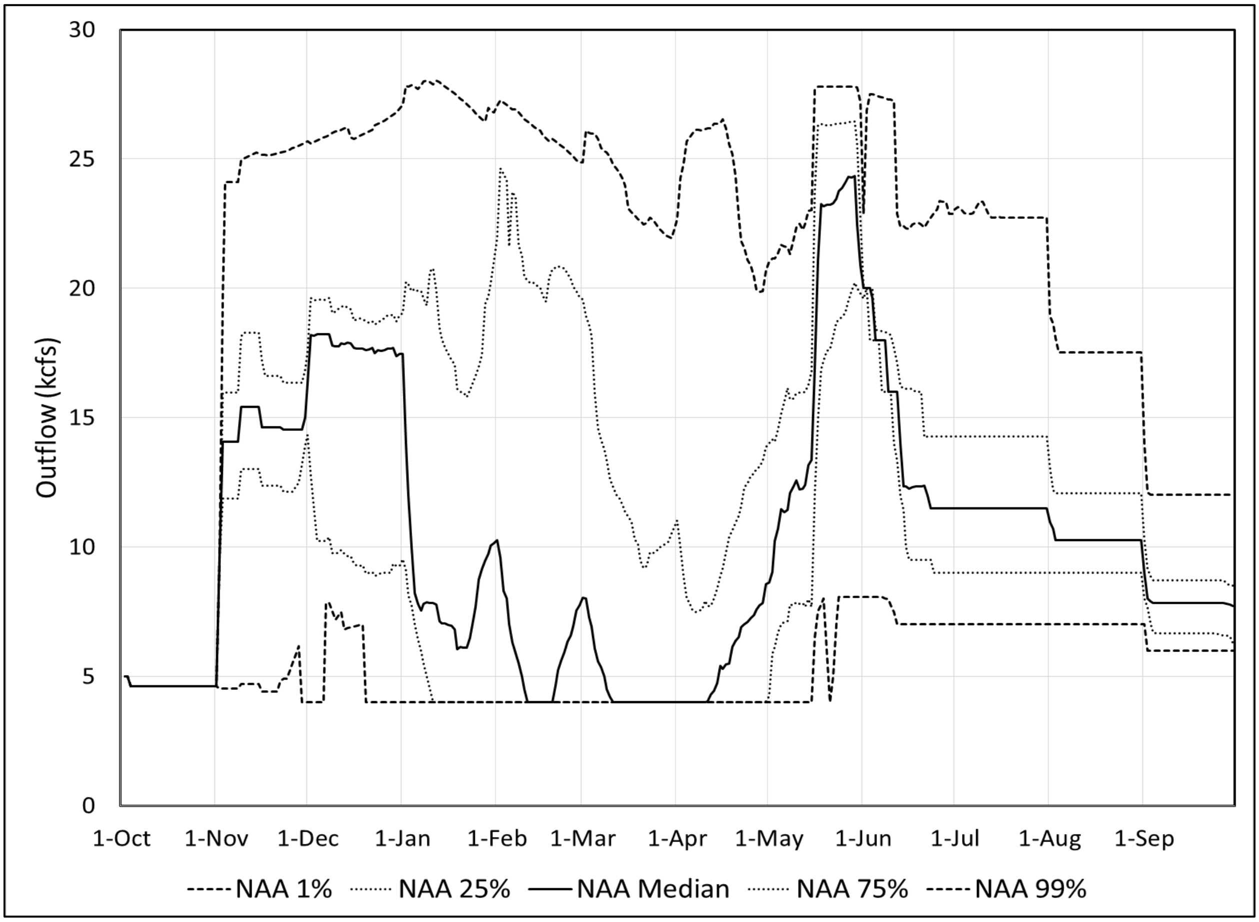

**Figure 3-9. Libby Dam Outflow Summary Hydrograph for No Action Alternative**

### Bonners Ferry Flow

A summary hydrograph showing the flow at Bonners Ferry, Idaho, for the No Action Alternative is shown in Figure 3-10.

Bonners Ferry is located along the Kootenai River, approximately 70 river miles downstream of Libby Dam. The general pattern throughout most of the water year is similar to that for Libby Dam outflow. In the late spring and early summer, flows at Bonners Ferry are consistently much higher than the Libby Dam outflow, when the spring freshet adds more local runoff to the Kootenai River downstream of Libby Dam.

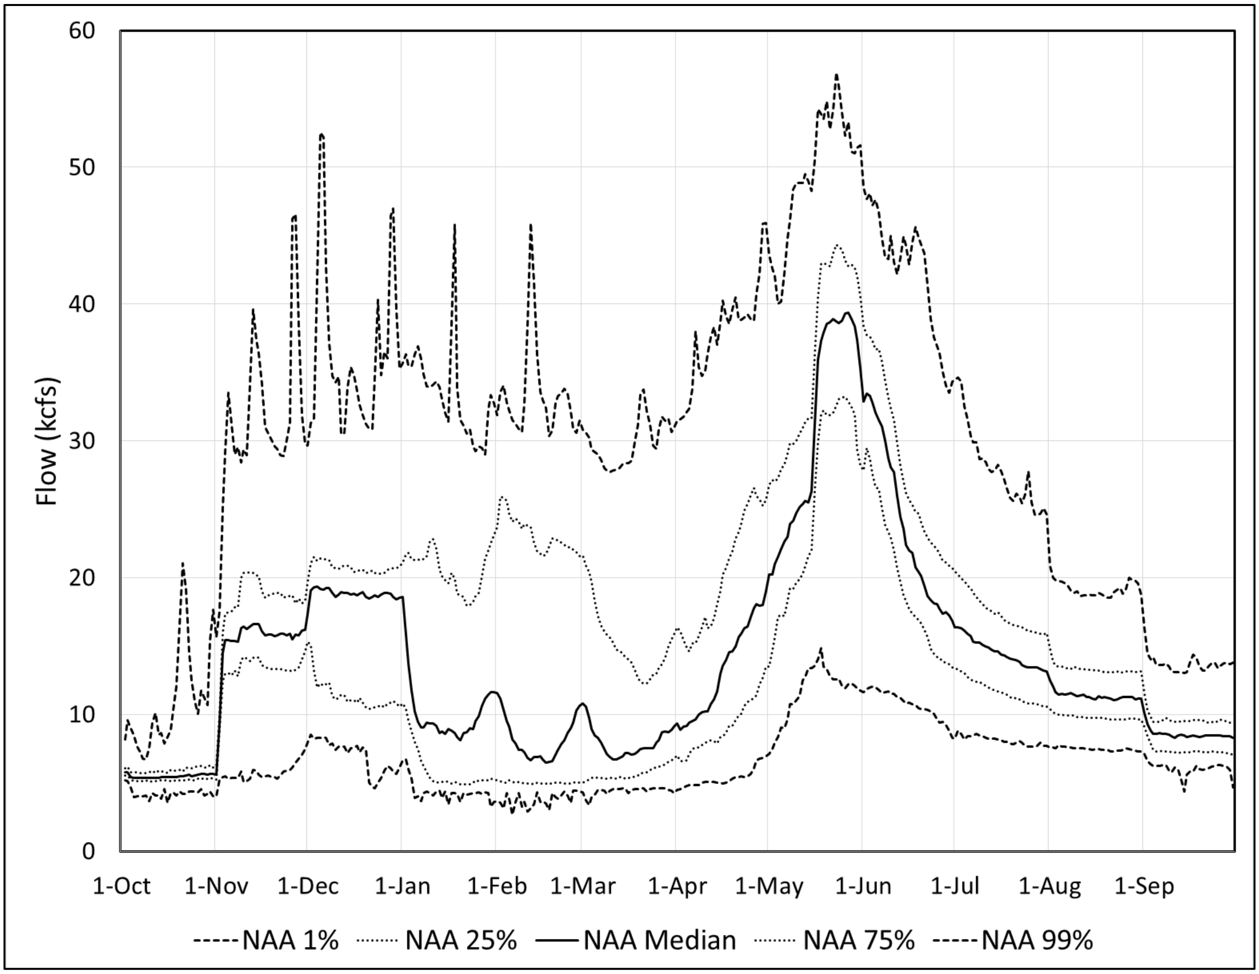

**Figure 3-10. Bonners Ferry Flow Summary Hydrograph for No Action Alternative**

**Hungry Horse Reservoir Elevation**

A summary hydrograph showing Hungry Horse Reservoir elevations for the No Action Alternative is shown in Figure 3-11.

There is not much variability in water levels at the start of the water year. Over the next several months, the range of the reservoir water level begins to spread, as Hungry Horse is operated to meet minimum flows and continues to draft depending on inflow conditions. The range of possible reservoir elevations widens further in the subsequent winter months, lasting into the early spring. The drawdown of the reservoir level that occurs in the winter and early spring months is guided by VarQ FRM requirements. In real time, however, the reservoir may also be deeper than the VarQ FRM elevation to operate for power, so long as there is a 75 percent chance of being at the elevation objective on April 10 (this is referred to as a variable draft limit). The reservoir is also deeper than the VarQ FRM elevation when needed to meet minimum flows for bull trout on the South Fork Flathead River and on the mainstem Flathead River at Columbia Falls. The reservoir typically experiences the deepest draft point in late April or early May to satisfy VarQ FRM requirements. The reservoir usually begins refilling in early

May and reaches its peak elevation in late June to early July. Hungry Horse Dam releases water and drafts over the summer to help meet flow objectives in the lower Columbia River for juvenile anadromous fish migration. The elevation objective at the end of September is either elevation 3,550 feet NGVD29 or elevation 3,540 feet NGVD29. The elevation objective of 3,540 feet NGVD29 applies in the driest 20 percent of years[9], based on the May issued April to August water supply forecast at The Dalles. In all other years, the elevation objective of 3,550 feet NGVD29 applies. In dry years, the need to satisfy local minimum flow requirements can cause the reservoir to be lower than its end of September elevation objective.

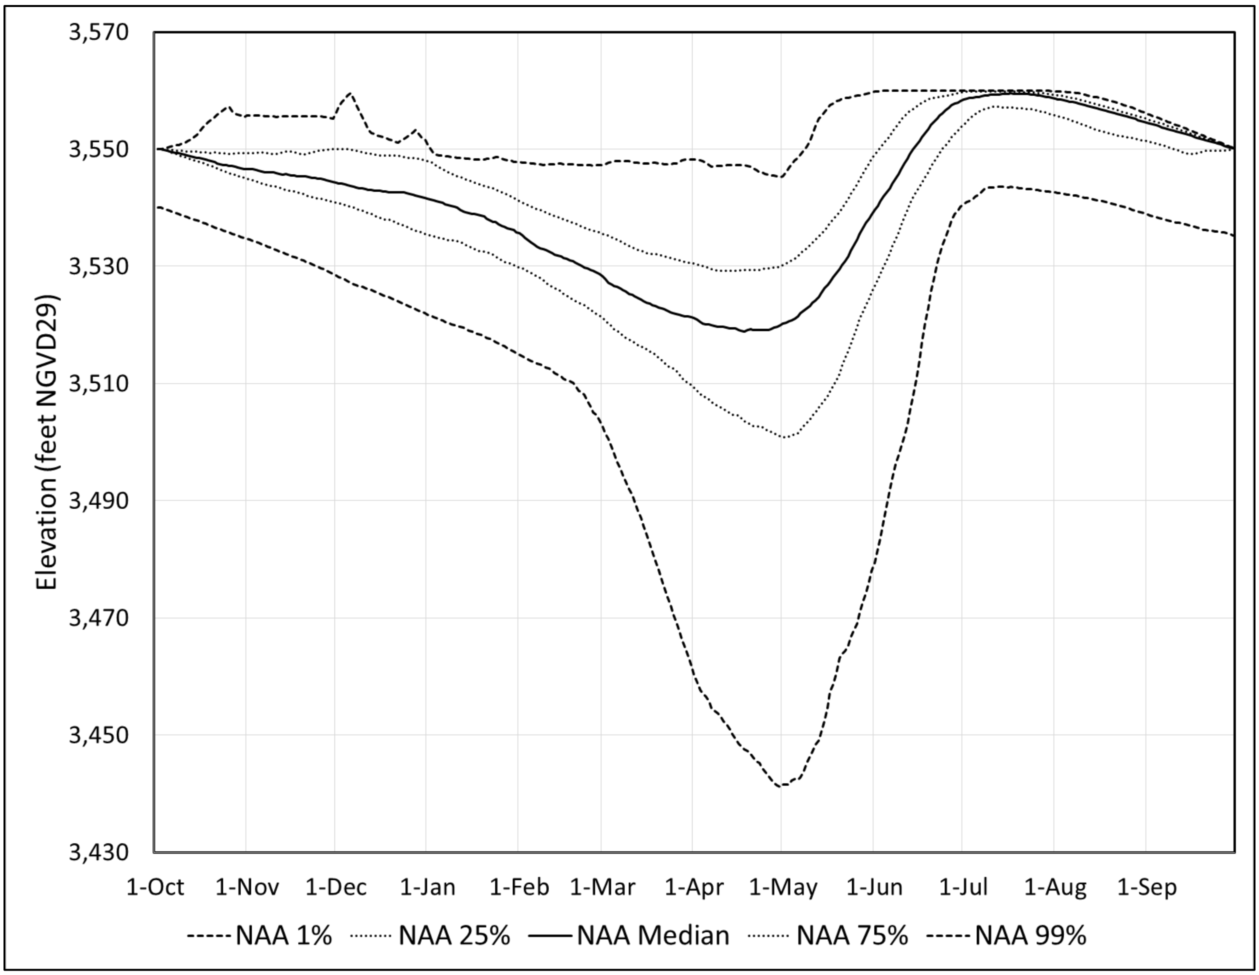

**Figure 3-11. Hungry Horse Reservoir Summary Hydrograph for No Action Alternative**

**Hungry Horse Dam Outflow**

A summary hydrograph showing outflow from Hungry Horse Dam for the No Action Alternative is shown in Figure 3-12.

[9] This driest 20 percent of years is based off the most recent 30-year period statistics developed by NOAA.

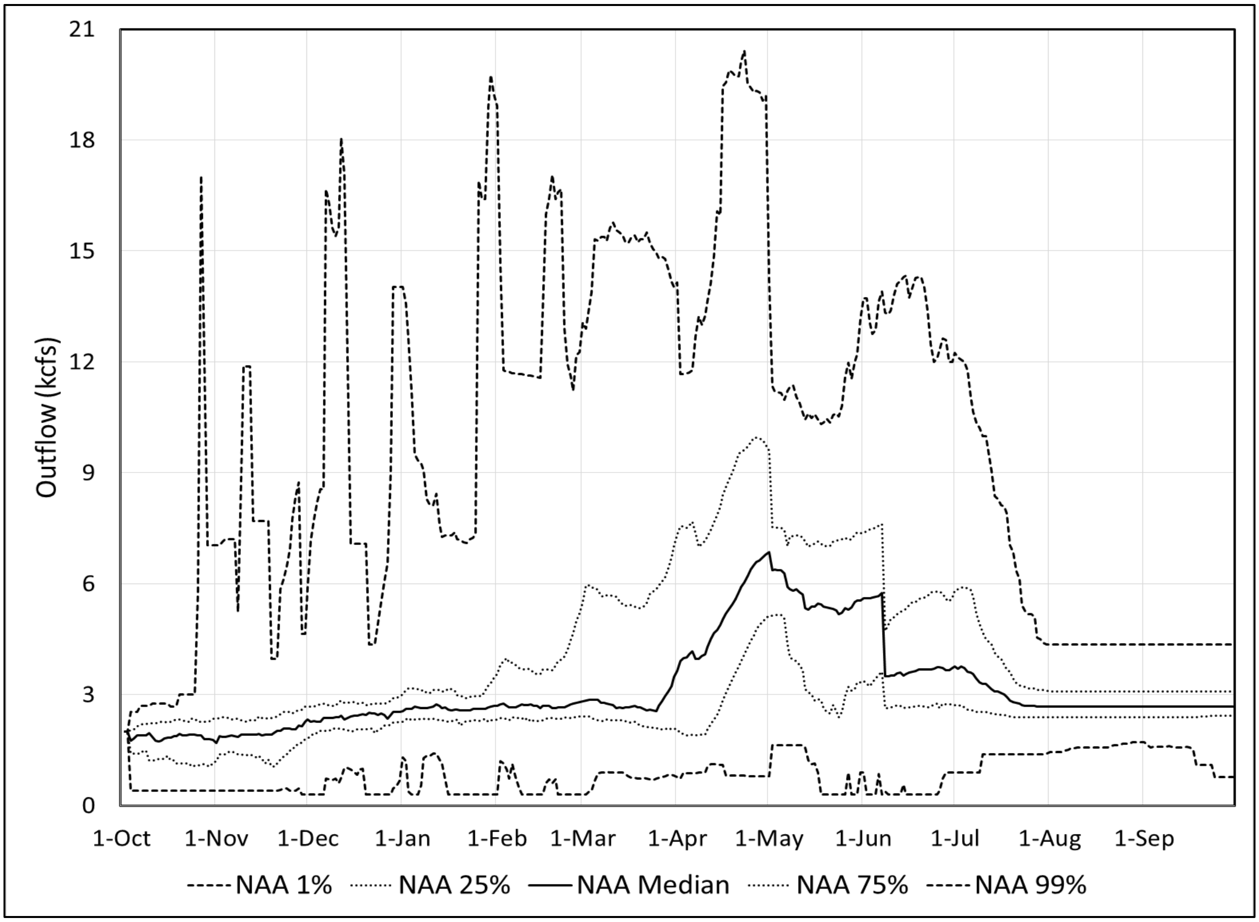

**Figure 3-12. Hungry Horse Dam Outflow Summary Hydrograph for No Action Alternative**

The Confederated Salish and Kootenai Tribes of the Flathead Reservation (CSKT) and the Kootenai Tribe of Idaho have expressed particular interest in any decisions relating to Libby Dam and Hungry Horse Dam. The CSKT has recognized Treaty rights and interests within and to waters and lands on the Kootenai River and the Flathead River systems. In CSKT's Tribal Perspectives, they assert that "the federal action agencies must consider the significant effects FCRPS operations will have on tribal waters when proposing Hungry Horse Reservoir drawdowns to support flow augmentation for anadromous fish, because these flows will pass through the Flathead Indian Reservation and accordingly, by timing and volume, affect tribal water quality." Outflow from October through January is usually less than 3 kcfs, to support local minimum flows in the South Fork and mainstem Flathead River. The range grows from February through April to satisfy FRM elevations guided by VarQ. By the beginning of May, the reservoir usually begins to refill, and outflow generally decreases over the remaining months of the water year. Hungry Horse Dam will operate for local FRM, reducing outflows, as long as there is enough space in the reservoir to manage the remaining runoff.

From January through April, the reservoir level is adjusted for FRM space requirements. The amount of reservoir draft or space is dependent on inflow forecasts. The objective of the FRM season is to provide enough space in the reservoir for system FRM operations in the lower

Columbia River, and also to provide local flood protection in the mainstem Flathead River near Columbia Falls, Montana.

**Columbia Falls Flow**

A summary hydrograph showing the flow at Columbia Falls, Montana, for the No Action Alternative is shown in Figure 3-13. Columbia Falls is on the mainstem of the Flathead River, approximately 11 river miles downstream of Hungry Horse Dam.

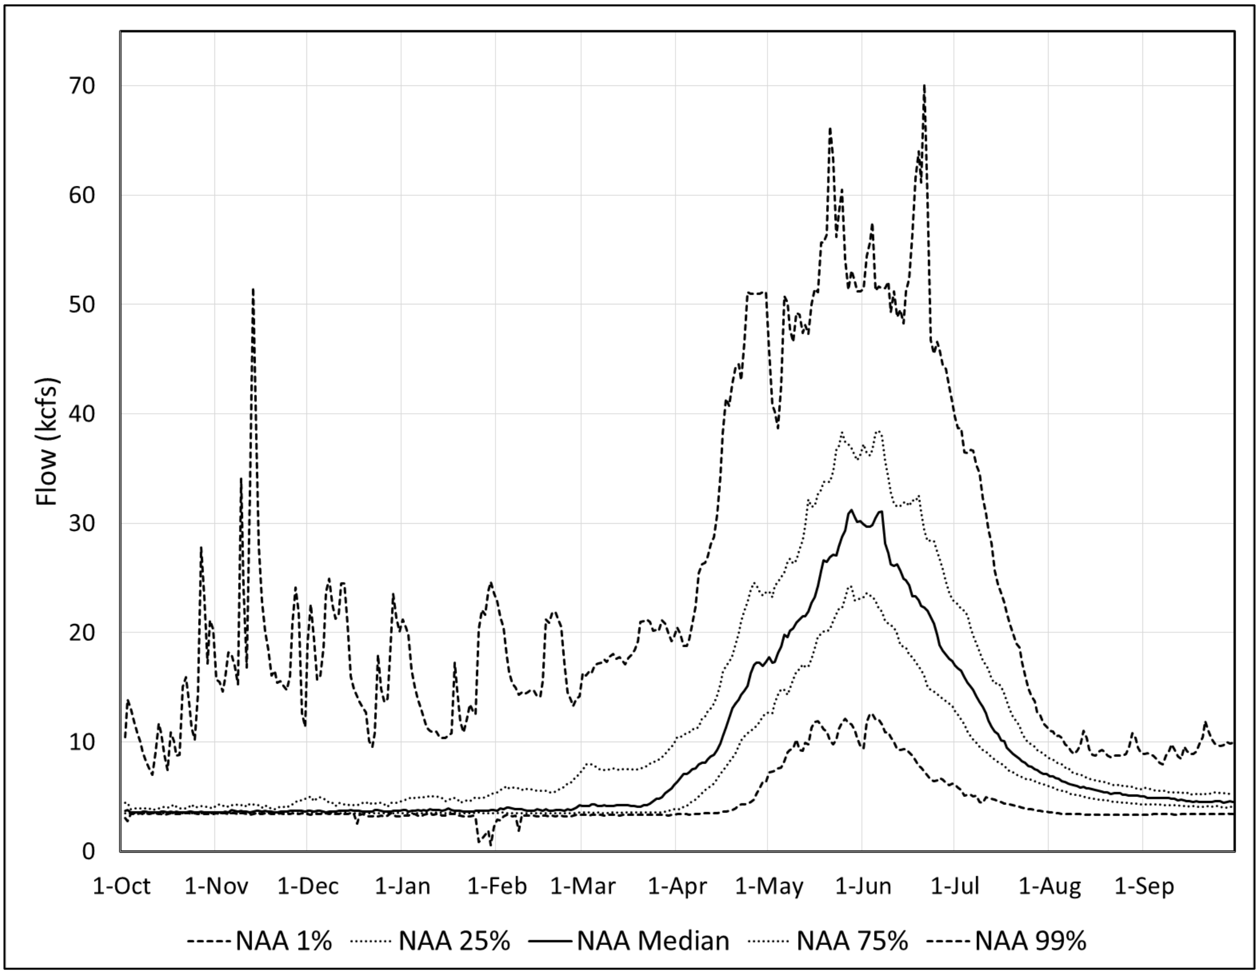

**Figure 3-13. Columbia Falls Flow Summary Hydrograph for No Action Alternative**

The general pattern throughout most of the water year is similar to that for Hungry Horse Dam outflow. In the late spring and early summer, flows at Columbia Falls are considerably higher than the Hungry Horse Dam outflow, when the spring freshet adds more local runoff to the forks of the Flathead River.

**Lake Pend Oreille Elevation**

A summary hydrograph showing Lake Pend Oreille elevations for the No Action Alternative is shown in Figure 3-14. For this alternative as well as the MOs evaluated, the Lake Pend Oreille levels presented are for the level at Hope, Idaho.

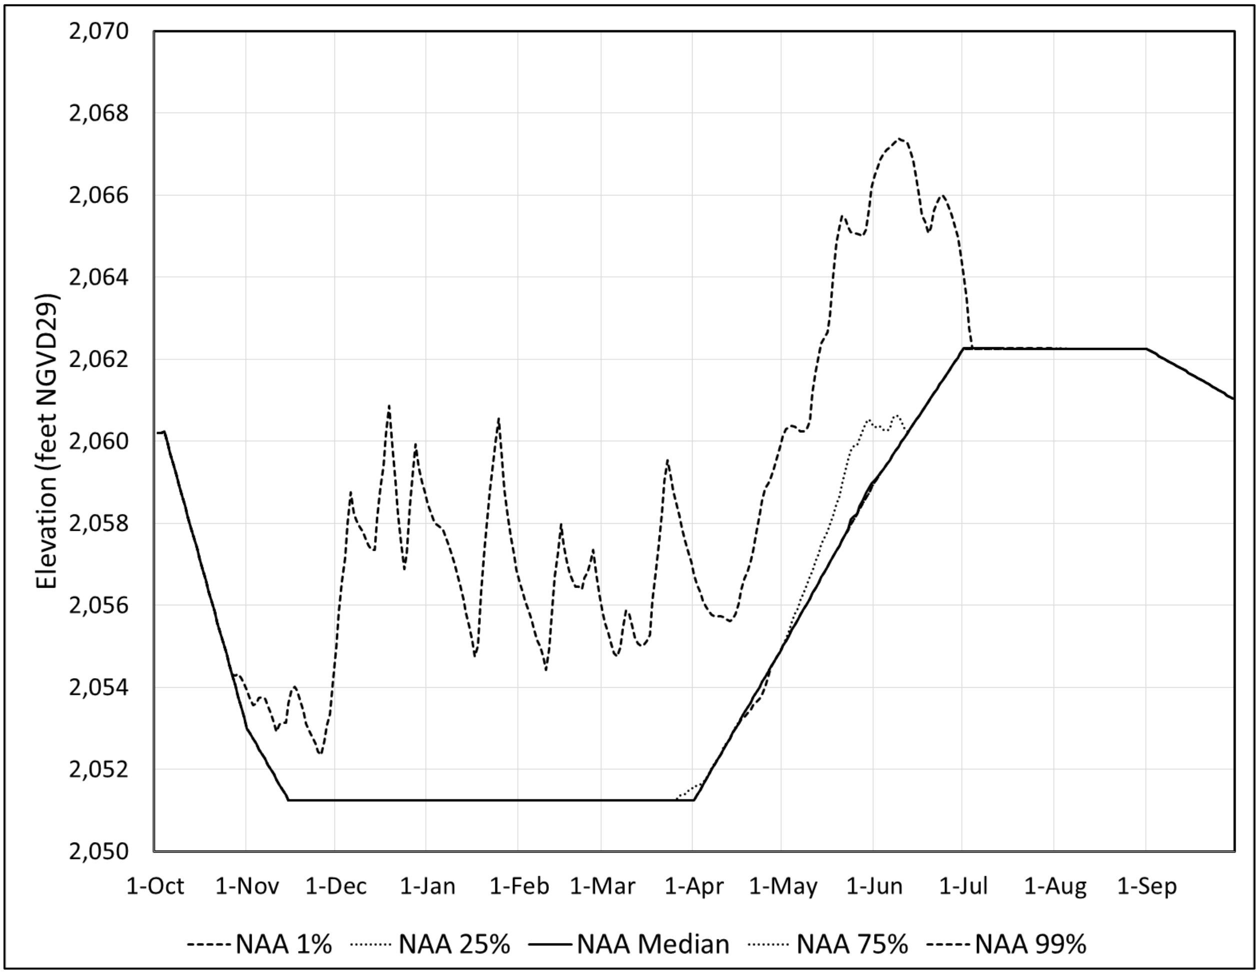

**Figure 3-14. Lake Pend Oreille Summary Hydrograph for No Action Alternative**

In the Lake Pend Oreille elevation summary hydrograph, the 99 percent, 75 percent, median, and 25 percent lines are on top of each other from October through late March, and remain close or identical to each other through the remainder of the water year. The lake level is consistently drawn down each fall and does not have a wide range of elevations in the winter months for the vast majority of water years. Elevated runoff, such as that caused by rain events in the fall or winter months, can drive the lake level up, as reflected in the 1 percent line, representing the maximum elevation. Actual fall and winter lake levels are driven by several factors: system FRM storage, the minimum control elevation related to kokanee salmon, and flexible winter power operations. The highest lake level occurs in the late spring or early summer. The maximum elevation is usually achieved on July 1 and maintained until September 1, at which point the lake level begins to drop. The level of Lake Pend Oreille is controlled by

Albeni Falls Dam most of the year, with the exception of the late spring/early summer when a natural riverbed constriction upstream of Albeni Falls Dam limits how much water is able to exit the lake.

### REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

#### Lake Roosevelt (Grand Coulee Dam Reservoir) Elevation

The reservoir behind Grand Coulee Dam is called Lake Roosevelt. The summary hydrograph showing Lake Roosevelt elevations for the No Action Alternative is shown in Figure 3-15.

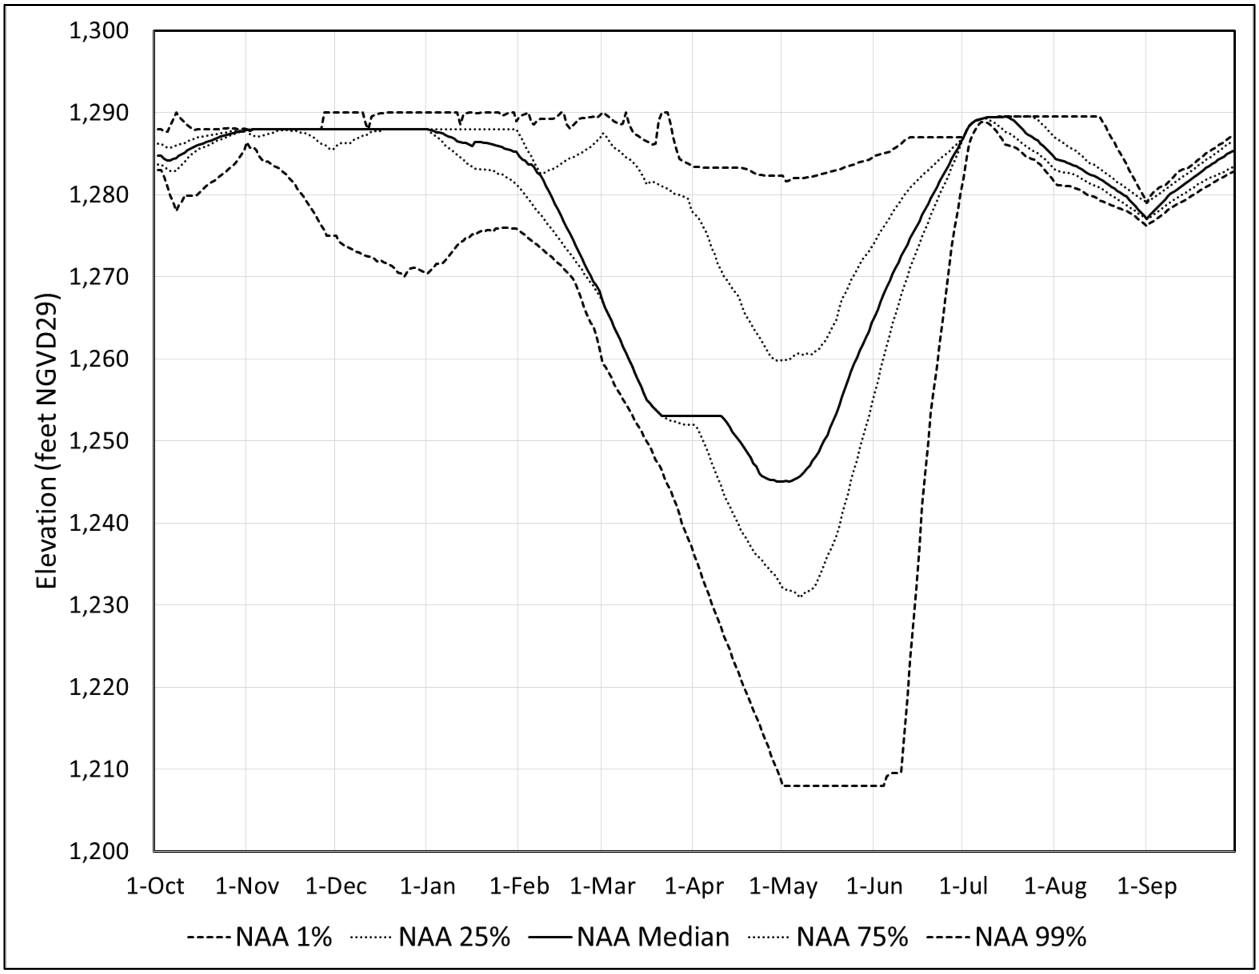

**Figure 3-15. Lake Roosevelt Summary Hydrograph for No Action Alternative**

There is little variability in water levels in the fall, as the Grand Coulee Project is operated to fill from the end of August elevation objective for flow augmentation to 1,283 feet NGDV29 by the end of September for resident fish purposes. The project continues to fill through October to as high as 1,288 feet NGVD29 in preparation for winter power operations and to support chum salmon spawning and incubation below Bonneville Dam. Over the winter months the range of reservoir water level begins to spread, and this generally continues through about mid-spring. Different objectives determine reservoir operations during this period: meeting system FRM requirements, generating power, and providing ecosystem flows (managing flows for chum salmon below Bonneville Dam, and for fall Chinook salmon at Vernita Bar). Grand Coulee Dam operates for multiple purposes throughout the year, including FRM, power, and operations for various fish species. The drawdown of the reservoir level that occurs in the winter and early spring months is guided by FRM requirements. The reservoir may also be deeper than the FRM elevation to operate for power, so long as there is an 85 percent chance of being at the spring elevation objective on April 10 to augment spring flows for migrating juvenile salmon and steelhead (this is referred to as a variable draft limit and is based on interpolation between FRM elevations). The time at which the reservoir begins to refill depends on the Columbia River Basin runoff conditions each year, typically beginning in April or May, and reaching at or near full pool in early July. Reservoir levels gradually drop over July and August, as the project is operated to augment flows to assist migrating juvenile anadromous fish in the lower Columbia River.

**Grand Coulee Dam Outflow**

A summary hydrograph showing outflow from Grand Coulee Dam for the No Action Alternative is shown in Figure 3-16.

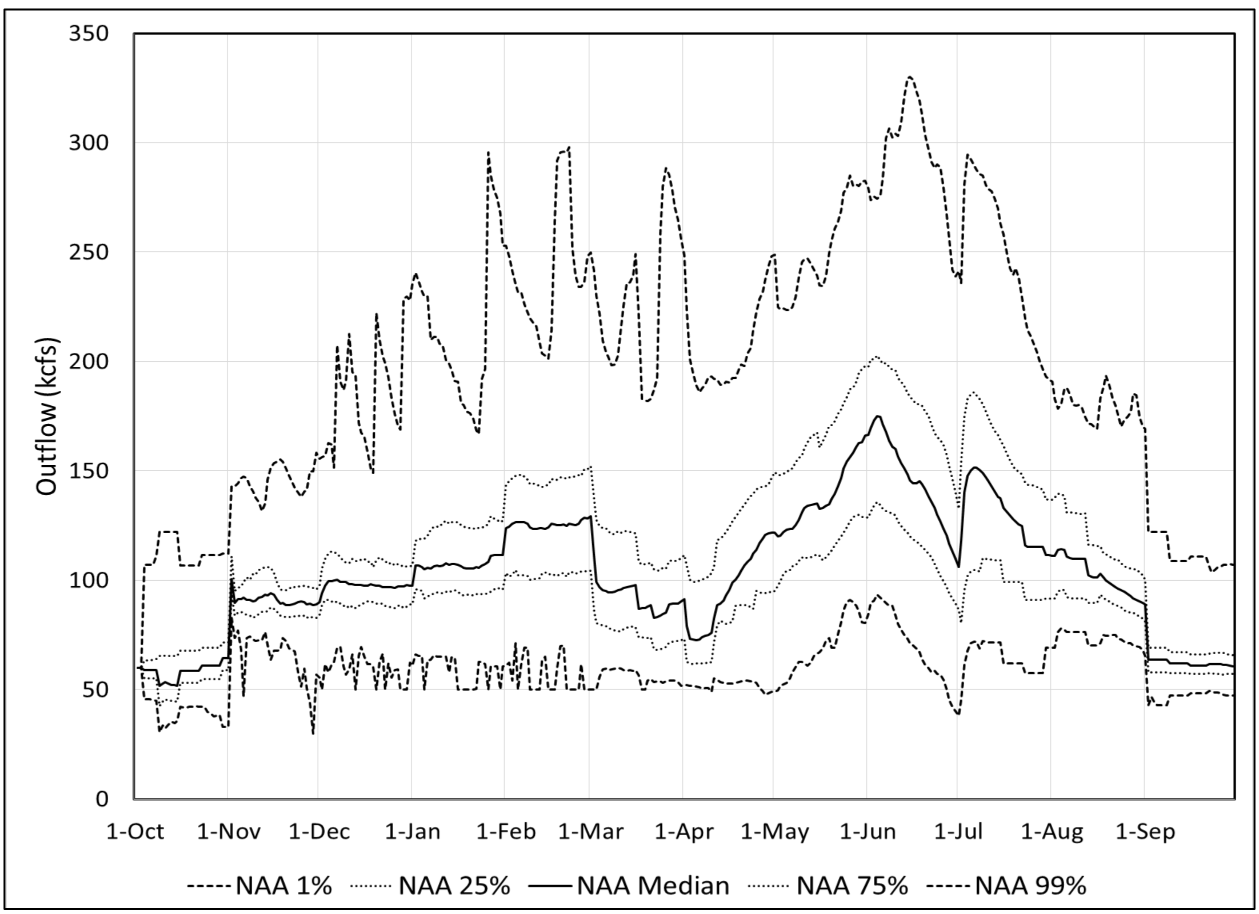

**Figure 3-16. Grand Coulee Dam Outflow Summary Hydrograph for No Action Alternative**

The months with highest flows are generally May and June, and the months with the lowest flows are generally September and October. As a multi-purpose project, there are multiple reasons for the releases at Grand Coulee Dam throughout the water year, which are broadly categorized in Figure 3-7. One of the purposes not portrayed in Figure 3-7, water supply, does not impact reservoir elevations but does impact outflows. Water is pumped out of Lake Roosevelt at Grand Coulee Dam to Banks Lake, which directly impacts the flows downstream. Further information on how Grand Coulee Dam operations are modeled is provided in the H&H Appendix (Appendix B, Part 3, *HEC-ResSim/WAT Documentation*).

### Middle Columbia River below Grand Coulee Dam

Chief Joseph Dam is a run-of-river project located downstream of Grand Coulee Dam. The elevation of the reservoir behind Chief Joseph Dam, known as Lake Rufus Woods, is fairly consistent through the entire calendar year, and outflows closely match those from Grand Coulee Dam. The reservoir elevation at Chief Joseph Dam ranges between 950.0 and 956.0 feet NGVD29. Table 3-6 shows the median values of monthly average flows at locations in the middle Columbia River for the No Action Alternative.

**Table 3-6. Middle Columbia River Monthly Average Flows (kcfs) for No Action Alternative**

| Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Lake Roosevelt Inflow[1/] | 64 | 82 | 92 | 95 | 100 | 65 | 69 | 131 | 166 | 133 | 98 | 75 |
| Grand Coulee | 59 | 91 | 97 | 108 | 126 | 93 | 97 | 138 | 150 | 134 | 102 | 63 |
| Chief Joseph | 58 | 91 | 96 | 108 | 127 | 94 | 98 | 139 | 150 | 135 | 103 | 63 |
| Wells | 59 | 93 | 98 | 110 | 129 | 95 | 101 | 150 | 163 | 141 | 105 | 65 |
| Priest Rapids | 60 | 96 | 102 | 115 | 133 | 100 | 108 | 162 | 178 | 147 | 108 | 68 |

1/ "Lake Roosevelt inflow" is the term used for flow in the Columbia River just downstream of the U.S.-Canada border (about 151 river miles upstream of Grand Coulee Dam).

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Dworshak Dam

A summary hydrograph showing Dworshak Reservoir elevations for the No Action Alternative is shown in Figure 3-17.

The water year generally begins with a reservoir elevation of about 1,520 feet NGVD29. Although there is a wide spread between the 99 percent chance and 1 percent chance exceedance lines for much of the year, the typical seasonal pattern is best understood from viewing the span between the 75 percent chance and 25 percent chance exceedance lines. From October through January, the water level in the reservoir can increase or decrease. The range of possible reservoir elevations widens further in the subsequent winter months, lasting into the early spring. The reservoir level in the winter and early spring months is guided by FRM requirements, and also by minimum outflows. The reservoir begins refilling in the spring and usually reaches its full pool elevation of 1,600 feet NGVD29 by July 1. The reservoir level is drawn down over the summer months to provide cool water to the Snake River, provide flows for salmon migration, and meet the flows per the agreement between the United States and the Nez Perce Tribe, ending at an elevation of 1,520 feet NGVD29 on September 30. Throughout the entire water year, the reservoir levels behind Dworshak Dam are the result of the operations for multiple purposes, broadly categorized in Figure 3-7. Further information on how Dworshak Dam operations are modeled is provided in the H&H Appendix (Appendix B, Part 3, *HEC-ResSim/WAT Documentation*).

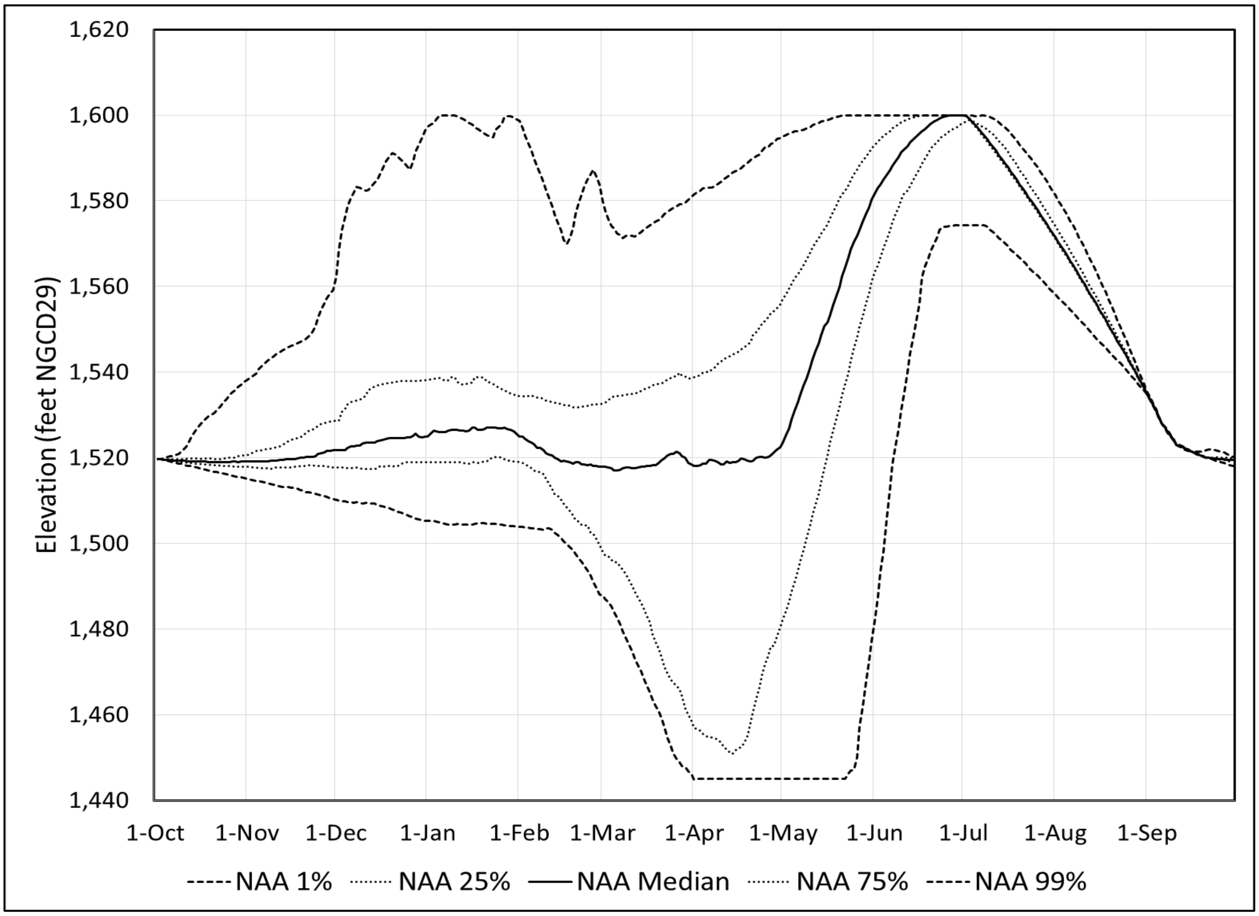

**Figure 3-17. Dworshak Reservoir Summary Hydrograph for No Action Alternative**

**Dworshak Dam Outflow**

A summary hydrograph showing outflow from Dworshak Dam for the No Action Alternative is shown in Figure 3-18.

Flows usually remain low from October through December. The flow in the winter months is generally higher than the fall, as the reservoir is drafted for FRM purposes. Outflow is generally reduced by May so that the reservoir can refill by the beginning of July. In July and August, outflow, typically ranging from 10 to 13 kcfs, is released for flow augmentation and water temperature moderation in the lower Snake River Basin. Releases during the month of September, while the reservoir is between 1,535 and 1,520 feet NGVD29, are made to provide water for salmon migration and to meet flows per the Agreement between the United States and the Nez Perce Tribe. The release is shaped to gradually reduce flows to minimum outflow of 1.6 kcfs over the course of the month.

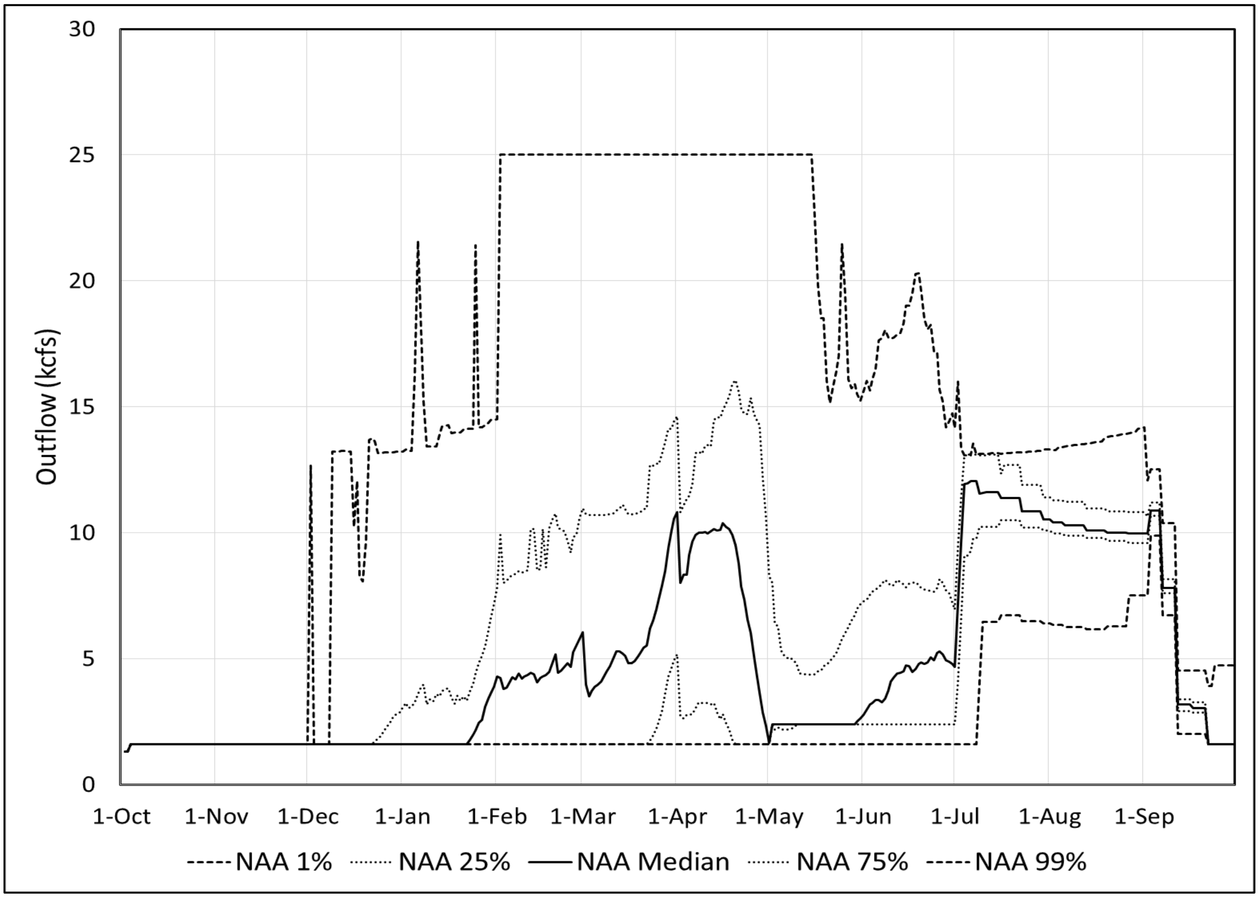

**Figure 3-18. Dworshak Dam Outflow Summary Hydrograph for No Action Alternative**

**Clearwater River below Dworshak Dam and the Lower Snake River**

Water released from Dworshak Dam passes through the four lower Snake River dams that operate as run-of-river projects: Lower Granite Dam, Little Goose Dam, Lower Monumental Dam, and Ice Harbor Dam. For the No Action Alternative, the lower Snake River dams are operated to their MOP range from April 3 through August 31; otherwise there is little change in their reservoir elevations through the calendar year. Table 3-7 shows the median values of monthly average flows at locations in the lower Snake River Basin for the No Action Alternative. Outflows from Dworshak Dam contribute to flows in the lower Snake River but are a smaller portion of the total flow than releases from the Hells Canyon Complex during fall, winter, and spring.

**Table 3-7. Lower Snake Basin Monthly Average Flows (kcfs) for No Action Alternative**

| Location | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Dworshak | 1.6 | 1.6 | 1.6 | 2.1 | 5.1 | 6.2 | 9.6 | 3.5 | 4.8 | 10.7 | 10.2 | 5.0 |
| Spalding, ID | 3.4 | 4.5 | 4.7 | 5.9 | 10.6 | 15.5 | 26.8 | 33.4 | 28.7 | 17.0 | 12.2 | 6.5 |
| Snake + Clearwater | 19.7 | 20.9 | 23.9 | 28.3 | 39.0 | 47.2 | 69.7 | 94.4 | 96.4 | 47.9 | 29.2 | 22.6 |
| Lower Granite | 19.8 | 21.0 | 23.7 | 28.4 | 39.3 | 48.0 | 71.8 | 95.6 | 97.4 | 48.6 | 29.1 | 22.5 |
| Ice Harbor | 20.2 | 21.4 | 24.5 | 29.4 | 42.0 | 50.7 | 73.0 | 95.4 | 97.2 | 48.4 | 28.1 | 21.2 |

## REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

### Lower Columbia River Reservoirs

McNary, John Day, The Dalles, and Bonneville Dams are referred to as the four lower Columbia River dams. They generally operate as run-of-river projects. For the No Action Alternative, John Day Dam is modeled operating to its MIP level from April 10 through September 30 but may provide some FRM space during winter or spring floods. Otherwise, there is little change in the reservoir elevations through the calendar year for any of the four lower Columbia River dams. The operating range for John Day Dam is shown in Figure 3-19.

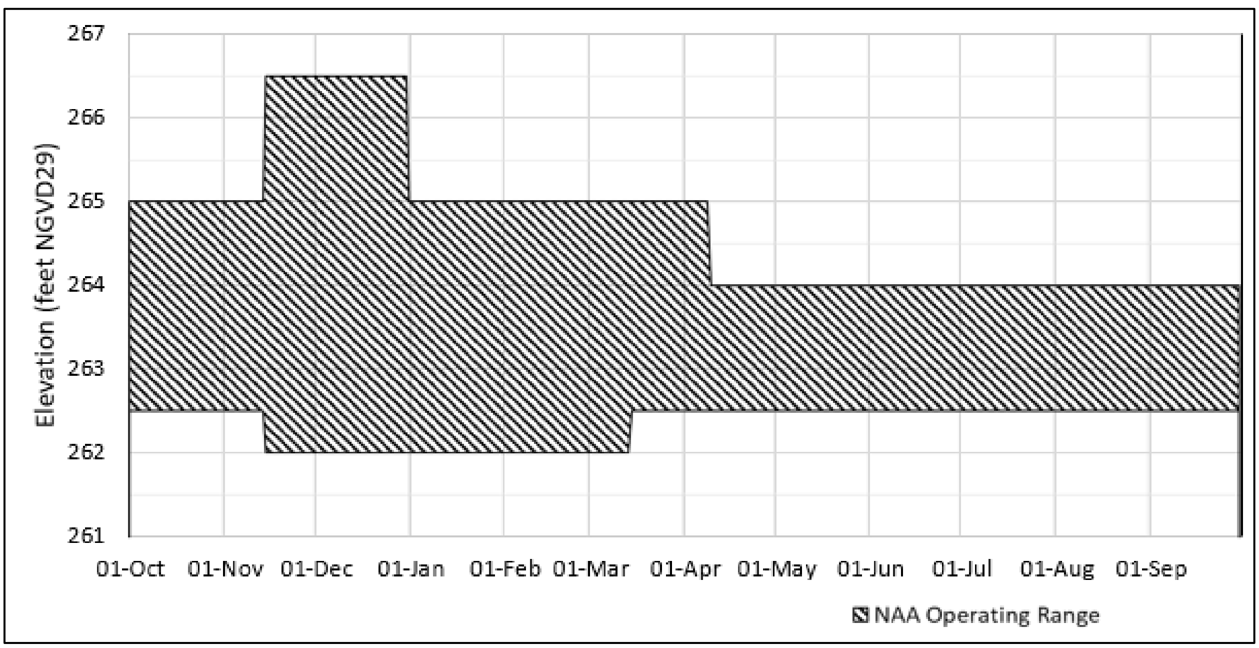

**Figure 3-19. John Day Dam Operating Range for No Action Alternative**

Note: John Day may be operated between 257 feet and 268 feet NGVD29 for FRM purposes. These limits are not shown on this figure in order to show greater detail in the vertical scale.

### Lower Columbia River Flows

Because McNary Dam is a run-of-river project, McNary Dam outflow is equivalent to the combined flow of the Columbia River though Region B and the Snake River through Region C. A summary hydrograph showing outflow from McNary Dam for the No Action Alternative is shown in Figure 3-20 Flows are generally highest in May and June.

Outflow patterns from McNary Dam generally persist through the three dams downstream, though there are tributaries that join the Columbia River downstream of McNary Dam and some shaping of flows by John Day Dam occurs during winter flood operations. On an hourly basis, river flows can increase or decrease dramatically for hydropower generation. Table 3-8 shows the median values of monthly average flows at locations along the lower Columbia River for the No Action Alternative.

**Table 3-8. Lower Columbia River Monthly Average Flows (kcfs) for No Action Alternative**

| Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Columbia + Snake | 83 | 122 | 134 | 151 | 181 | 157 | 188 | 260 | 288 | 199 | 140 | 91 |
| McNary | 85 | 124 | 136 | 154 | 182 | 159 | 192 | 260 | 285 | 198 | 141 | 93 |
| John Day | 85 | 125 | 140 | 156 | 185 | 165 | 198 | 267 | 288 | 197 | 141 | 93 |
| The Dalles | 90 | 130 | 146 | 163 | 192 | 172 | 206 | 273 | 293 | 202 | 146 | 97 |

## SUMMARY OF EFFECTS

Under the No Action Alternative, all CRS projects are modeled to represent the current operating rules and constraints. The eight run-of-river dams (Ice Harbor, Lower Monumental, Little Goose, Lower Granite, Chief Joseph, Bonneville, The Dalles, and McNary) are each operated with water levels that are within a seasonal elevation range. The hourly, daily, and weekly water level will vary within that range to meet multiple operating purposes. While this hourly and daily fluctuation in water level and reservoir release can affect river flow, it does not result in major seasonal shifts of river flow and the shape of the flow hydrograph. Some water is diverted from these reservoirs to meet water supply needs.

Five of the storage dams (Libby, Hungry Horse, Albeni Falls, Grand Coulee, and Dworshak) are operated in, generally, a seasonal cycle and do affect the shape of the hydrograph. The cycle starts in the early winter with each reservoir slowly lowering its water level (referred to as drawdown) to meet many purposes: to generate hydropower, to allow capture of winter rain events, to prepare to capture forecast spring snowmelt runoff, and to provide water for fish species. The amount that reservoir water levels are lowered depends on many factors including existing temperature and precipitation as well as on forecasts (predictions) of the amount of snowmelt that is expected later that year. Storage reservoirs usually reach their lowest level in late March or April. Once snow begins to melt and flow into the rivers in late spring and early summer, the reservoirs begin to capture the snowmelt runoff and increase their water level. They do this in order to prevent flooding as well as to fill the reservoirs for summer. In the late spring and early summer, flow in all rivers in the basin is usually at its highest due to natural snowmelt. As spring runoff begins to decrease, reservoir water levels increase to close to full and remain there for varying periods of time after which they slowly begin to lower their water elevation and release water to provide higher flows in the river than would occur naturally in the late summer into early fall. Some water is diverted from these reservoirs to meet water supply needs. Towards the end of fall, the operating cycle of storage reservoirs begins again.

John Day Dam is a storage reservoir but it is often operated more like a run-of-river project, within seasonal water elevation ranges. It can, however, lower its water surface elevation, when necessary, to prepare to capture water from winter or spring floods.

#### *3.2.4.4 Multiple Objective Alternative 1*

As the effects of MO1 are presented, they will be displayed along with the No Action Alternative to illuminate the timing and magnitude of differences in water conditions between it and the No Action Alternative. The operational measure (or measures) from MO1 which would result in changes from the No Action Alternative are identified to the extent that this is possible based on experience with system operation and hydroregulation modeling. However, because the measures were combined into an alternative that was then modeled, isolating the effect a single measure would have is not possible in many cases. Further supporting details are included in the H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*).

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Lake Koocanusa (Libby Dam Reservoir) Elevation**

Under MO1, the *Modified Draft at Libby*, *December Libby Target Elevation*, and *Sliding Scale at Libby and Hungry Horse* measures would have a direct effect on Libby Dam operations.

Reservoir water levels in Lake Koocanusa would differ from the No Action Alternative, as shown in Figure 3-21.

MO1 would have the same end-of-November target reservoir elevation as the No Action Alternative. However, over the course of December, the reservoir elevations for MO1 would differ from those under the No Action Alternative due to the *December Libby Target Elevation* measure, which calls for an end-of-December target elevation of 2,420 feet NGVD29 in all years. Most of the time, this would make the reservoir elevation on December 31 higher than the No Action Alternative; however, in about the driest 30 percent of forecast years at Libby Dam (those forecasted to have an April to August runoff volume of 5.67 Maf or less), the reservoir elevation on December 31 would be lower than the No Action Alternative.

From December 31 through mid-February, reservoir levels would generally be higher under MO1 than they would be for the No Action Alternative, though for the driest forecast years, the reservoir would be lower (shown in Figure 3-22).

The *Modified Draft at Libby* measure would begin influencing reservoir elevations after December 31, and its effects are best understood by looking at the spring, when the lowest reservoir elevation typically occurs. While the *December Libby Target Elevation* measure generally delays the lowering of the reservoir, it is the *Modified Draft at Libby* measure that causes the spring reservoir elevation to be lower than the No Action Alternative when the seasonal water supply forecast is less than 6.9 Maf at Libby Dam. This is not the case for all years, though, as demonstrated by the 75 percent exceedance lines for MO1 and the No Action Alternative. There, the case is the opposite; the reservoir elevation under MO1 would be higher than that for the No Action Alternative through about the first half of spring.

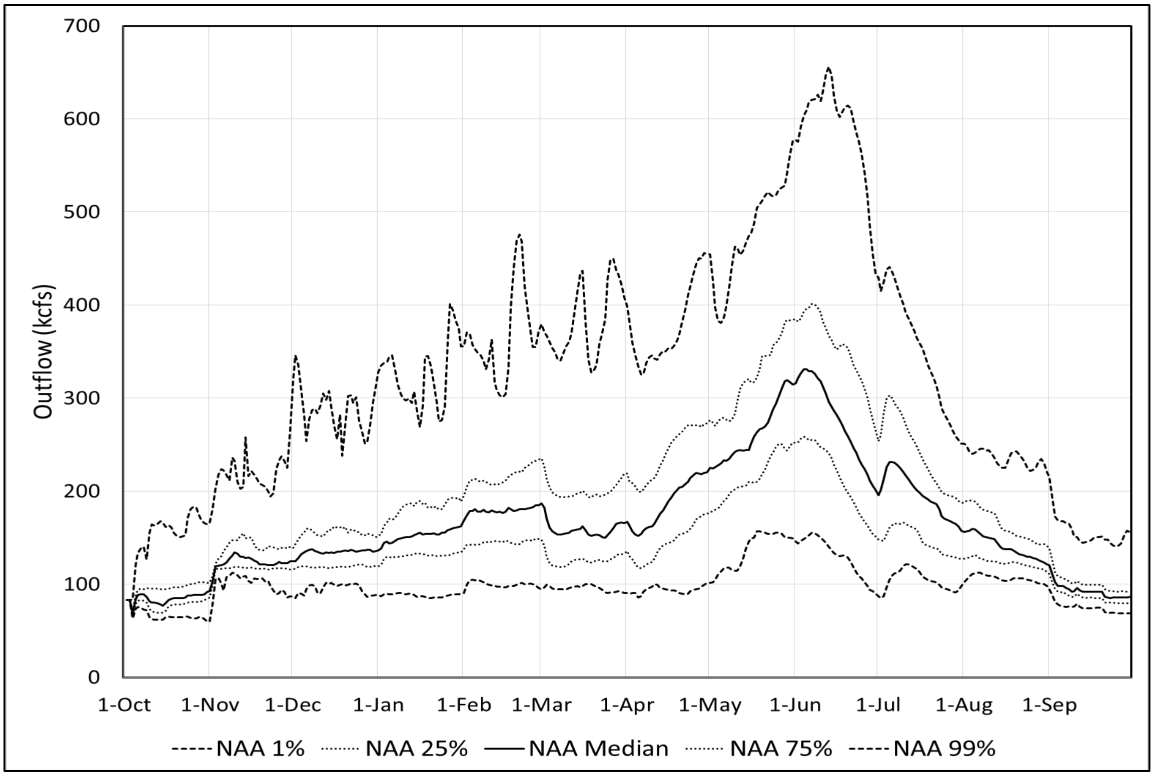

**Figure 3-20. McNary Dam Outflow Summary Hydrograph for No Action Alternative**

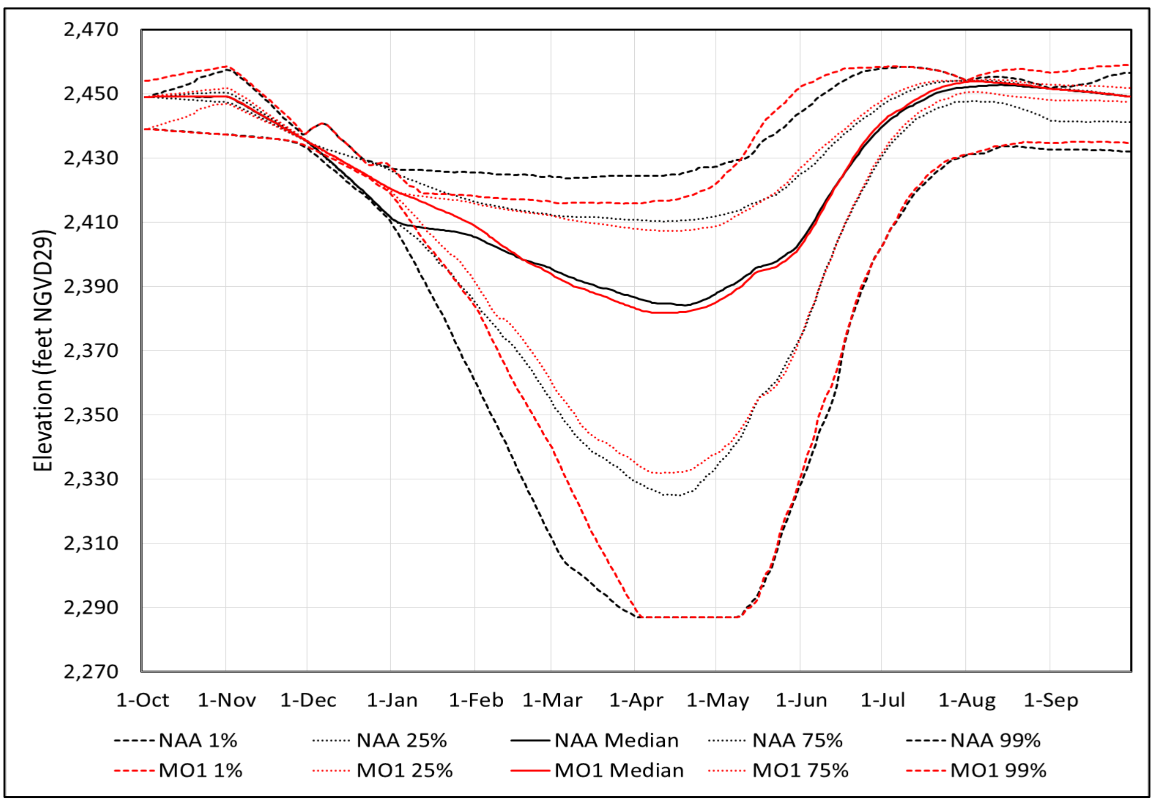

**Figure 3-21. Lake Koocanusa Summary Hydrograph for Multiple Objective Alternative 1**

The *Modified Draft at Libby* measure would result in a general increased likelihood of reservoir refill in all water year types. For MO1, there would be a 51 percent chance of the reservoir reaching elevation 2,454 feet NGVD29 or higher (within 5 feet of the full pool elevation of 2,459 feet NGVD29) by July 31, as compared to a 39 percent chance for the No Action Alternative. The peak reservoir elevation would usually be achieved in July or early August.

During the months of August and September, the reservoir elevation for MO1 would generally be about one to four feet higher than for the No Action Alternative. The reason for this is the *Modified Draft at Libby* measure, which tends to increase the peak refill elevation, and the *Sliding Scale at Libby and Hungry Horse* measure which calls for a sliding scale end-of-September target elevation that would be dependent on the Libby Dam water supply forecast, rather than the system-wide water supply forecast at The Dalles. The *Sliding Scale at Libby and Hungry Horse* measure targets a higher elevation than the No Action Alternative in the wettest 25 percent of years.

Reservoir water levels in Lake Koocanusa under MO1 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-22.

Finally, the three panels in Figure 3-23 show monthly elevation duration curves for July, August, and September, respectively. The curve for MO1 is plotted along with the curve for the No Action Alternative in each month, showing that the reservoir level would be higher in each of the 3 months for MO1. In July, this is attributable to the *Modified Draft at Libby* measure, which tends to increase the peak refill elevation. In August the higher reservoir levels are attributable to a combination of the *Modified Draft at Libby* and *Sliding Scale at Libby and Hungry Horse* measures. In September, the higher reservoir levels are attributable to the *Sliding Scale at Libby and Hungry Horse* measure, which has fewer years drafting to 2,439 feet NGVD29 than the No Action Alternative (due to the change in forecast location), and the wettest years only needing a draft to 2,454 feet NGVD29.

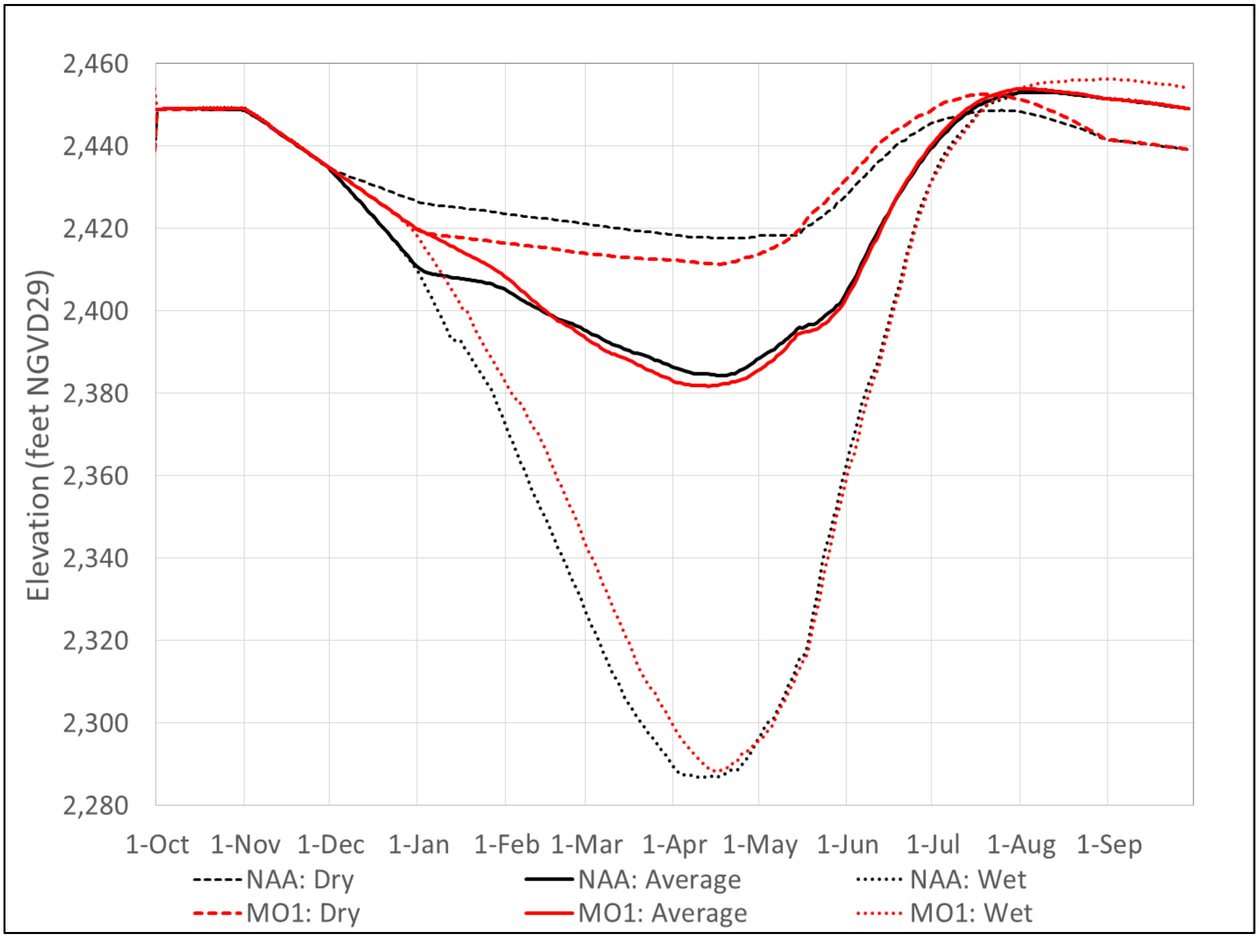

**Figure 3-22. Lake Koocanusa Water Year Type Hydrographs for Multiple Objective Alternative 1**

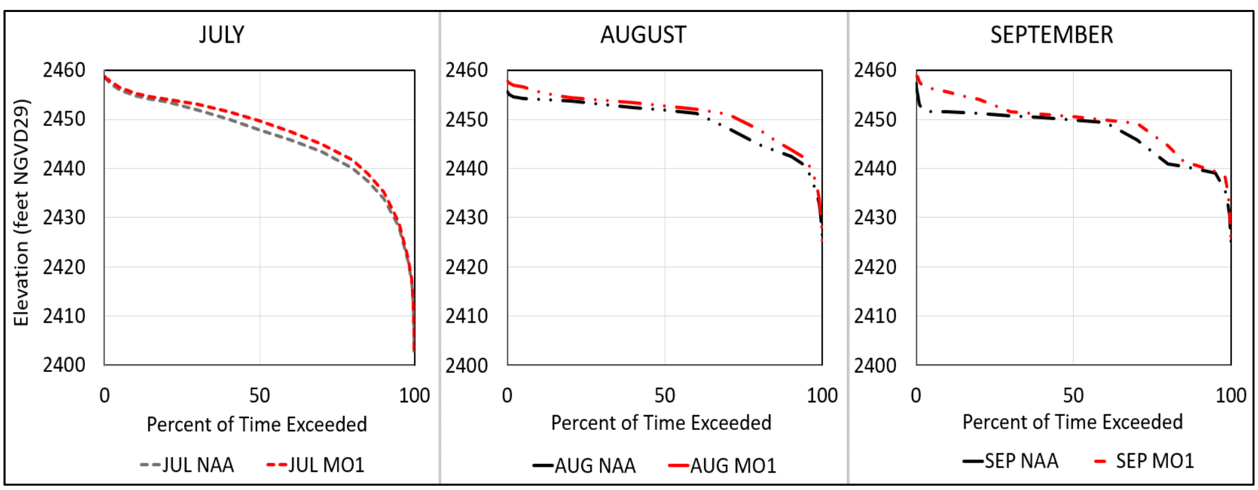

**Figure 3-23. Lake Koocanusa Summer Elevations for Multiple Objective Alternative 1**

### Libby Dam Outflow

Under MO1, the *Modified Draft at Libby*, *December Libby Target Elevation*, and *Sliding Scale at Libby and Hungry Horse* measures would have a direct effect on Libby Dam outflows. The outflows would differ from the No Action Alternative in a variety of ways throughout the year. Figure 3-24 shows median hydrographs for Libby Dam outflow in dry, average, and wet years.

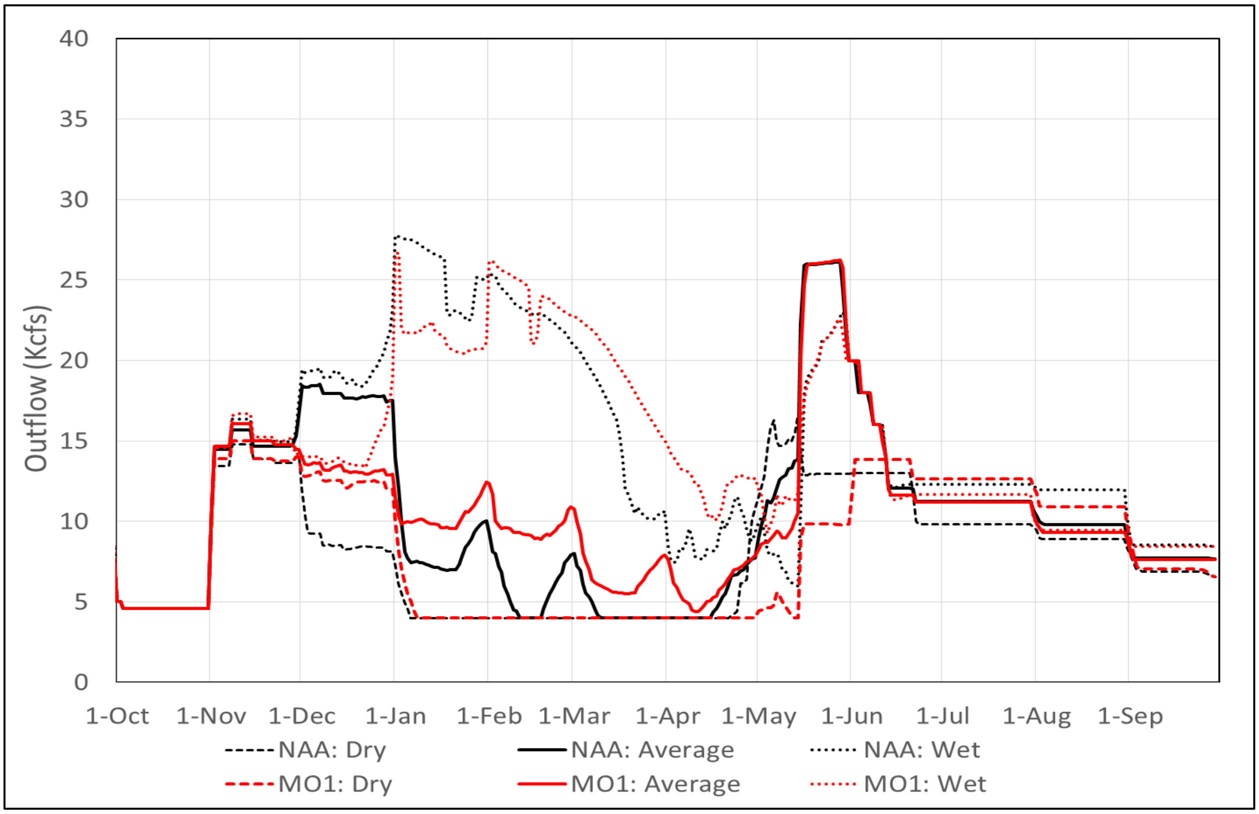

**Figure 3-24. Libby Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 1**

The change in average monthly outflow throughout the water year is presented in Table 3-9. A range of exceedance percentiles is presented because in some months, the direction and magnitude of change varies depending on whether one looks at flows more likely to be exceeded (99 percent exceedance, 75 percent exceedance) or flows less likely to be exceeded (25 percent exceedance, 1 percent exceedance).

Average outflow from Libby Dam under MO1 would differ from the No Action Alternative:

- In December, the median value of the monthly average outflow would decrease by 4.4 kcfs due to the *December Libby Target Elevation* measure. The flows at the 25 percent and 1 percent exceedance levels (higher flows) would also decrease, while the flows at the 75 percent and 99 percent exceedance levels would increase.

- In January, February, and March the median value of the monthly average outflow would increase by 1.7, 3.3, and 1.6 kcfs, respectively. These outflow increases are caused by the reservoir being lowered at a faster rate under MO1 than the No Action Alternative for many years, caused by the *December Libby Target Elevation* measure as well as the *Modified Draft at Libby* measure.
- In April and May, the median value of the monthly average outflow would decrease by 0.6 kcfs and 0.7 kcfs, respectively. However, Figure 3-24 shows that outflows would be higher in April and May for wet years and lower for dry years. These changes are related to the VarQ update that is part of the *Modified Draft at Libby* measure that would account for future volume releases and refill the reservoir more aggressively.
- In June and July, the median value of the monthly average outflows would be similar to the No Action Alternative. However, in late June and July of dry years, the outflow would increase by about 3 kcfs under MO1 from that in the No Action Alternative because under MO1, there would be less space to fill due to more aggressive planned refill of the reservoir.
- In August and September, the median value of the monthly average outflow would decrease by 0.7 and 0.2 kcfs, respectively. The *Sliding Scale at Libby and Hungry Horse* measure, which calls for a sliding scale end-of-September target elevation based on the Libby Dam water supply forecast and a higher elevation target in the wettest 25 percent of years, is the primary cause of these changes.

**Table 3-9. Libby Dam Monthly Average Outflow for Multiple Objective Alternative 1 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

Note: Ave. = average; mo. = monthly. Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows lower than the No Action Alternative flows; green shading denotes MO1 flows higher than the No Action Alternative flows.

### Bonners Ferry Flow

Under MO1, the *Modified Draft at Libby*, *December Libby Target Elevation*, and *Sliding Scale at Libby and Hungry Horse* measures would affect flows at Bonners Ferry. In general, the flows would differ from the No Action Alternative in much the same way as at Libby Dam, and for the same reasons. The change in average monthly flow at Bonners Ferry throughout the water year is presented in Table 3-10.

**Table 3-10. Bonners Ferry Monthly Average Flow for Multiple Objective Alternative 1 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

### Hungry Horse Reservoir Elevation

Under MO1, the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures would have a direct effect on Hungry Horse Dam operations.

Reservoir water levels would differ from the No Action Alternative, as shown in Figure 3-25.

The water year would begin with the reservoir levels for MO1 being lower than those for the No Action Alternative. This is because the operations associated with the *Hungry Horse Additional Water Supply* measure would leave the reservoir at a lower elevation on September 30 than under the No Action Alternative, and the condition would carry over to the following water year. It should be noted that when MO1 was modeled, the initial Hungry Horse Reservoir levels at the start of each water year were erroneously set lower than intended. This initialization error had little effect downstream from Hungry Horse Dam. Hungry Horse Dam's modeled releases were up to 1 kcfs lower than they should have been, but by the time flow reaches Flathead Lake, the MO1 results have little error. A subsequent sensitivity analysis revealed that this initialization error primarily affected results in the fall and winter. In the summary hydrograph shown in Figure 3-25, the median and higher elevations should have water levels 1 to 3 feet higher than shown from October through May. Below the median, the results should be 5 to 10 feet higher from October through February.

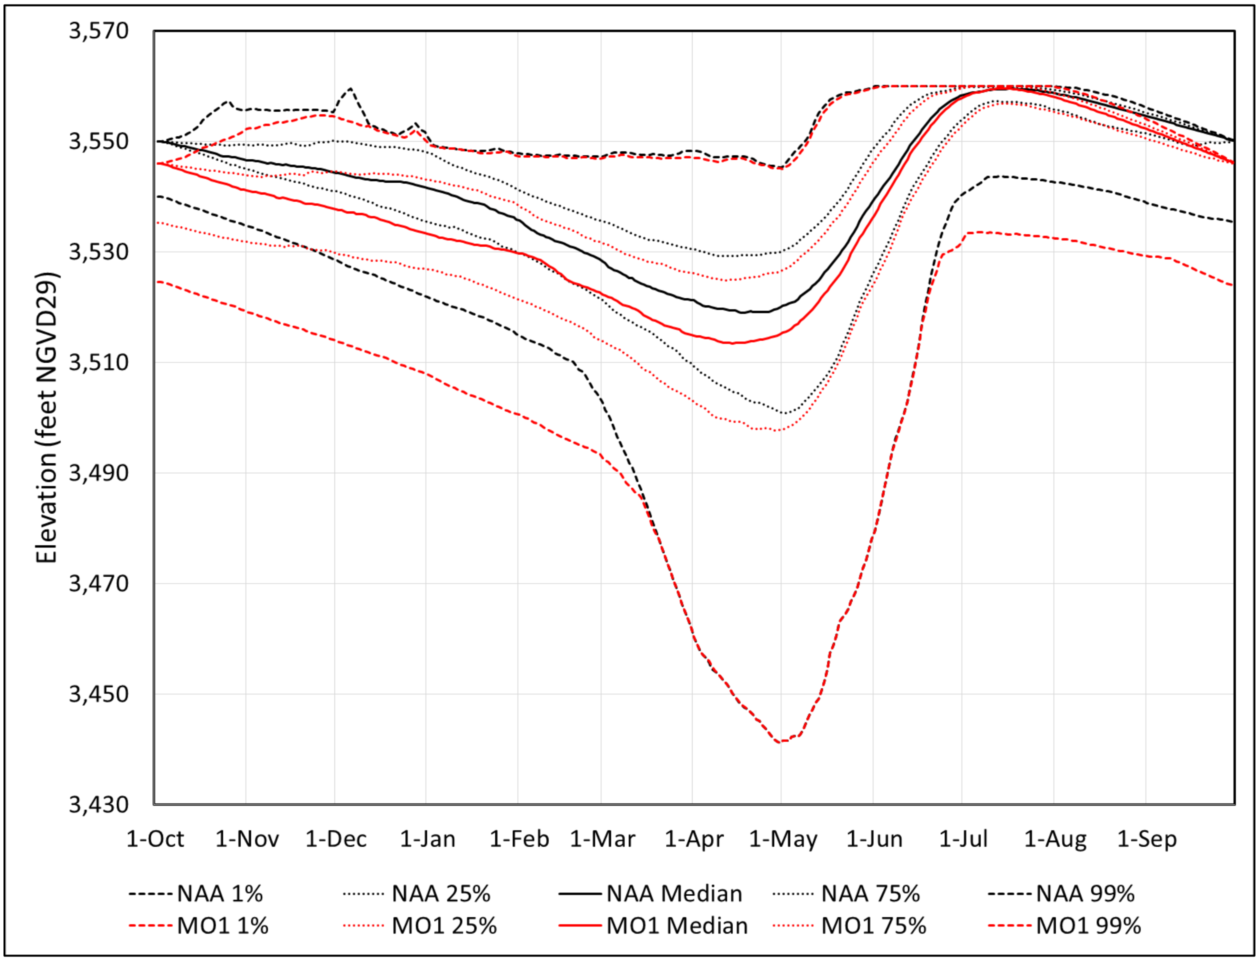

**Figure 3-25. Hungry Horse Reservoir Summary Hydrograph for Multiple Objective Alternative 1**

Overall, reservoir elevations under MO1 would be lower than for the No Action Alternative. At the median level, reservoir elevations would be about 4 feet lower in November through April and 0 to 2 feet lower in May through August. By the end of September, reservoir levels under MO1 would typically be 4 feet lower than the No Action Alternative. The *Sliding Scale at Libby and Hungry Horse* measure results in reducing the draft requirements in some years, by setting a higher elevation target for summer flow augmentation than the No Action Alternative.

Water levels at Hungry Horse Reservoir under MO1 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-26.

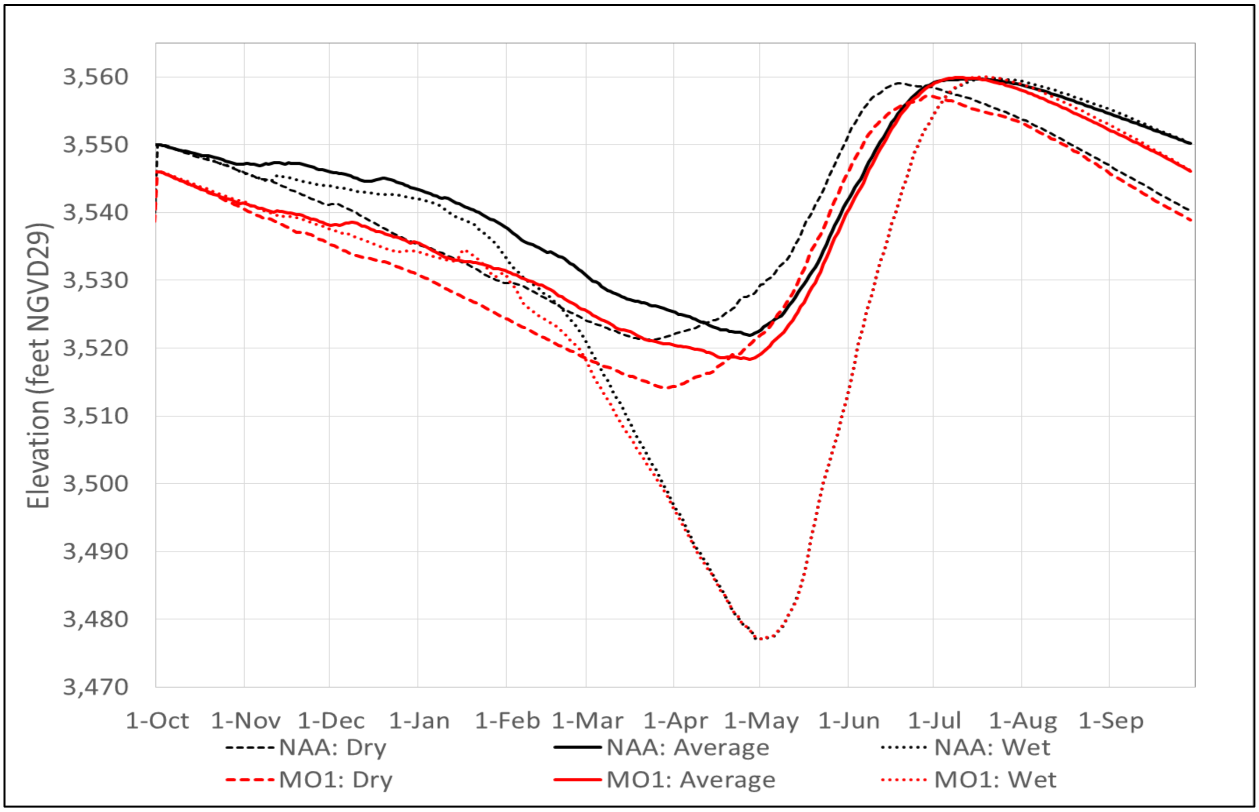

**Figure 3-26. Hungry Horse Reservoir Water Year Type Hydrographs for Multiple Objective Alternative 1**

Finally, the three panels in Figure 3-27 show Hungry Horse Reservoir elevation duration curves for the months of July, August, and September, respectively. While other months also have differences, these three are shown because of interest in summer reservoir elevations. In general, the reservoir level in the summer months would be lower for MO1 than for the No Action Alternative. For instance, the daily reservoir elevation in September would be above elevation 3,550 feet NGVD29 only about 30 percent of the time under MO1, whereas it would be above that elevation about 70 percent of the time under the No Action Alternative.

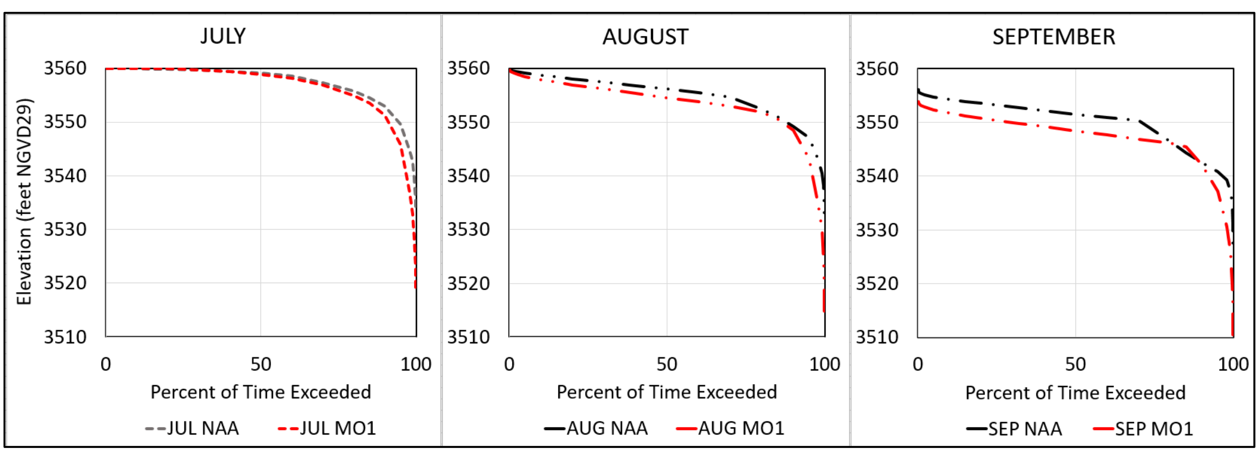

**Figure 3-27. Hungry Horse Reservoir Summer Elevations for Multiple Objective Alternative 1**

**Hungry Horse Dam Outflow**

Under MO1, the Hungry Horse Additional Water Supply and *Sliding Scale at Libby and Hungry Horse* measures would have a direct effect on Hungry Horse Dam outflows. The outflows would differ from the No Action Alternative depending on the time of year. Figure 3-28 shows median hydrographs for Hungry Horse Dam outflow in dry, average, and wet years.

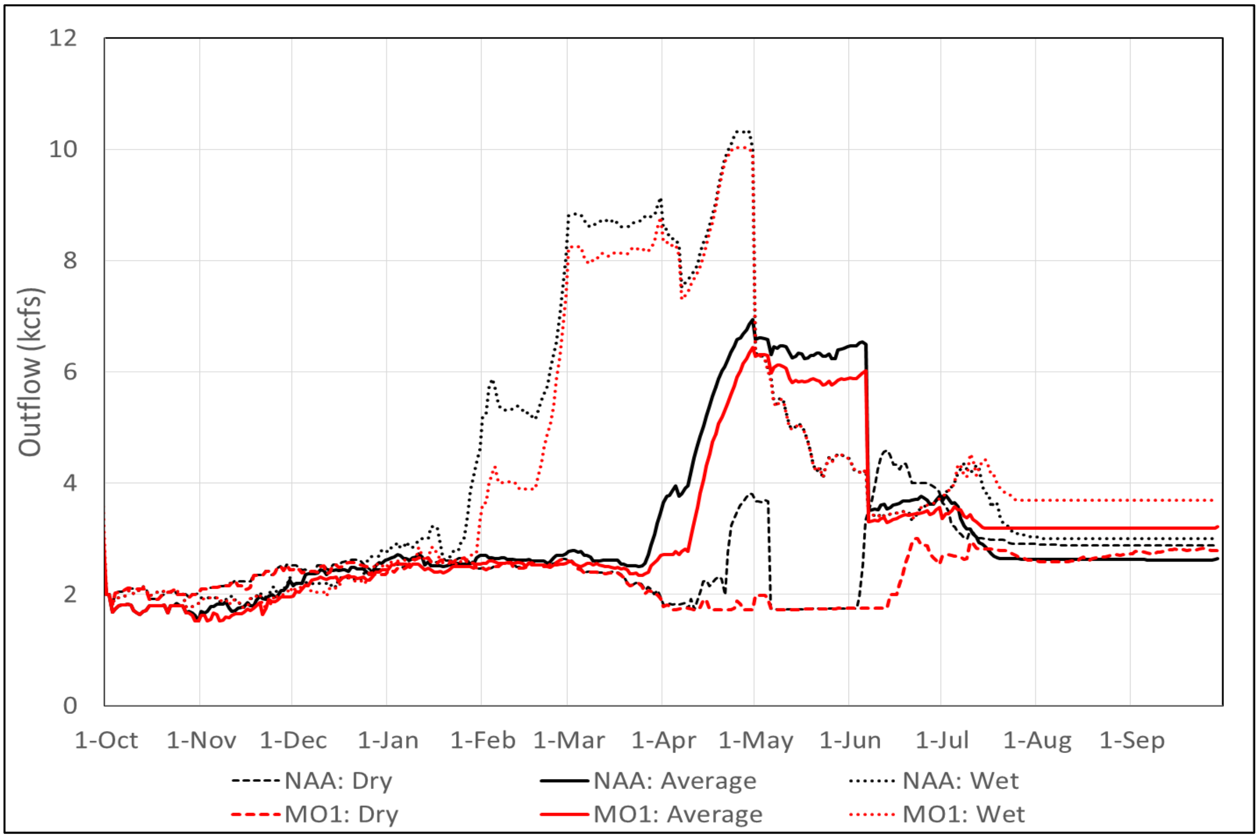

**Figure 3-28. Hungry Horse Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 1**

The change in average monthly outflow from Hungry Horse Dam throughout the water year is presented in Table 3-11.

Average outflow from Hungry Horse Dam would differ from the No Action Alternative:

- In August and September, the median value of the monthly average outflow would increase as compared to the No Action Alternative. The measures driving these changes are the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures.
- After September and through the spring, reservoir outflows would generally be lower than for the No Action Alternative. The lower outflows would occur because the reservoir would be drafted deeper at the end of September, and so would begin the water year at a lower elevation than under the No Action Alternative.

**Table 3-11. Hungry Horse Dam Monthly Average Outflow for Multiple Objective Alternative 1 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows lower than the No Action Alternative flows; green shading denotes MO1 flows higher than the No Action Alternative flows.

While the initial Hungry Horse Reservoir levels at the start of each water year were erroneously set lower than intended, the effects of this initialization on Hungry Horse discharge are smaller than the effects on reservoir elevation. The results in the table above are close to what would be expected for MO1. Winter flows would be lower than for the No Action Alternative, with flows at the 1 percent exceedance level being the most affected, with an artificial modeling reduction from the lower starting pool initialization error. (The artificial modeling reduction ranges from 0.2 to 0.9 kcfs at the 1 percent exceedance level.) By May and June, the artificial modeling reduction in flows from the initialization error is just 0.1 to 0.2 kcfs for most water year types. Moving downstream through the system, flow effects from initialization have less and less of an effect as the total river flows become larger and larger.

### Columbia Falls Flow

Under MO1, the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures would affect flows at Columbia Falls. Compared to the No Action Alternative, there would be increased flow in August and September in virtually all years, while the other months of the year would have flows similar to or less than those under the No Action Alternative, while still meeting minimum flow requirements. The change in average monthly flow at Columbia Falls throughout the water year, as compared to the No Action Alternative, is presented in Table 3-12.

**Table 3-12. Columbia Falls Monthly Average Flow for Multiple Objective Alternative 1 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

| | | 99% | 0% | 0% | 0% | -1% | 0% | 0% | -7% | -2% | -3% | -5% | 2% | 10% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows lower than the No Action Alternative flows; green shading denotes MO1 flows higher than the No Action Alternative flows.

### Lake Pend Oreille Elevation

While the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures in MO1 would affect Hungry Horse Dam operations, the changes would not impact annual peak reservoir levels and would not change the timing of refill or drawdown. Thus, there would not be any noticeable difference in the level of Lake Pend Oreille as compared to the No Action Alternative.

### Albeni Falls Outflow

Under MO1, the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures would affect the monthly average outflow from Albeni Falls Dam, but to a lesser degree than at Hungry Horse Dam or Columbia Falls. In January through July, and again in September, the median value of the monthly average outflow from Albeni Falls Dam under MO1 would be 0.1 kcfs to 0.7 kcfs less than the No Action Alternative, depending on the month. This is shown in Table 3-13.

**Table 3-13. Pend Oreille Basin Monthly Average Flows for Multiple Objective Alternative 1 (as change from No Action Alternative)**

| | Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Columbia River flow upstream of Grand Coulee Dam

Under MO1, the *Modified Draft at Libby*, *December Libby Target Elevation*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would affect Columbia River flow upstream of Grand Coulee Dam. The flows are depicted in Figure 3-29, which shows flows near RM 748 (just downstream of the U.S.-Canada border, about 151 river miles upstream of Grand Coulee Dam).

Figure 3-29 characterizes the timing and magnitude of flow changes between the No Action Alternative and MO1 due to the combined effect of measures at Libby Dam and Hungry Horse Dam. Changes in flow between MO1 and the No Action Alternative would be most noticeable in December. In December, the median flow for MO1 would be about 4 kcfs lower than for the No Action Alternative due to the *December Libby Target Elevation* measure.

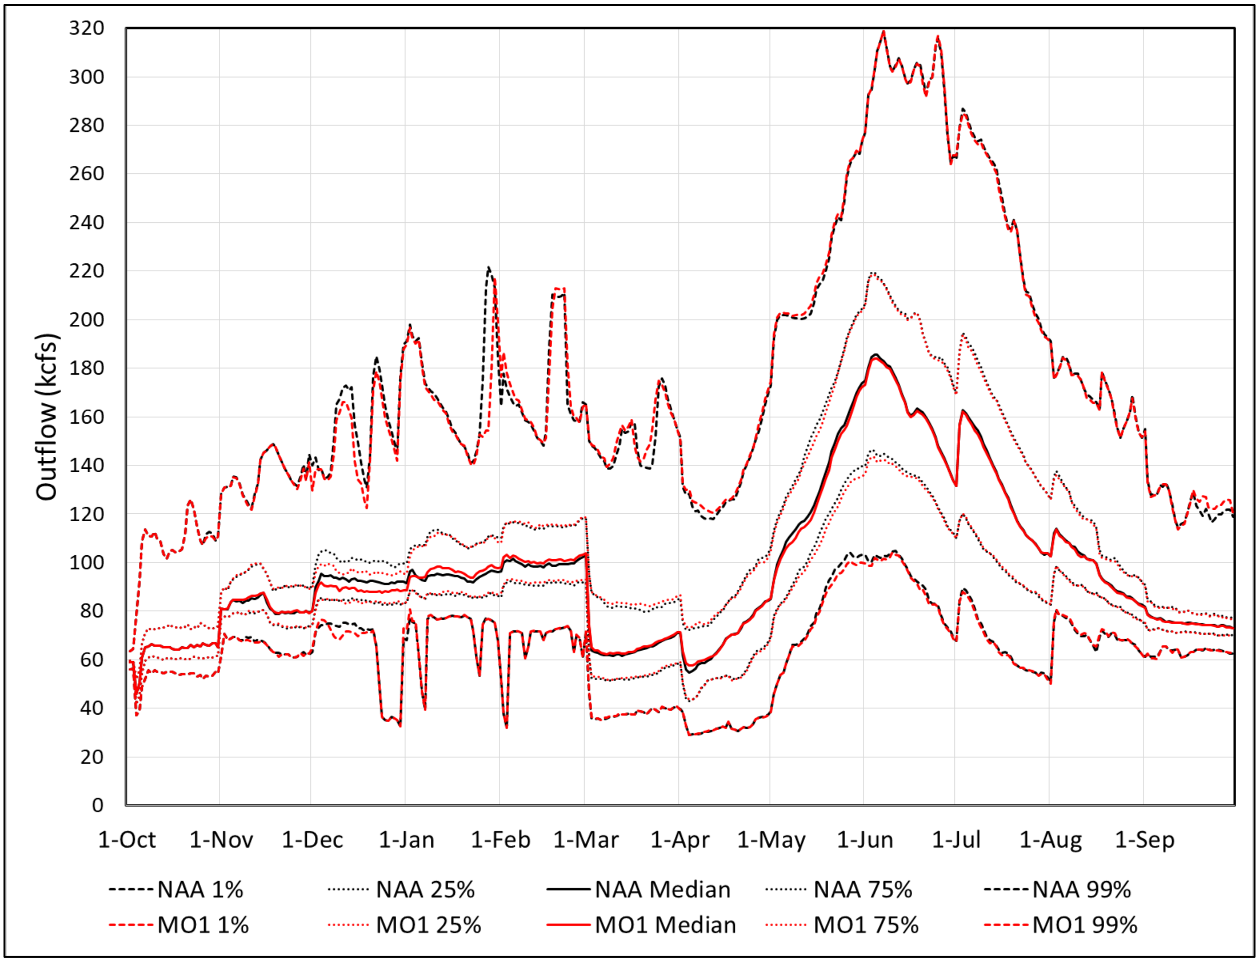

**Figure 3-29. Lake Roosevelt Inflow Summary Hydrograph for Multiple Objective Alternative 1**

**Lake Roosevelt (Grand Coulee Dam Reservoir) Elevation**

Under MO1, the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures relate directly to Grand Coulee Dam and would influence reservoir elevations at Lake Roosevelt.

In addition to the operational measures listed above, the *Modified Draft at Libby*, *December Libby Target Elevation*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would affect inflow to Grand Coulee Dam. The hydroregulation modeling performed for MO1 incorporates all of these measures, but because each measure was not evaluated in isolation from the others, drawing a direct linkage between a single measure and an effect is not always possible. The effects that would occur from a measure or combination of measures are identified and discussed to the extent possible.

Reservoir water levels in Lake Roosevelt under MO1 would differ from the No Action Alternative, as shown in Figure 3-30.

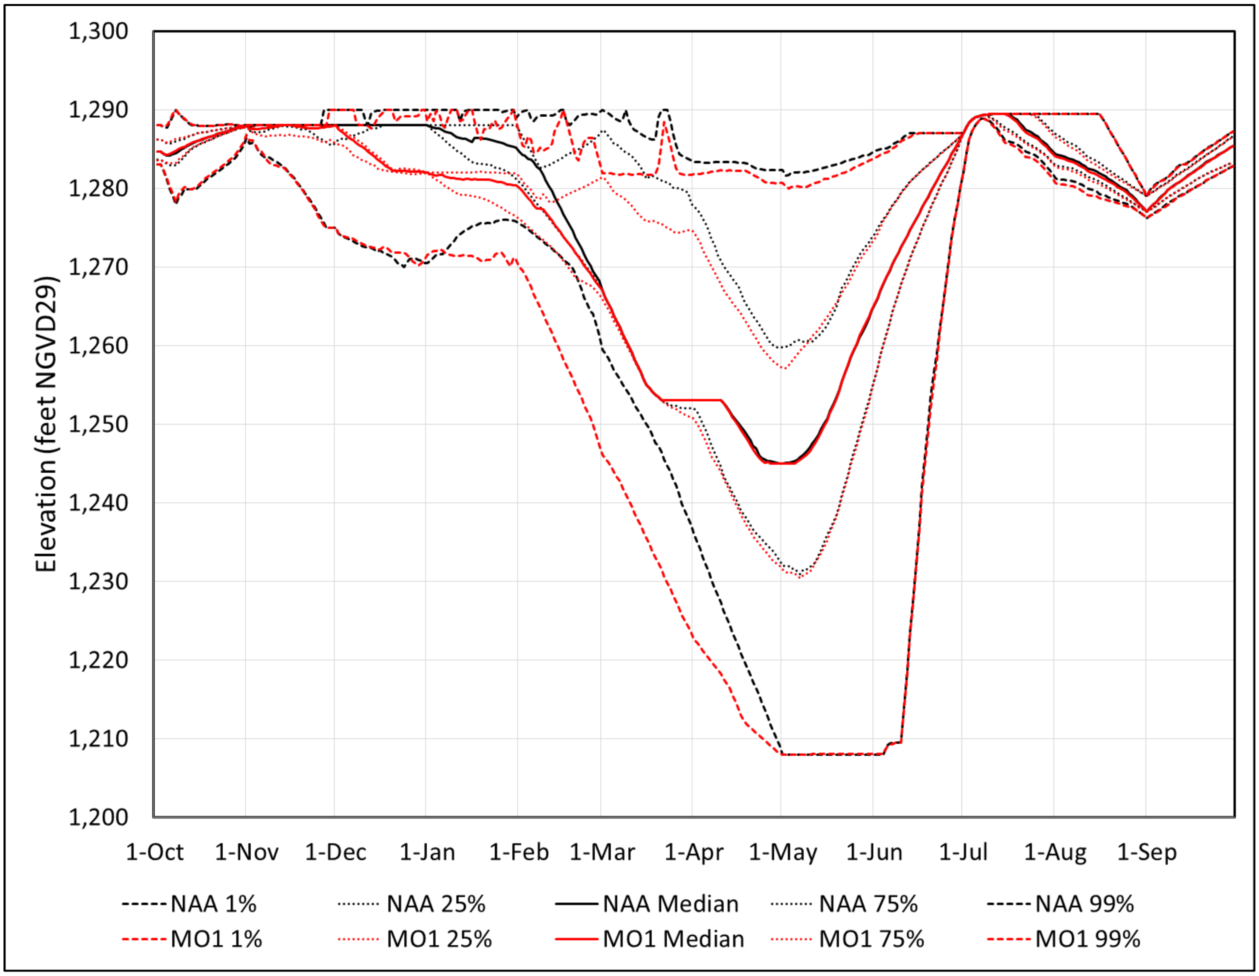

**Figure 3-30. Lake Roosevelt Summary Hydrograph for Multiple Objective Alternative 1**

Under MO1, the reservoir elevation would be lower from December through February in virtually all years, as compared to the No Action Alternative. This is primarily due to the *Winter System FRM Space* measure, which would increase the space available at Grand Coulee Dam for FRM in the winter months when rain-induced floods may occur. The *Winter System FRM Space* measure calls for 650 kaf of space in the reservoir by the end of December. The *Planned Draft Rate at Grand Coulee* measure decreases the daily draft rate in planning drawdown to the deepest draft point, as determined by the *Update System FRM Calculation* measure. In the wettest years the *Planned Draft Rate at Grand Coulee* measure requires earlier draft, but this earlier draft is largely started already due to the *Winter System FRM Space* measure. From mid-December through January, the median monthly reservoir elevation would be about 5 feet lower under MO1 than it would be under the No Action Alternative. By January 31, the reservoir level would consistently be about 4 to 6 feet lower under MO1 than it would be under the No Action Alternative. By March 1, the median reservoir levels for MO1 realign with those in the No Action Alternative, and match almost exactly from May through November. The *Lake Roosevelt Additional Water Supply* measure would be implemented starting in the spring, increasing pumping from Lake Roosevelt. This would affect reservoir outflows but not reservoir elevations.

In some years, the reservoir elevation under MO1 would be lower than the No Action Alternative until the start of May due to *Update System FRM Calculation*. This generally occurs in years with high runoff volumes (the highest 20 percent of years), when the earlier planned drawdown called for by the *Update System FRM Calculation* measure comes into play, and is the governing reason for the reservoir's drawdown trajectory.

Under MO1, the probability of drafting to very low reservoir elevations (elevation 1,222 feet NGVD29 or below) at Lake Roosevelt on April 30 would increase when compared to the No Action Alternative. This is due to an element in the *Update System FRM Calculation* measure which calls for the FRM space requirement at Grand Coulee Dam to increase as the water supply forecast increases. This is in contrast to the FRM space requirement at Grand Coulee Dam for the No Action Alternative, which has a "flat spot" at elevation 1,222.7 feet NGVD29 where the FRM space requirement does not increase right away with the runoff forecast over a certain range of runoff conditions.

The effects of MO1 on the April 30 level of Lake Roosevelt are summarized below:

- The chance of drawing the reservoir down to "empty" (elevation 1,208 feet NGVD29) on April 30 would be about 7 percent for MO1, as compared to about a 5 percent chance for the No Action Alternative.
- The chance of drawing the reservoir down to elevation 1,222 feet NGVD29 or below on April 30 would be about 15 percent for MO1, as compared to about 8 percent for the No Action Alternative.

Finally, Figure 3-31 shows median hydrographs for Lake Roosevelt in dry, average, and wet years. The figure provides another way to picture the effects described above, this time categorized by water year type.

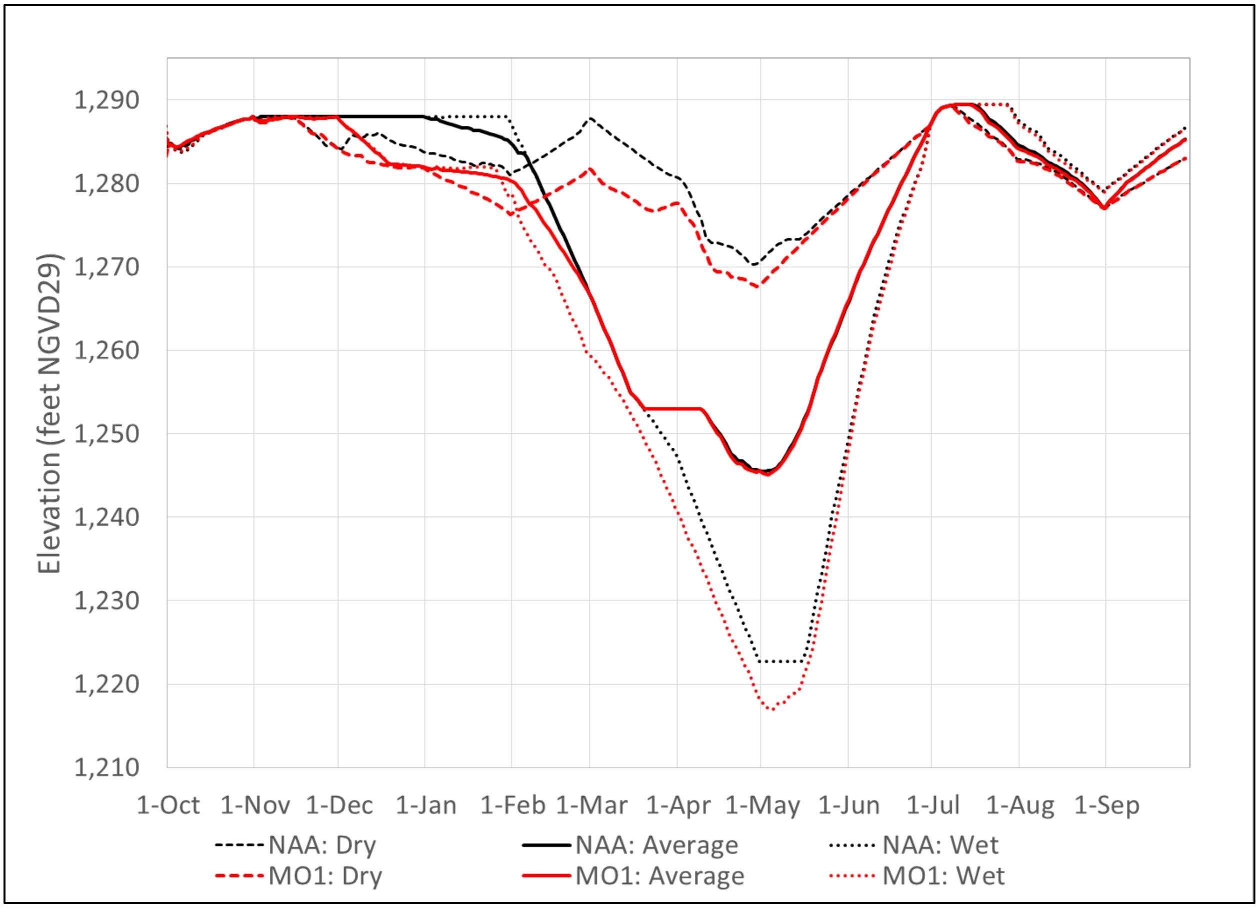

**Figure 3-31. Lake Roosevelt Water Year Type Hydrographs for Multiple Objective Alternative 1**

**Grand Coulee Dam Drum Gate Maintenance**

Drum gate maintenance at Grand Coulee Dam is planned to occur annually during March, April, and May, but is not conducted in all years. The reservoir must be at or below elevation 1,255 feet NGVD29 for 8 weeks to complete drum gate maintenance. Under MO1, the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures would influence reservoir elevations during spring months.

The changes in elevations for MO1 that influence the decision to conduct drum gate maintenance would not change significantly relative to the No Action Alternative (April 30 FRM elevation targets and drum gate initiation methodology is discussed in more detail in Part 1 of Appendix B). The decision to conduct drum gate maintenance is based on the February water supply forecast and the resulting April 30 FRM elevation projection (April 30 FRM elevation target at or below 1,255 or 1,265 feet NGVD29 depending on how recently the maintenance has been conducted). That is not to say the spring elevations are the same for the two alternatives, but rather there are a similar number of years that elevations would allow for drum gate maintenance. In both MO1 and the No Action Alternative, drum gate maintenance would be achievable in 65 percent of the years.

### Grand Coulee Dam Outflow

Under MO1, the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Winter System FRM Space*, and *Lake Roosevelt Additional Water Supply* measures would directly affect outflows from Grand Coulee Dam. In addition, the *Modified Draft at Libby*, *December Libby Target Elevation*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would affect inflows and outflows at Grand Coulee Dam. The outflows from Grand Coulee Dam would differ from the No Action Alternative depending on the time of year, as seen in Figure 3-32.

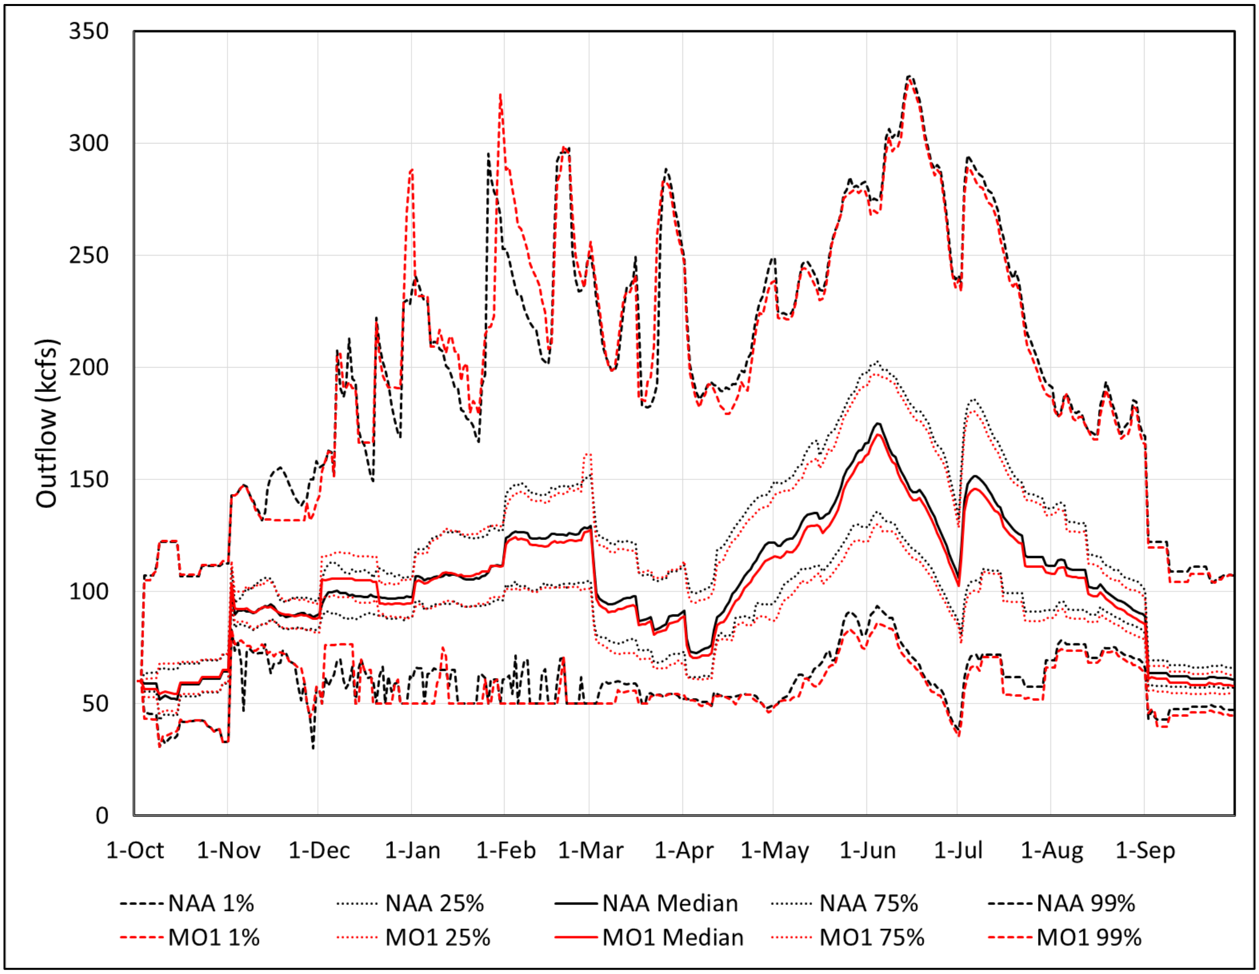

**Figure 3-32. Grand Coulee Dam Outflow Summary Hydrograph for Multiple Objective Alternative 1**

The change in average monthly outflow throughout the water year is presented in Table 3-14.

The *Lake Roosevelt Additional Water Supply* measure calls for an increased volume of water to be pumped from Lake Roosevelt into Banks Lake, which would directly affect Grand Coulee Dam outflows. Because several other measures in MO1 would also affect Grand Coulee Dam's outflow, the effects of MO1 are described below, identifying the measure (or combination of measures) responsible for the change where possible.

**Table 3-14. Grand Coulee Dam Monthly Average Outflow for Multiple Objective Alternative 1 (as change from No Action Alternative)**

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows lower than the No Action Alternative flows; green shading denotes MO1 flows higher than the No Action Alternative flows.

From the fall through spring, the outflow from Grand Coulee Dam under MO1 would differ from the No Action Alternative due to several FRM-related measures at Grand Coulee Dam.

- In December, the median value of the monthly average outflow would increase by 3.8 kcfs, primarily due to the *Winter System FRM Space* measure which creates winter FRM space in Grand Coulee's reservoir.
- In January, the median value of the monthly average outflow would increase by 0.6 kcfs. This may be caused by the *Winter System FRM Space* measure, which continues to draft Grand Coulee's reservoir in January if the winter FRM space is not achieved by the end of December. The *Update System FRM Calculation* and *Planned Draft Rate at Grand Coulee* measures can also influence flows in January.
- The *Planned Draft Rate at Grand Coulee* measure would reduce the designed draft rate for the Grand Coulee Dam Storage Reservation Diagram (SRD), which aims to initiate the system FRM draft earlier in the winter. However, the *Winter System FRM Space* measure would have a larger effect on the winter releases as even with the earlier draft targets, Grand Coulee Dam's median average outflow in February and March would be reduced by 2.5 and 2.3 kcfs, respectively.
- In February and March, the median value of the monthly average outflow would decrease by 2.5 and 2.3 kcfs, respectively.
- In April the volume of water to be pumped from Lake Roosevelt into Banks Lake would increase due to the *Lake Roosevelt Additional Water Supply* measure. The April through

September period would have the greatest total pumping volumes, as well as the greatest additional pumping volumes as called for in the *Lake Roosevelt Additional Water Supply* measure.

- In April, the median value of the monthly average outflow would decrease by 4.6 kcfs; the *Lake Roosevelt Additional Water Supply* measure's increased pumping from Lake Roosevelt into Banks Lake accounts for the majority (3.2 kcfs) of this decrease. The *Update System FRM Calculation* and *Planned Draft Rate at Grand Coulee* measures, as well as changes to inflow from measures changing operations at upstream storage projects, would also affect Grand Coulee Dam outflows in April.
- The median value of the monthly average outflow would decrease by 6.1 and 4.5 kcfs for May and June, respectively. The *Lake Roosevelt Additional Water Supply* measure's increased pumping from Lake Roosevelt into Banks Lake accounts for the majority of this outflow reduction, but not all of it. The *Lake Roosevelt Additional Water Supply* measure would decrease outflows by 3.2 and 3.0 kcfs in May and June, respectively. The *Update System FRM Calculation* measure and changes to inflow from operational measures changing operations at upstream storage projects, would also affect flows in May and June.
- In July, August, and September, the median value of the monthly average outflow would be reduced by 4.6, 3.4, and 3.0 kcfs, respectively. This is almost exclusively due to the *Lake Roosevelt Additional Water Supply* measure. The *Lake Roosevelt Additional Water Supply* measure would decrease flows by 4.2, 2.6, and 2.5 kcfs in July, August, and September respectively.
- The *Grand Coulee Maintenance Operations* measure would not impact reservoir elevations or total outflows, but would reduce the hydraulic capacity through the power plants, resulting in additional spill and an increase in TDG in some situations.

Finally, Figure 3-33 shows median hydrographs for Grand Coulee Dam outflow in dry, average, and wet years. The figure provides another way to picture the effects described above, this time categorized by water year type.

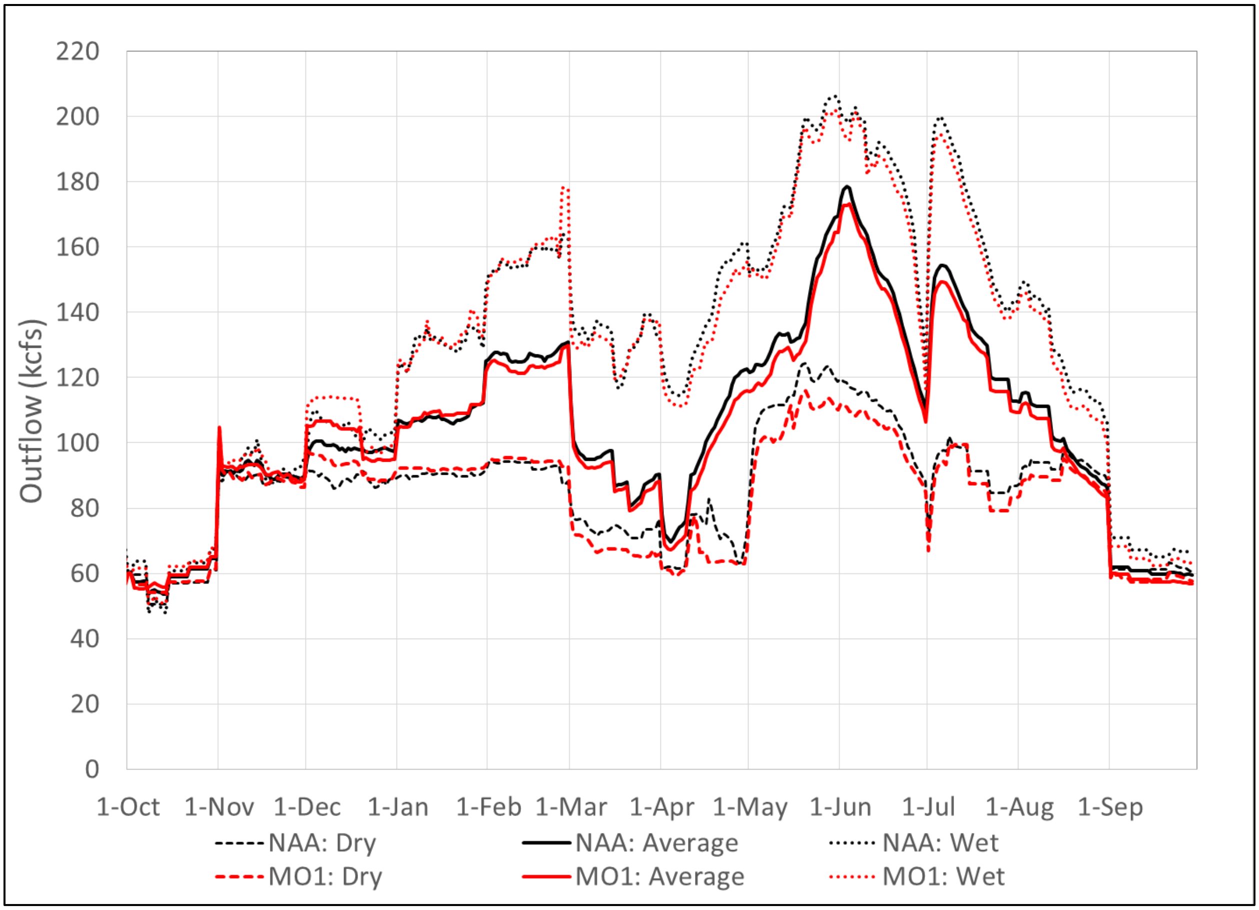

**Figure 3-33. Grand Coulee Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 1**

**Middle Columbia River below Grand Coulee Dam**

Under MO1, the pattern of flow changes in the middle Columbia River would be similar to those described for Grand Coulee Dam outflow, with the changes occurring for the same reasons as described for Grand Coulee Dam outflow. An additional measure, *Chief Joseph Dam Project Additional Water Supply*, calls for an increase in water diversion (at a maximum rate of 0.05 kcfs) from the Columbia River for the Chief Joseph Dam. The total flow impact from the *Chief Joseph Dam Project Additional Water Supply* measure is 9.6 kaf annually, which is significantly smaller than the impacts from the *Lake Roosevelt Additional Water Supply* measure that reduces flows an additional 1.1 Maf annually. The maximum diversion rate associated with the *Chief Joseph Dam Project Additional Water Supply* measure is two orders of magnitude less than that for the *Lake Roosevelt Additional Water Supply* measure. The reservoir elevation at Chief Joseph Dam would not change from the No Action Alternative.

Table 3-15 shows changes in the median values of monthly average flows at locations in the middle Columbia River.

**Table 3-15. Middle Columbia River Monthly Average Flows for Multiple Objective Alternative 1 (as change from No Action Alternative)**

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows lower than the No Action Alternative flows; green shading denotes MO1 flows higher than the No Action Alternative flows.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Dworshak Reservoir Elevation

Under MO1, the *Modified Dworshak Summer Draft* measure would have a direct effect on Dworshak Dam operations. Reservoir water levels would differ from the No Action Alternative, as shown in Figure 3-34.

In MO1, the *Modified Dworshak Summer Draft* measure would modify the timing of water releases from Dworshak Dam in the summer to provide cooler water in the lower Snake River during peak adult fish migration periods. The reservoir would start drafting the day after refill, which means it would start drafting sometime after June 20 and no later than July 5. In contrast, under the No Action Alternative, the reservoir draft begins as early as July 1 and no later than July 7. The end of August target elevation would be 1,540 feet NGVD29 for years when the Dworshak water supply forecast is at or above the 80th percentile, and 1,545 feet NGVD29 when the forecast is below the 80th percentile. These are both higher than the end of August target for the No Action Alternative with the goal of reducing the discharge in August to save some cooling water for September. The end of September target elevation would be 1,520 feet NGVD29, the same as for the No Action Alternative.

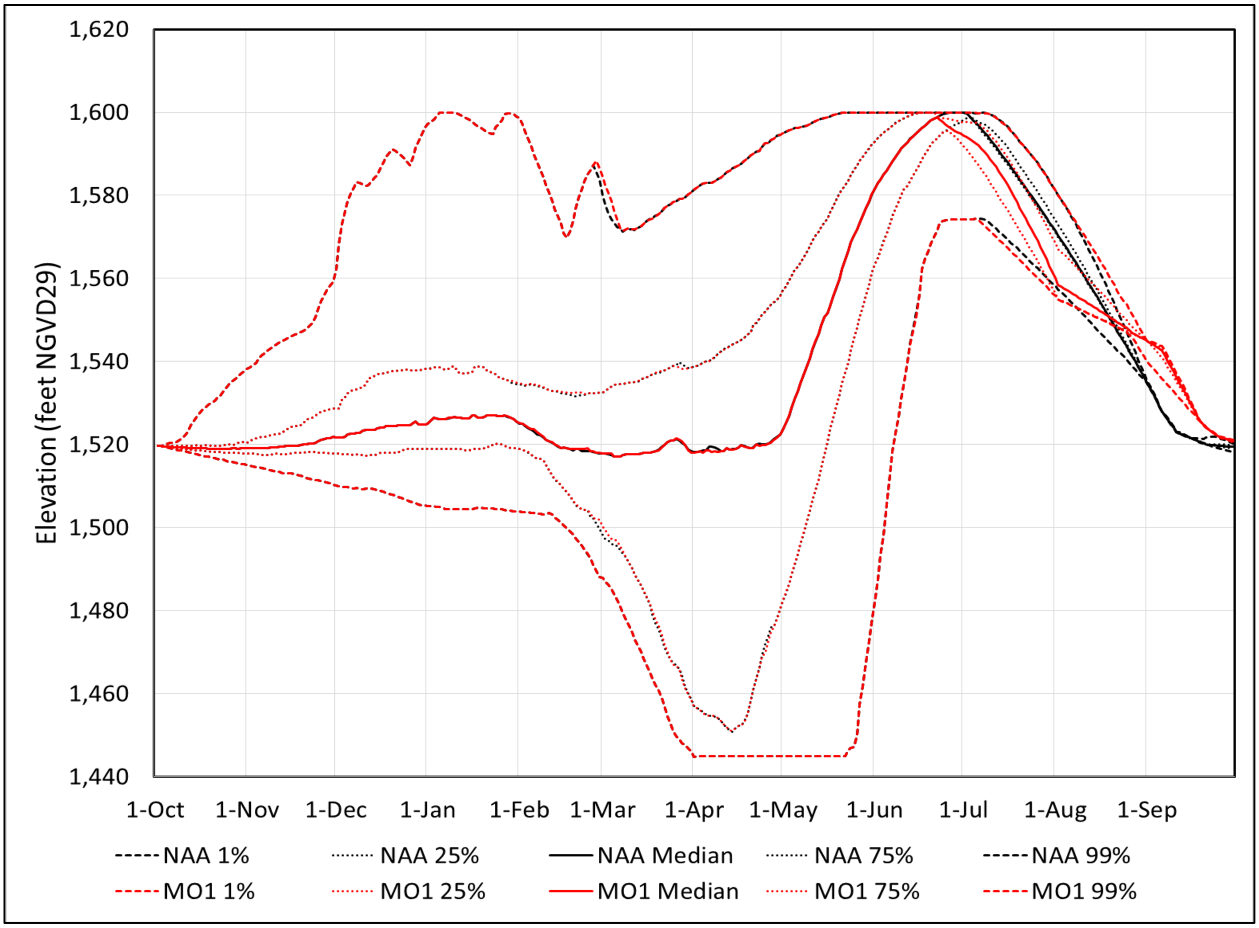

**Figure 3-34. Dworshak Reservoir Summary Hydrograph for Multiple Objective Alternative 1**

Dworshak Dam's reservoir elevation under MO1 would differ from the No Action Alternative due to the *Modified Dworshak Summer Draft* measure:

- From June 20 through mid to late August, reservoir water levels would be lower than those for the No Action Alternative. (The difference varies by day but is generally about 5 to 10 feet lower.)
- From mid to late August through September, reservoir water levels would be higher than those for the No Action Alternative. (The difference varies by day, but is generally about 5 to 10 feet higher.)

At the end of September, the reservoir water level for MO1 would be the same as for the No Action Alternative.

Under the No Action Alternative, Dworshak Reservoir refills to the normal full pool elevation of 1,600 feet NGVD29 in about 80 percent of years. Under MO1, the probability of refilling would decrease by 1 to 3 percent on account of forcing the draft to initiate several days earlier than the No Action Alternative. Under MO1, typical reservoir levels on June 30 would be 3 to 8 feet lower than for the No Action Alternative.

Water levels at Dworshak reservoir under MO1 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-35.

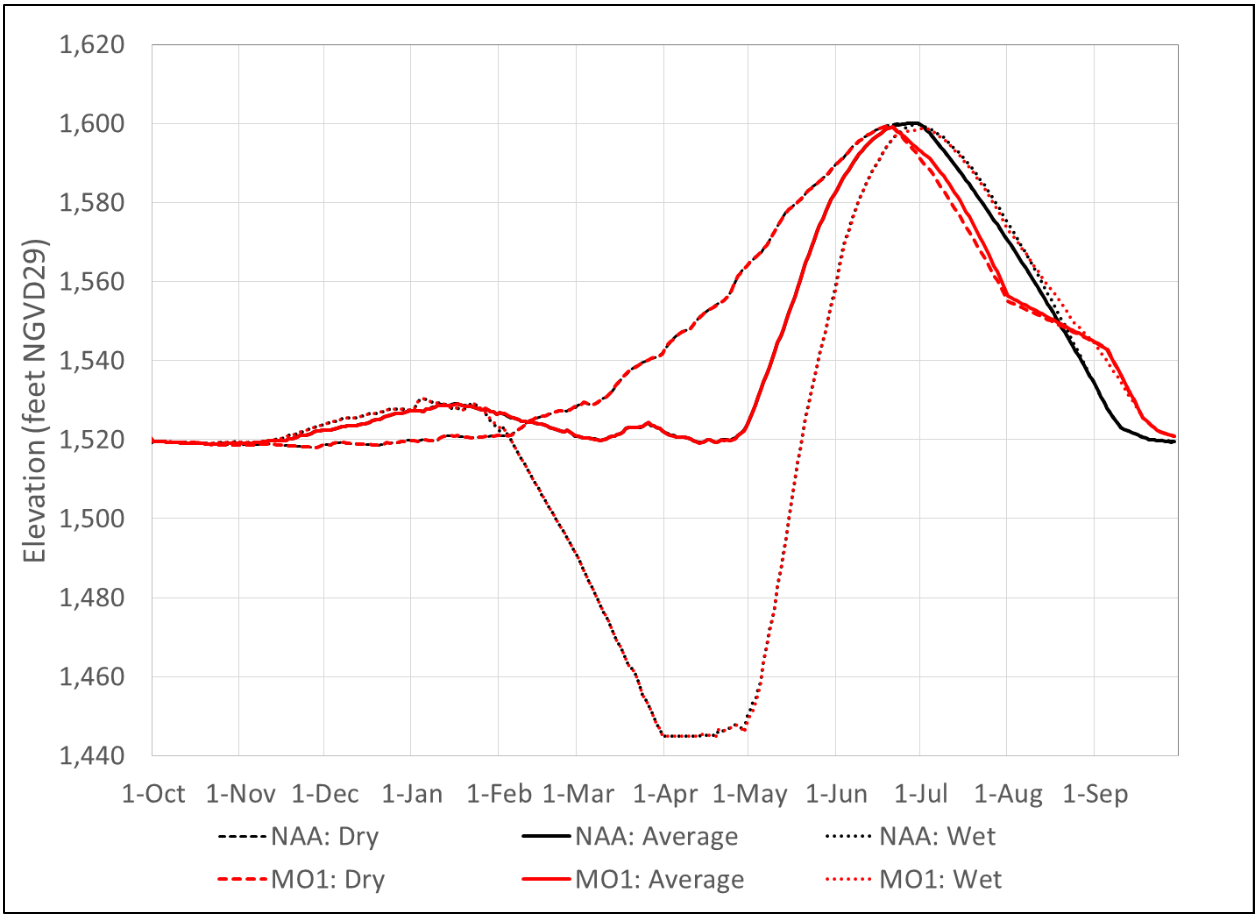

**Figure 3-35. Dworshak Reservoir Water Year Type Hydrographs for Multiple Objective Alternative 1**

**Dworshak Dam Outflow**

Under MO1, the *Modified Dworshak Summer Draft* measure would have a direct effect on Dworshak Dam outflows. The outflows would differ from the No Action Alternative from June through September, as seen in Figure 3-36.

The change in average monthly outflow is characterized in Table 3-16. The months of June, July, and September would all have an increase in outflow as compared to the No Action Alternative. The month of August would have a decrease in outflow as compared to the No Action Alternative.

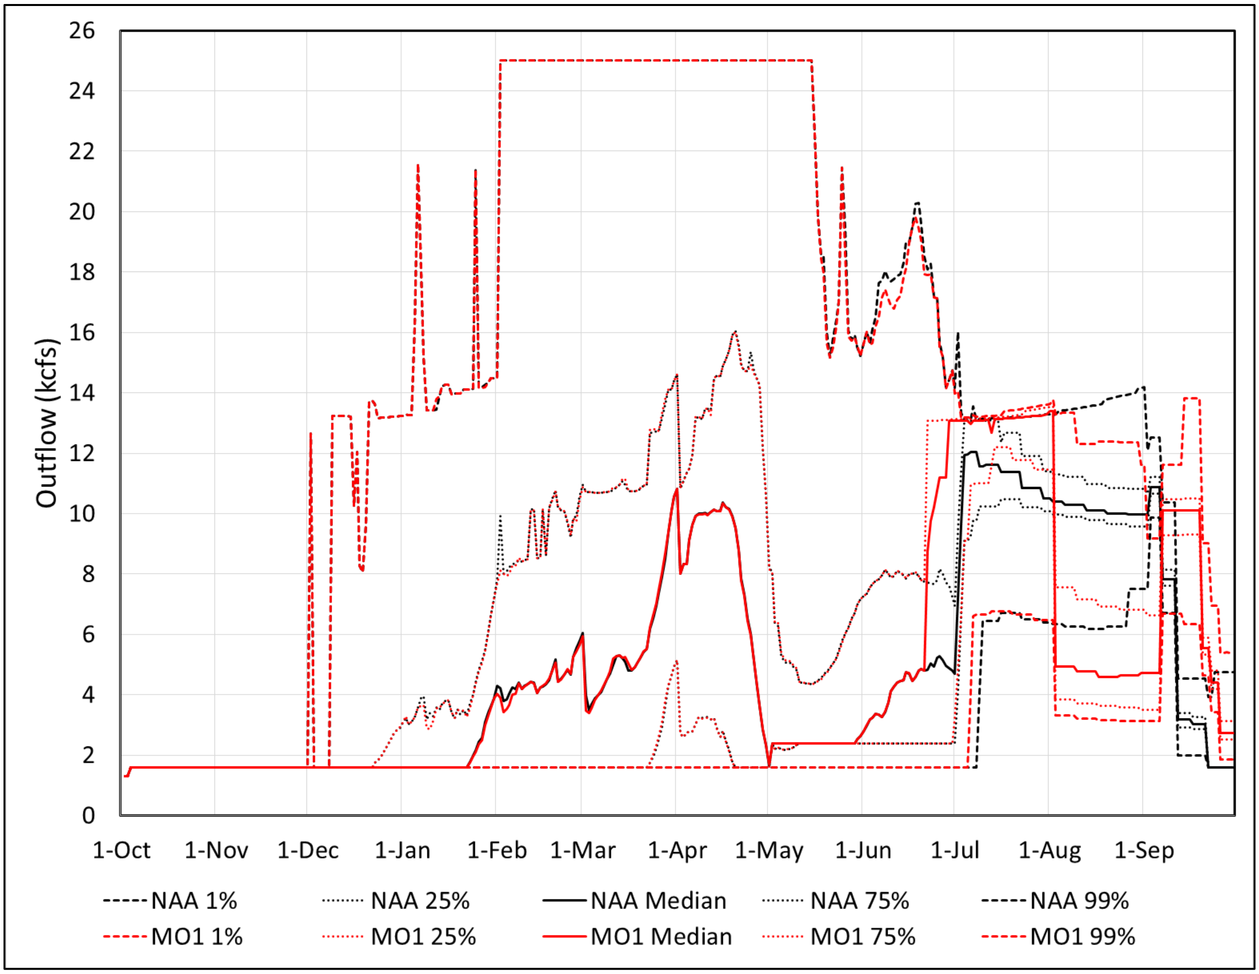

**Figure 3-36. Dworshak Dam Outflow Summary Hydrograph for Multiple Objective Alternative 1**

From a comparison of MO1 with the No Action Alternative several conclusions can be made:

- In June and July, the median value of the monthly average outflow would increase by 1.6 kcfs due to the *Modified Dworshak Summer Draft* measure.
- In August, the median value of the monthly average outflow would decrease by 4.9 kcfs due to the *Modified Dworshak Summer Draft* measure.
- In September, the median value of the monthly average outflow would increase by 1.8 kcfs due to the *Modified Dworshak Summer Draft* measure.

Finally, Figure 3-37 shows median hydrographs for Dworshak Dam outflow in dry, average, and wet years. The figure provides another way to picture the effects described above, this time categorized by water year type.

**Table 3-16. Dworshak Dam Monthly Average Outflow for Multiple Objective Alternative 1 (as change from No Action Alternative)**

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows lower than the No Action Alternative flows; green shading denotes MO1 flows higher than the No Action Alternative flows.

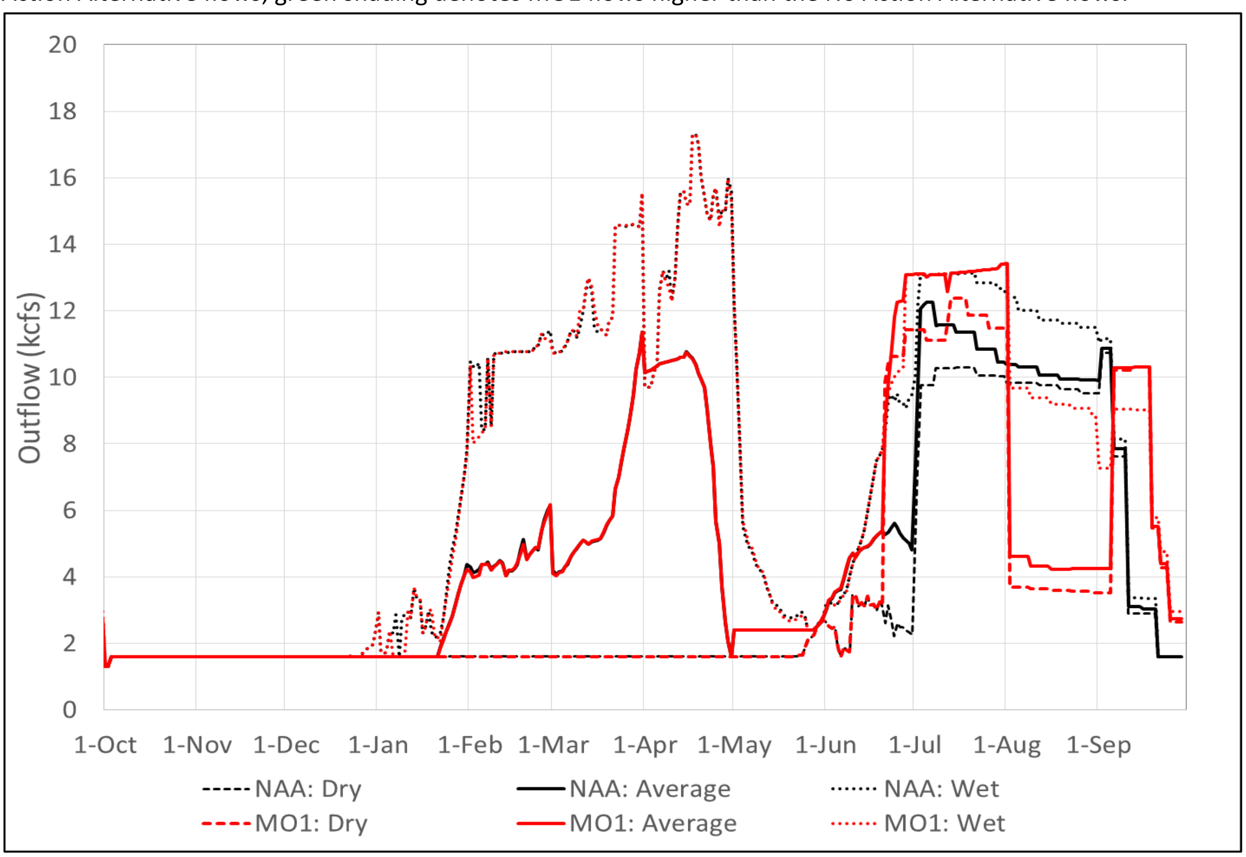

**Figure 3-37. Dworshak Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 1**

### Lower Snake River Reservoir Elevations

Under MO1, the reservoir elevations at the four lower Snake River dams would differ from those of the No Action Alternative during the MOP season from April 3 through August 31 due to the *Increased Forebay Range Flexibility* measure. At each project the measure would increase the MOP range from 1.0 foot under the No Action Alternative to 1.5 feet under MO1. This is a 0.5-foot MOP range increase and a 0.5-foot increase in the upper elevation. There would be no changes the rest of the year. The MOP elevation ranges at each of the four lower Snake River dams are described below:

- Lower Granite Dam: 733.0 to 734.5 feet NGVD29, compared to 733.0 to 734.0 feet NGVD29 for No Action Alternative
- Little Goose Dam: 633.0 to 634.5 feet NGVD29, compared to 633.0 to 634.0 feet NGVD29 for No Action Alternative
- Lower Monumental Dam: 537.0 to 538.5 feet NGVD29, compared to 537.0 to 538.0 feet NGVD29 for No Action Alternative
- Ice Harbor Dam: 437.0 to 438.5 feet NGVD29, compared to 437.0 to 438.0 feet NGVD29 for No Action Alternative.

### Clearwater River below Dworshak Dam and the Lower Snake River

Under MO1, the pattern of outflow changes from Dworshak Dam in June through September would continue downstream. While the percent changes in flow from the No Action Alternative would be pronounced in the Clearwater River system, they would become diluted at the confluence of the Clearwater River and the Snake River near Lewiston, Idaho. This is seen in Table 3-17, which shows changes in median values of monthly average flows. All changes are attributable to the *Modified Dworshak Summer Draft* measure in MO1.

**Table 3-17. Lower Snake Basin Monthly Average Flows for Multiple Objective Alternative 1 (as change from No Action Alternative)**

| | Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

| | Ice Harbor | 0% | 0% | 0% | 0% | 0% | 0% | 0% | 0% | 1% | 2% | -16% | 9% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO1 flows greater than the No Action Alternative flows; green shading denotes MO1 flows less than the No Action Alternative flows.

## REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

### Lower Columbia River Reservoir Elevations

Under MO1, there would be no changes to the reservoir elevations at McNary Dam, The Dalles Dam, or Bonneville Dam. At John Day Dam, the *Predator Disruption Operations* and *Increased Forebay Range Flexibility* measures relate to the reservoir operating range. The range in April and May is due to the *Predator Disruption Operations* measure; the range in June through September is due to the *Increased Forebay Range Flexibility* measure. The operations associated with these measures at John Day Dam are as follows:

- The operating range in April and May would be 263.5 to 265.0 feet NGVD29, compared to 262.5 to 264.0 feet NGVD29 for the No Action Alternative. This is the same flexibility in elevation but shifted 1 foot higher than the range in the No Action Alternative.
- The operating range in June through September would be 262.5 to 264.5 feet NGVD29, compared to 262.5 to 264.0 feet NGVD29 for the No Action Alternative. This would be a broader operating range than that for the No Action Alternative, allowing reservoir levels up to 0.5 foot higher.

The operating range for John Day Dam for Multi Objective Alternative 1 is shown in Figure 3-38. The No Action Alternative operating range is shown for comparison purposes.

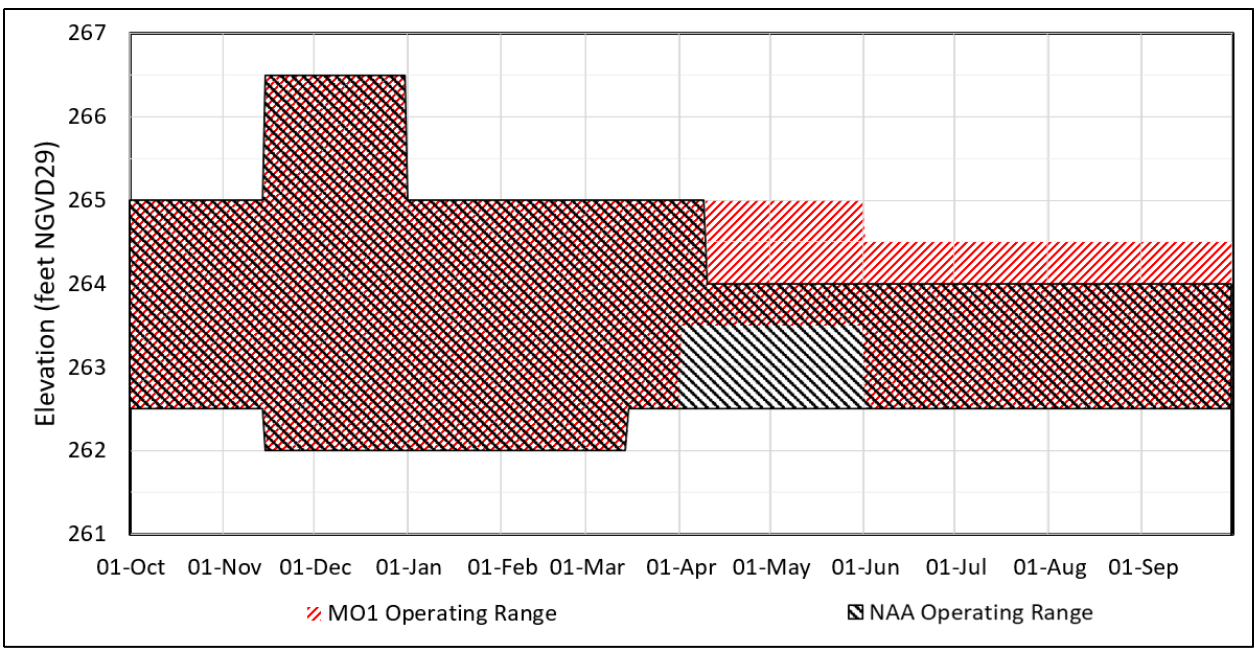

**Figure 3-38. John Day Dam Operating Range for Multiple Objective Alternative 1**

Note: John Day may be operated between 257 feet and 268 feet NGVD29 for FRM purposes. These limits are not shown on this figure in order to show greater detail in the vertical scale.

**Lower Columbia River Flows**

Under MO1, the *Modified Draft at Libby*, *December Libby Target Elevation*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Winter System FRM Space*, *Lake Roosevelt Additional Water Supply*, *Hungry Horse Additional Water Supply*, *Chief Joseph Dam Project Additional Water Supply*, *Modified Dworshak Summer Draft*, and *Sliding Scale at Libby and Hungry Horse* measures would cause changes in flow patterns in the lower Columbia River.

At McNary Dam, the outflows under MO1 would differ from the No Action Alternative to various extents through the water year. The magnitude and timing of differences in flow are displayed in Figure 3-39. In general, flows in December under MO1 tend to be higher than those for the No Action Alternative; flows in August under MO1 tend to be lower than those for the No Action Alternative. There are slight differences in other months as well, but not as pronounced as these 2 months.

In addition to the daily flow values depicted in Figure 3-39, the monthly average outflows from McNary Dam that would occur under MO1 were compared to those for the No Action Alternative, and from which the following conclusions were drawn:

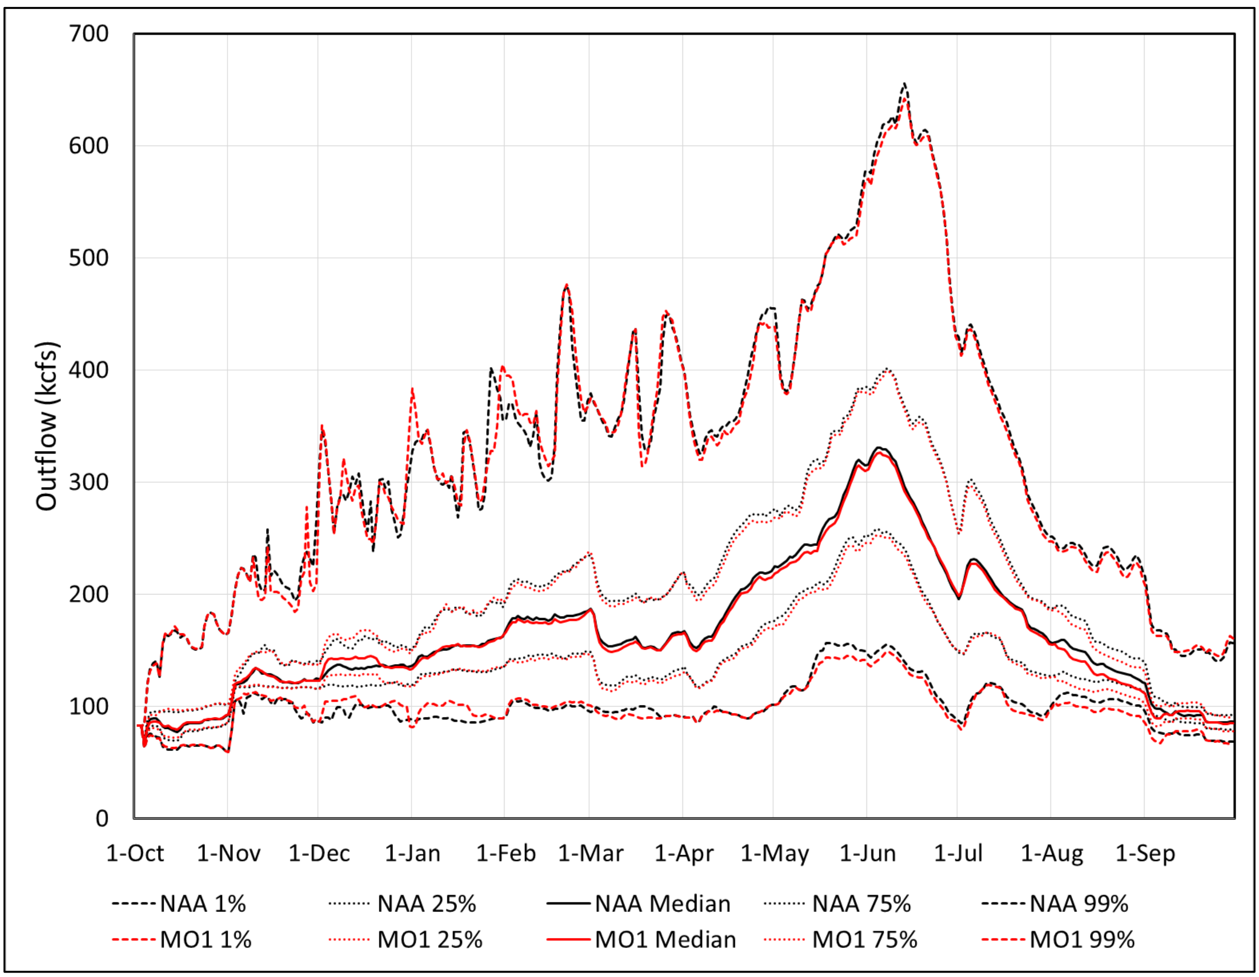

**Figure 3-39. McNary Dam Outflow Summary Hydrograph for Multiple Objective Alternative 1**

- In December, the median value of the monthly average outflow would increase by 4.5 kcfs. A combination of measures would cause this, with the *Winter System FRM Space* measure being the main reason for the flow increases.
- In August, the median value of the monthly average outflow would decrease by 8.5 kcfs. A combination of measures would cause this. The *Modified Dworshak Summer Draft* measure at Dworshak Dam (modifying the timing of water releases in the summer), the *Lake Roosevelt Additional Water Supply* measure at Grand Coulee Dam (increasing the volume of water pumped from Lake Roosevelt into Banks Lake), the *Hungry Horse Additional Water Supply* measure on the Flathead River (reducing flows below Flathead Lake by approximately 0.5 kcfs), and the *Sliding Scale at Libby and Hungry Horse* measure at Libby Dam (changing the end of September target reservoir elevation) would all play a role in this flow reduction, as would several of the other measures.

Finally, Figure 3-40 shows median hydrographs for McNary Dam outflow in dry, average, and wet years. The figure provides another way to picture the effects described above, this time categorized by water year type.

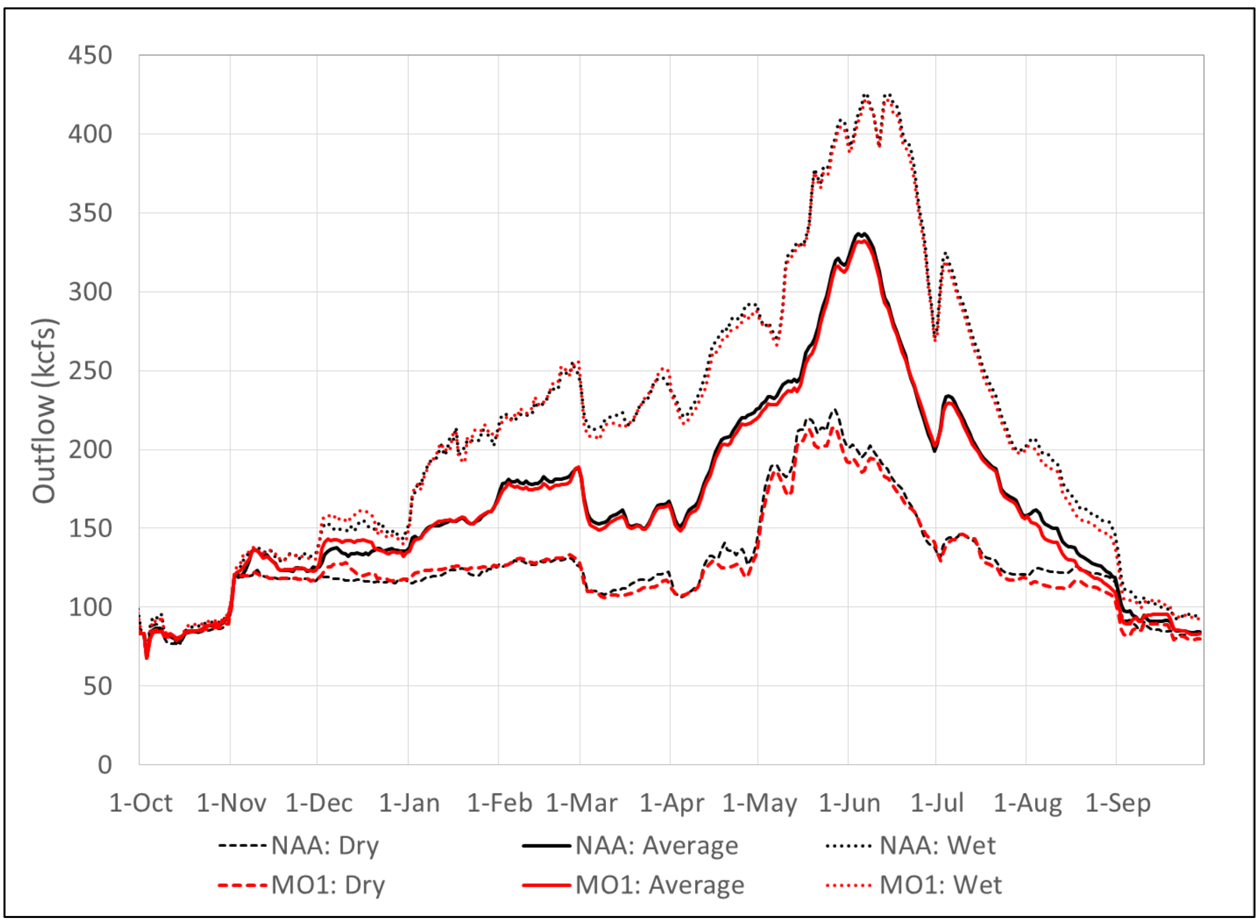

**Figure 3-40. McNary Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 1**

The effects on McNary Dam outflow from MO1 would occur similarly, and for the same reasons, at John Day Dam, The Dalles Dam, and Bonneville Dam. Along the lower Columbia River, the median value of the average monthly flow for MO1 would be higher than the No Action Alternative in some months (for example, December), and lower in others (for example, August). The flow change patterns seen at the confluence of the Columbia and Snake Rivers continue downstream to other locations. This is seen in Table 3-18.

**Table 3-18. Lower Columbia River Monthly Average Flows for Multiple Objective Alternative 1 (as change from No Action Alternative)**

## SUMMARY OF EFFECTS

In MO1, the largest changes in water levels occur at Libby, Grand Coulee, and Dworshak Dams. At Libby Dam, Lake Koocanusa water levels are less variable in the winter and spring, with notably deeper drafts in low forecast years and less-deep drafts in large forecast years. Lake Roosevelt water levels are notably lower in the winter due to additional winter FRM space, and slightly higher later in the year. Dworshak Reservoir water levels are lower in late June through mid-August, and then higher mid-August through September. Smaller but notable water level changes occur at Hungry Horse Reservoir, where additional water demands in the summer months result in slightly lower reservoir levels most of the year. Similarly, average water levels at John Day Dam and the lower Snake River projects are slightly higher in the spring and summer months due to increased forebay operating range flexibility.

The largest impacts to river flow occur immediately below Libby, Grand Coulee, and Dworshak Dams, and total flow changes are largest below Grand Coulee Dam. At Libby, the largest changes are decreases in December and May in most years combined with more flow being released in January through March. Additional winter FRM space in Lake Roosevelt translates to notably higher December releases from Grand Coulee and an increased occurrence of high releases in the winter as the dam is operated to reduce winter peak flows and stages in the lower Columbia River near Portland. Water supply delivery increases from Grand Coulee and Chief Joseph Dams result in consistently lower spring and summer flows in the Columbia River downstream. Below Dworshak Dam, flows are higher late June and July, notably lower in August, and then higher in September. In the lower Columbia River, flows are slightly higher in December and slightly lower in the spring and summer months. With the exception of August, which would be more than 5 percent lower in most years, changes in average monthly flow through the lower Columbia River are within 3 percent of the No Action Alternative for all months for most years.

#### *3.2.4.5 Multiple Objective Alternative 2*

As the effects of MO2 are presented, they will be displayed along with the No Action Alternative to illuminate the timing and magnitude of differences in water conditions between it and the No Action Alternative. Similar to previous sections, the operational measure (or measures) from MO2 which would result in changes from the No Action Alternative are identified to the extent possible.

It should be noted that the *Ramping Rates for Safety* measure in MO2 would allow for less restrictive ramping rates at all CRS projects, meaning that changes in outflow could be greater in magnitude than for the No Action Alternative. This measure was implemented to the extent possible in the hydroregulation modeling (ramping rates at Libby and Hungry Horse Dams were doubled) but it is not reflected in modeling at the other CRS projects. Effects on power generation and transmission are discussed in Section 3.7.3 of this EIS.

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Lake Koocanusa (Libby Dam Reservoir) Elevation**

Under MO2, the *Ramping Rates for Safety*, *Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, and *December Libby Target Elevation* measures would have a direct effect on Libby Dam operations.

Reservoir water levels in Lake Koocanusa would differ from the No Action Alternative, as shown in Figure 3-41.

MO2 would generally have the same end-of-October reservoir elevation as the No Action Alternative. However, over the course of November and December, the reservoir elevations for MO2 would be lower than for the No Action Alternative due to the combination of the *Slightly*

*Deeper Draft for Hydropower* measure with the *December Libby Target Elevation* measure, resulting in an end-of-December elevation of 2,400 feet NGVD29 in most years.

Through the remaining winter months and into the early spring, reservoir levels would generally continue to be lower under MO2 than they would be for the No Action Alternative, though this is not always the case as seen in the 99 percent exceedance and 75 percent exceedance lines. The reservoir elevations that would occur in the winter and early spring are driven by the prolonged effect of the lower end of December elevation (from the *Slightly Deeper Draft for Hydropower* measure in combination with the *December Libby Target Elevation* measure); the lower elevation permitted in April and May from the *Slightly Deeper Draft for Hydropower* measure, and/or the *Modified Draft at Libby* measure. It should be noted that MO2 targets a reservoir elevation of 2,400 feet NGVD29 at the end of December due to the *Slightly Deeper Draft for Hydropower* measure, but uses draft targets in January, February, and March set by an SRD (*Modified Draft at Libby* measure) designed to accommodate an end-of-December elevation of 2,420 (NGVD29). The result of this combination of measures is that in higher water supply years the reservoir is not drafted as deeply in January through March as would be desired to achieve April FRM draft targets while striving for relatively stable outflow.

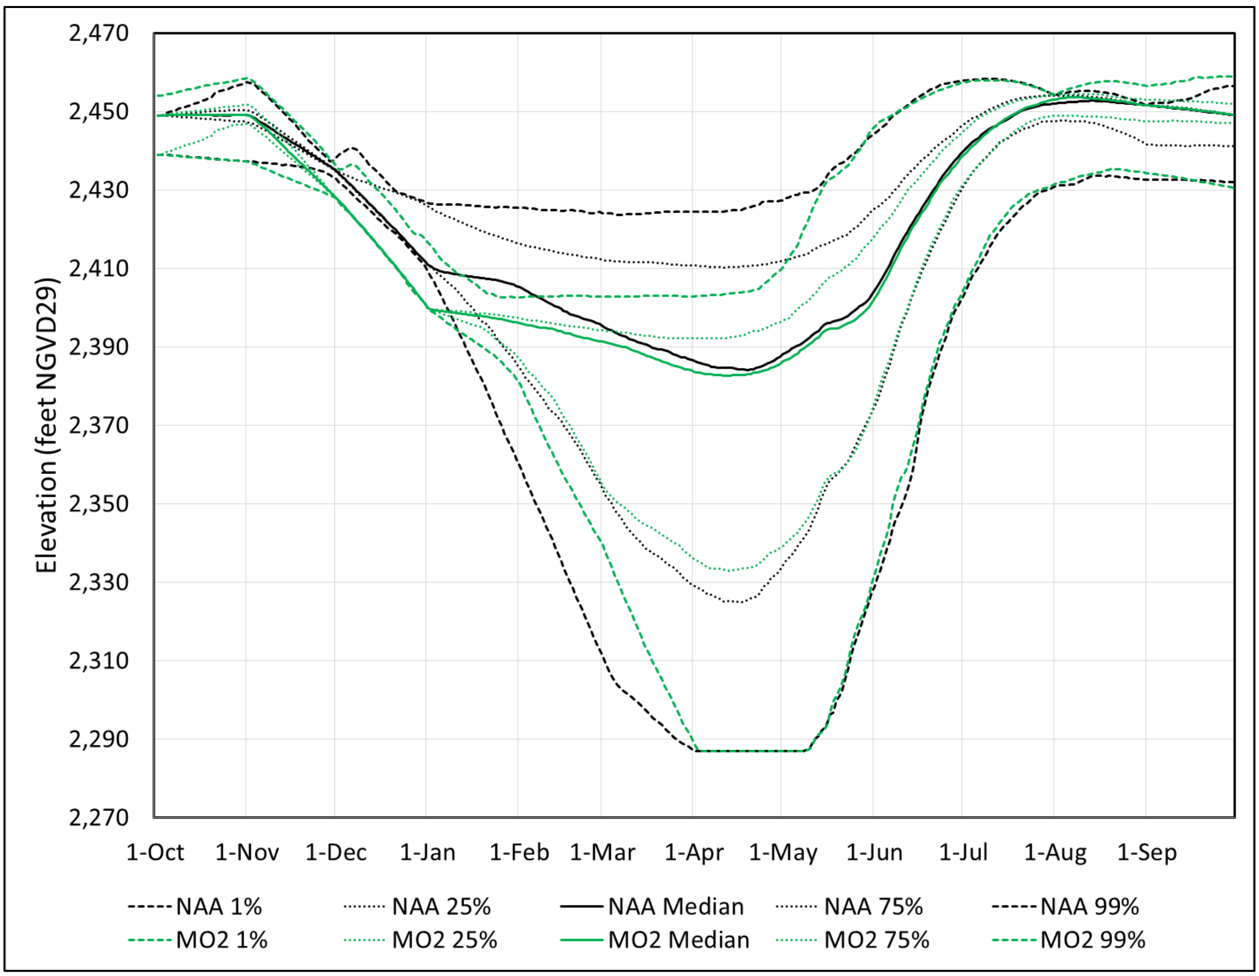

**Figure 3-41. Lake Koocanusa Summary Hydrograph for Multiple Objective Alternative 2**

By April or May, the reservoir would generally begin refilling. The modified refill operation called for in the *Modified Draft at Libby* measure would generally improve the probability of refilling the reservoir, though in the driest years the reservoir would have less success in refilling (as compared to the No Action Alternative) due to the lower winter and early spring reservoir elevations that would occur with the *Slightly Deeper Draft for Hydropower* measure. Overall, MO2 would have a 44 percent chance of the reservoir reaching elevation 2,454 feet NGVD29 or higher (within 5 feet of the full pool elevation of 2,459 feet NGVD29) by July 31, as compared to a 39 percent chance for the No Action Alternative. The peak reservoir elevation would usually be achieved in July or early August.

During the months of August and September, the reservoir elevation for MO2 would generally be about 1 to 4 feet higher than for the No Action Alternative. The reason for this is the *Modified Draft at Libby* measure, which tends to increase the peak refill elevation, and the *Sliding Scale at Libby and Hungry Horse* measure which calls for a sliding scale end-of-September target elevation that would be dependent on the Libby Dam water supply forecast, rather than the system-wide water supply forecast at The Dalles. The *Sliding Scale at Libby and Hungry Horse* measure targets a higher elevation than the No Action Alternative in the wettest 25 percent of years.

As already discussed, the timing of and extent to which the reservoir elevation for MO2 would differ from the No Action Alternative would vary throughout the year. It is helpful to examine the changes that would occur based on the water year type, as shown in the median hydrographs for dry, average, and wet years in Figure 3-42. Dry years would see the most pronounced difference, with lower reservoir elevations beginning in November and December, and continuing through the winter and early spring, when they would be 20 to 25 feet lower than under the No Action Alternative. Average years would also have lower reservoir elevations, with the difference being most pronounced in the late fall and early winter months. Wet years would also differ, having lower reservoir elevations in November and December, and similar or higher elevations through the remainder of the water year.

Finally, the three panels in Figure 3-43 show monthly elevation duration curves for July, August, and September, respectively. The curve for MO2 is plotted along with the curve for the No Action Alternative in each month. For July, the MO2 curve is virtually identical to the No Action Alternative. In August and September, the reservoir elevation under MO2 would tend to be the same or higher than the No Action Alternative. The higher elevations in late summer are attributable to the *Sliding Scale at Libby and Hungry Horse* measure, which has fewer years drafting to 2,439 feet NGVD29 than the No Action Alternative due to the change in forecast location, and the wettest years only needing a draft to 2,454 feet NGVD29.

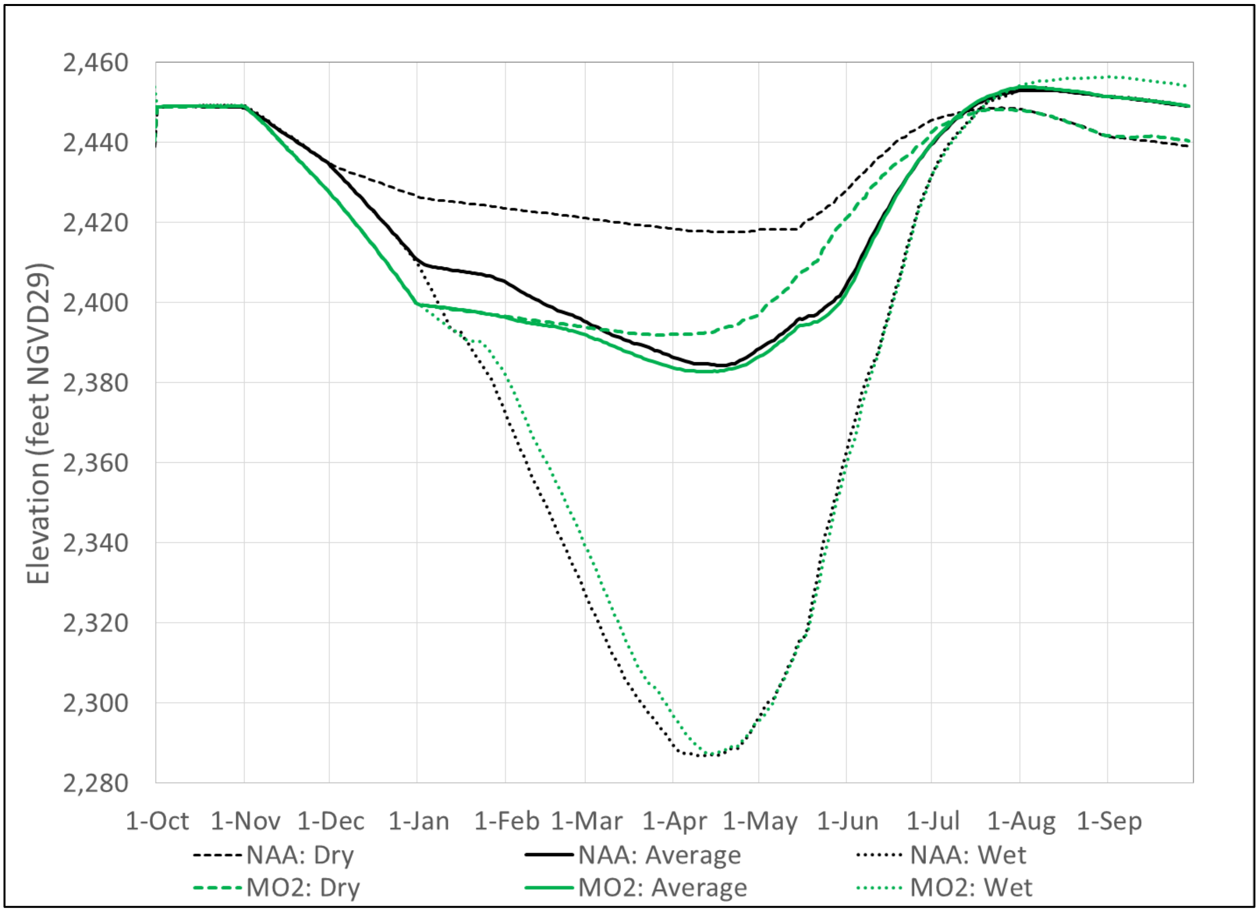

**Figure 3-42. Lake Koocanusa Water Year Type Hydrographs for Multiple Objective Alternative 2**

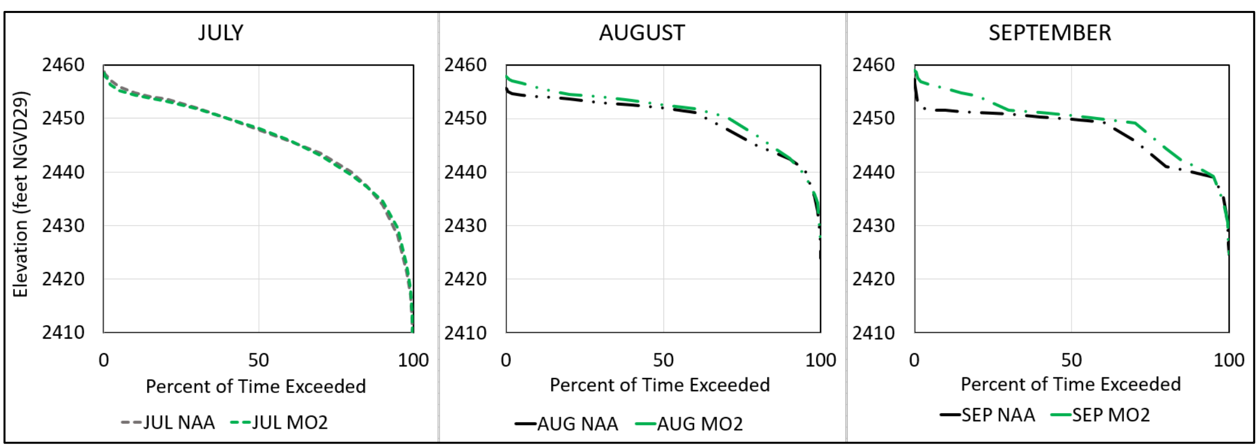

**Figure 3-43. Lake Koocanusa Summer Elevations for Multiple Objective Alternative 2**

**Libby Dam Outflow**

Under MO2, the *Ramping Rates for Safety*, *Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, and *December Libby Target Elevation* measures would have a direct effect on Libby Dam outflow. As seen in Figure 3-44, the change in outflows from the No Action Alternative varies throughout the year. Figure 3-44 shows median hydrographs for Libby Dam outflow in dry, average, and wet years.

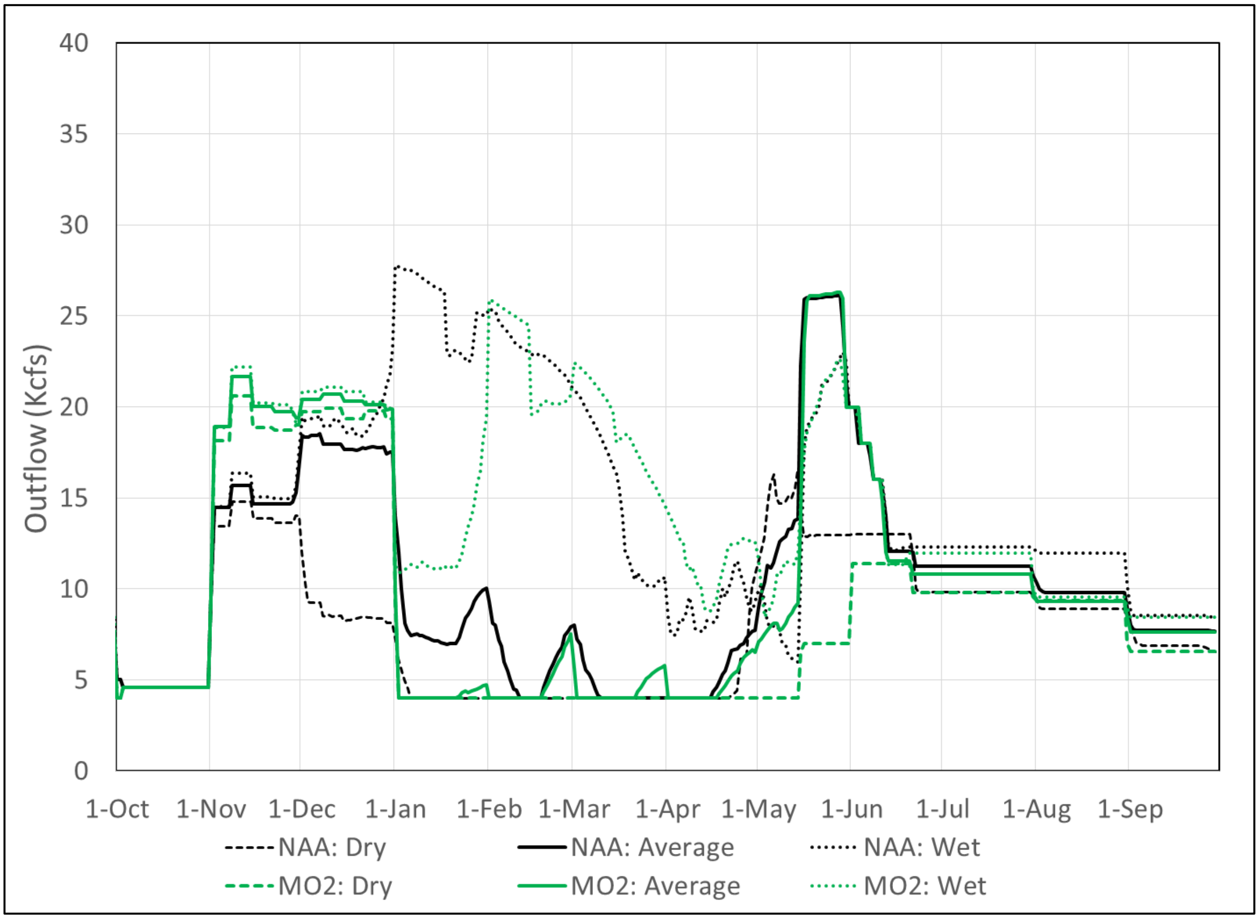

**Figure 3-44. Libby Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 2**

Throughout the year, the *Ramping Rates for Safety* measure would allow less restrictive ramping rates, meaning that changes in outflow from Libby Dam (increases or decreases) could be greater in magnitude than for the No Action Alternative. This measure would not discernibly alter the monthly average outflow but could change the outflow for a few days following a sharp rise or drop in flow. It should be noted that the HEC-ResSim hydroregulation modeling does not incorporate hourly, daily, or weekly load shaping at any dam. Load shaping can cause fluctuations between higher and lower releases.

The change in average monthly outflow throughout the water year is presented in Table 3-19.

**Table 3-19. Libby Dam Monthly Average Outflow for Multiple Option Alternative 2 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

| | | 75% | -1% | 35% | 97% | -16% | 0% | 0% | -9% | -37% | -4% | 0% | 0% | -8% |
| | | 99% | -1% | 53% | 130% | 8% | 0% | 0% | 0% | -54% | -25% | -7% | -7% | 0% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

Average outflow from Libby Dam under MO2 would differ from the No Action Alternative:

- In November and December, the monthly average outflows would increase. At the median level, the increase in November would be 4.9 kcfs and the increase in December would be 2.4 kcfs. The December increases would be most pronounced in the lowest water supply forecast years, with increases of 9.6 and 10.7 kcfs, respectively, at the 75 percent and 99 percent exceedance levels. The outflow increases are caused by the reservoir drafting to elevation 2,400 feet NGVD29 in most years, the result of the *Slightly Deeper Draft for Hydropower* measure in combination with the *December Libby Target Elevation* measure.
- In January through March, monthly average outflows would generally be the same or lower than the No Action Alternative. At the median level, they would decrease by 3.7, 1.4, and 0.6 kcfs, respectively.
- Overall April and May median monthly average outflows would decrease by 1.8 and 1.1 kcfs, respectively, from the No Action Alternative. These changes are related to the *Modified Draft at Libby* measure that would account for future volume releases and refill the reservoir more aggressively.
- In June and July, monthly average outflows would generally be lower than the No Action Alternative. At the median level, they would decrease by 0.7 and 0.8 kcfs, respectively. However, the very highest releases under MO2 would be greater than those for the No Action Alternative.

- In August and September, monthly average outflows would be lower than the No Action Alternative. At the median level, they would decrease by 0.9 and 0.4 kcfs, respectively. The *Sliding Scale at Libby and Hungry Horse* measure, which calls for a sliding scale end-of-September target elevation based on the Libby Dam water supply forecast, and a higher elevation target in the wettest 25 percent of years, is the primary cause of these changes.

### Bonners Ferry Flow

Under MO2, the *Ramping Rates for Safety*, *Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, and *December Libby Target Elevation* measures would affect flows at Bonners Ferry. In general, the flows would differ from the No Action Alternative in much the same way as at Libby Dam, and for the same reasons. The change in average monthly flow at Bonners Ferry throughout the water year is presented in Table 3-20.

**Table 3-20. Bonners Ferry Monthly Average Flow for Multiple Objective Alternative 2 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| NAA | Ave. mo. outflow (kcfs) | 1% | 9.0 | 26.6 | 29.2 | 31.3 | 29.7 | 27.5 | 30.4 | 40.8 | 40.7 | 27.2 | 19.0 | 13.3 |

| | | 75% | -1% | 34% | 79% | -12% | -2% | -2% | -5% | -24% | -3% | -2% | -3% | -4% |
| | | 99% | -1% | 49% | 119% | 5% | 0% | 0% | 0% | -34% | -23% | -15% | -11% | -2% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

### Hungry Horse Reservoir Elevation

Under MO2, several measures would have a direct effect on Hungry Horse Dam operations: the *Ramping Rates for Safety*, *Slightly Deeper Draft for Hydropower*, and *Sliding Scale at Libby and Hungry Horse* measures.

Reservoir water levels would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-45.

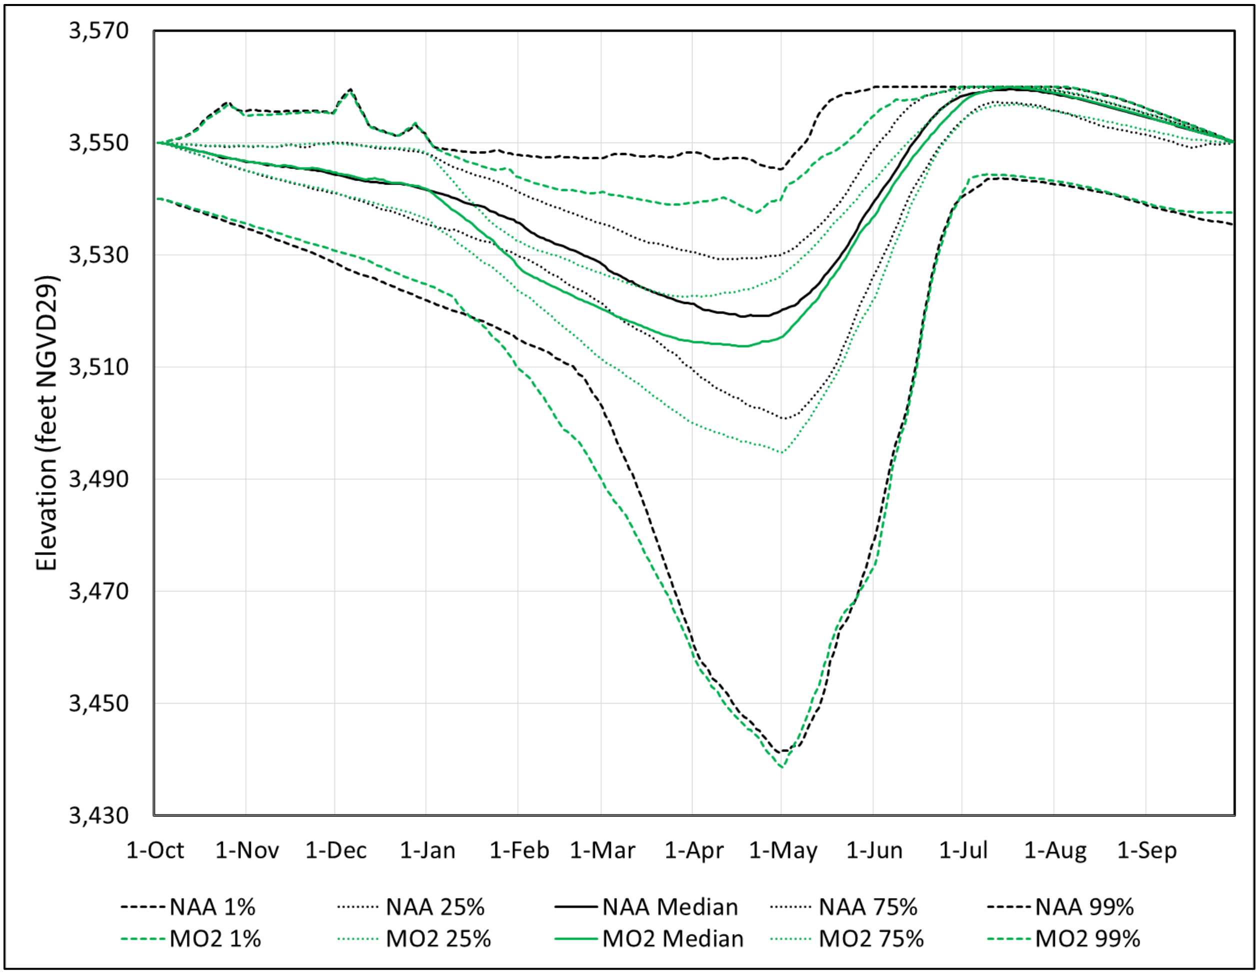

**Figure 3-45. Hungry Horse Reservoir Summary Hydrograph for Multiple Objective Alternative 2**

From October through December, the reservoir elevations under MO2 would generally be the same as the No Action Alternative. Starting in January the reservoir elevation would be lower due to the *Slightly Deeper Draft for Hydropower* measure, which allows flexibility for additional hydropower generation by drafting below the FRM elevations. Through the end of April, the reservoir elevation would continue to be lower on account of the *Slightly Deeper Draft for Hydropower* measure. During the months of January through April, the median daily reservoir elevation for MO2 would be 4 to 8 feet lower than for the No Action Alternative.

Beginning in May the reservoir would begin to refill, but would remain lower than the No Action Alternative, still on account of the *Slightly Deeper Draft for Hydropower* measure. By the end of June, the reservoir elevation under MO2 would be close to that for the No Action Alternative. Overall, there would be little difference in elevations in July, August, and September, though the latter 2 months would have higher elevations in some years on account of the *Sliding Scale at Libby and Hungry Horse* measure.

Water levels at Hungry Horse Reservoir under MO2 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-46. This grouping by water year type shows some effects that are not otherwise seen in the summary hydrograph presented in Figure 3-46. Wet and average years have earlier, deeper drafts from January through April, whereas the dry years show little difference from the No Action Alternative during this period. From the late spring through July, the dry years show the most difference from the No Action Alternative, with the dry years having lower reservoir elevations.

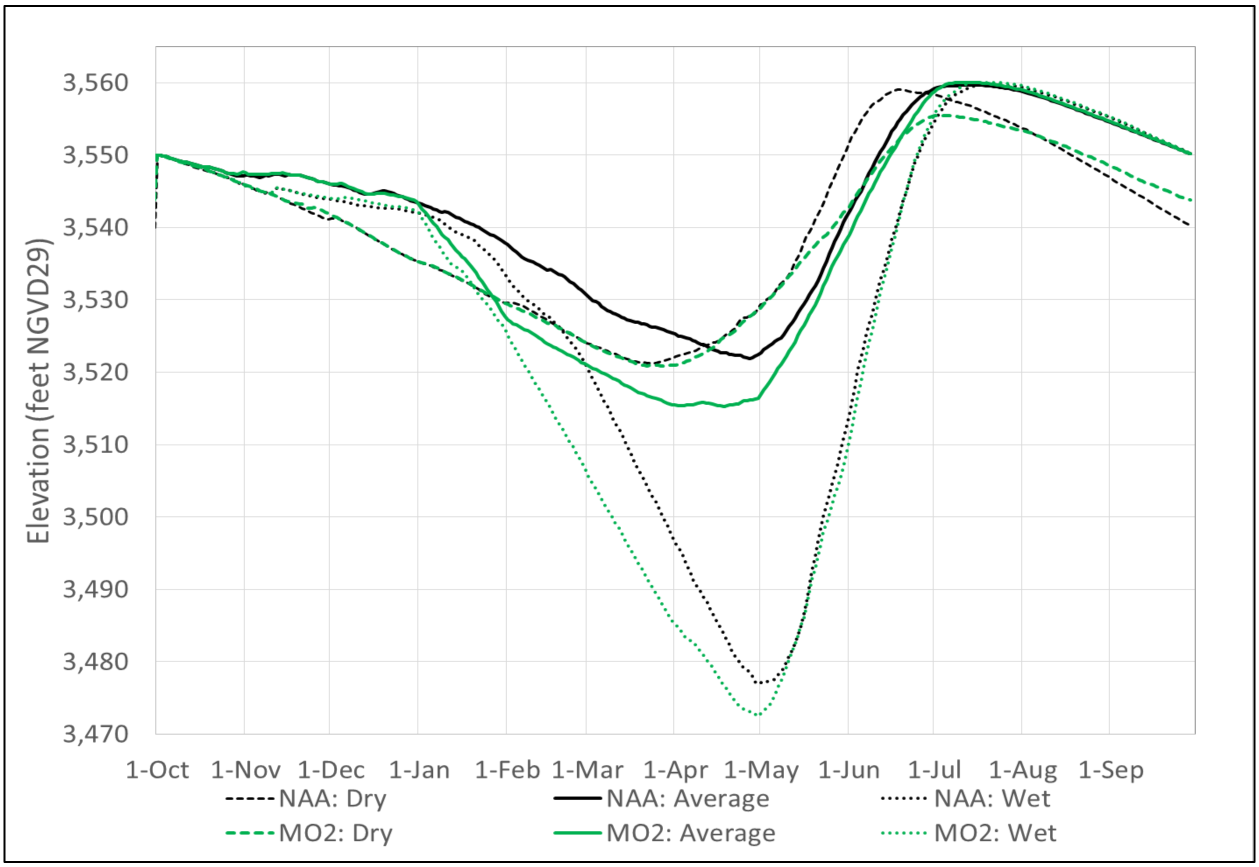

**Figure 3-46. Hungry Horse Reservoir Water Year Type Hydrographs for Multiple Objective Alternative 2**

Finally, the three panels in Figure 3-47 show Hungry Horse Reservoir elevation duration curves for the months of July, August, and September, respectively. While other months have larger differences, these three are shown because of interest in summer reservoir elevations. In general, the reservoir levels in July would be the same for MO2 as for the No Action Alternative. August and September would have higher elevations in some years, on account of the *Sliding Scale at Libby and Hungry Horse* measure, which has fewer years drafting to 3,540 feet NGVD29 than the No Action Alternative due to the change in forecast location. For instance, the daily reservoir elevation in September would be above elevation 3,550 feet NGVD29 about 77 percent of the time under MO2, whereas it would be above that elevation about 71 percent of the time under the No Action Alternative.

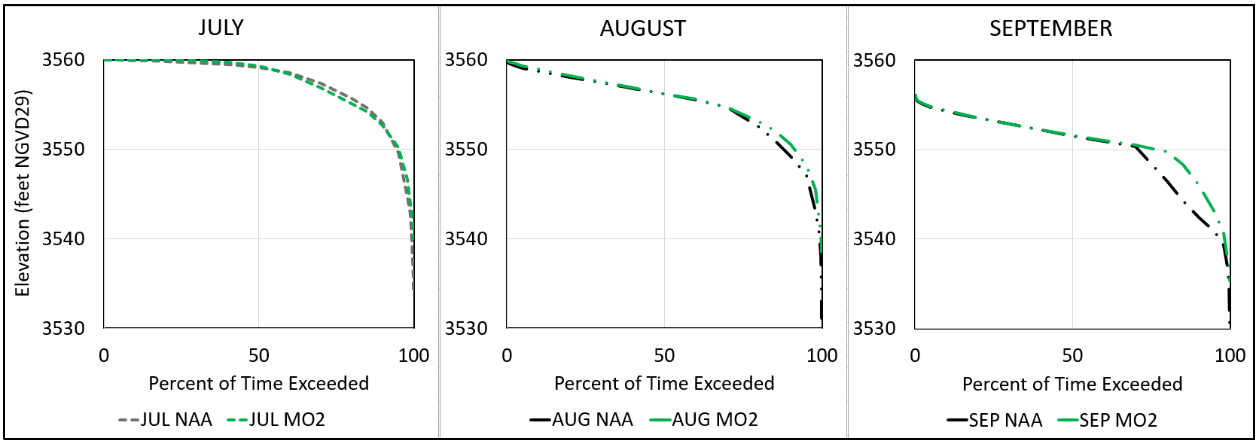

**Figure 3-47. Hungry Horse Reservoir Summer Elevations for Multiple Objective Alternative 2**

### Hungry Horse Dam Outflow

Under MO2, the *Ramping Rates for Safety*, *Slightly Deeper Draft for Hydropower*, and *Sliding Scale at Libby and Hungry Horse* measures would have a direct effect on Hungry Horse Dam outflows. The outflows would differ from the No Action Alternative depending on the time of year. Figure 3-48 shows median hydrographs for Hungry Horse Dam outflow in dry, average, and wet years.

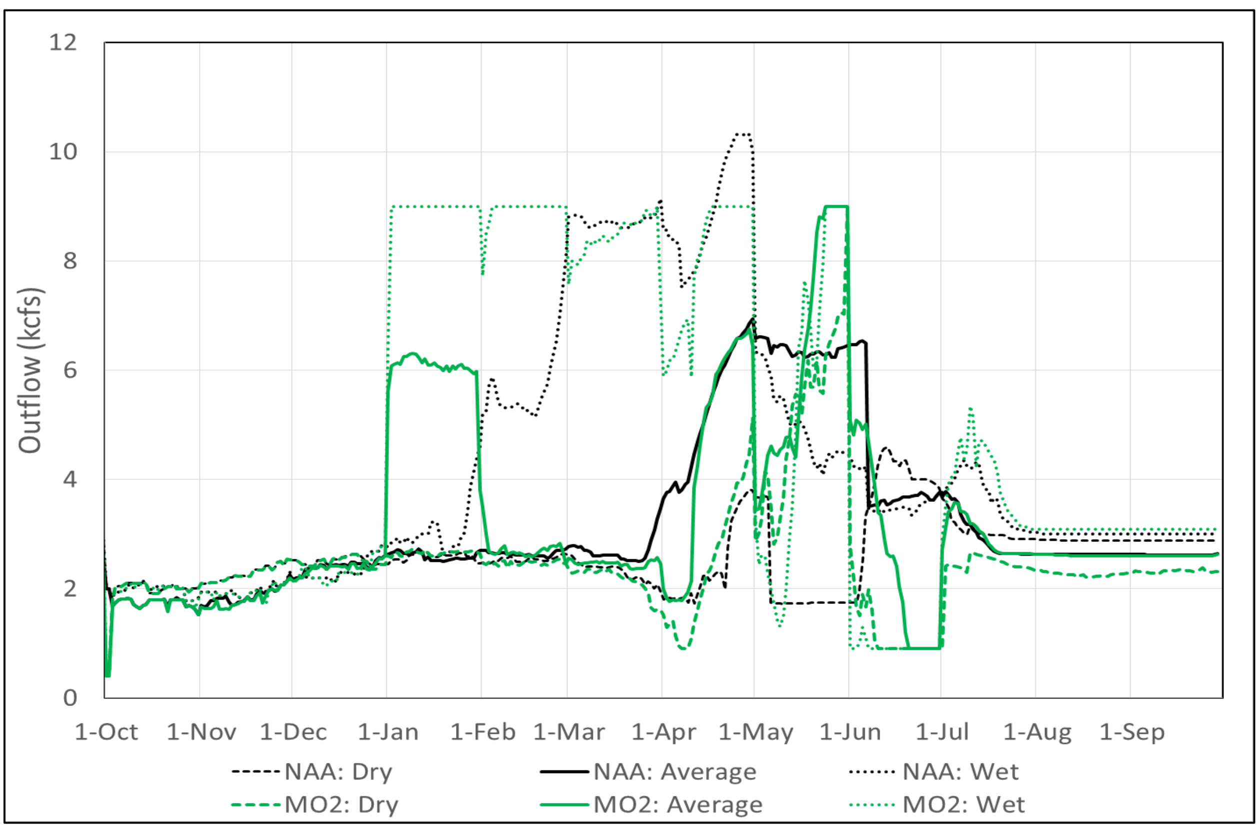

**Figure 3-48. Hungry Horse Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 2**

The change in average monthly outflow from Hungry Horse Dam throughout the water year is presented in Table 3-21.

**Table 3-21. Hungry Horse Dam Monthly Average Outflow for Multiple Objective Alternative 2 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| NAA | Ave. mo. outflow (kcfs) | 1% | 2.5 | 4.7 | 6.9 | 7.1 | 11.5 | 14.5 | 15.6 | 9.6 | 10.7 | 6.9 | 4.4 | 4.4 |

| | | 25% | -0.1 | 0.0 | 0.0 | 5.6 | 2.0 | -0.5 | -1.4 | 0.0 | -1.5 | -0.1 | -0.1 | -0.1 |
| | | 50% | -0.1 | 0.0 | 0.0 | 2.8 | 0.1 | -0.2 | -0.9 | -0.1 | -1.6 | -0.3 | 0.0 | 0.0 |
| | | 75% | -0.1 | 0.0 | 0.0 | 0.4 | 0.0 | -0.2 | -0.4 | 0.1 | -1.6 | -0.3 | -0.1 | -0.1 |
| | | 99% | 0.1 | 0.2 | 0.0 | 0.1 | 0.1 | -0.2 | -0.5 | 0.4 | -0.6 | -0.1 | -0.2 | -0.2 |
| | Percent change | 1% | 3% | -17% | -7% | 29% | -2% | -13% | -17% | 3% | 1% | -1% | -15% | -15% |
| | | 25% | -5% | -1% | 0% | 179% | 50% | -8% | -17% | -1% | -25% | -3% | -4% | -4% |
| | | 50% | -6% | -2% | -1% | 108% | 2% | -8% | -17% | -2% | -37% | -10% | -1% | -1% |
| | | 75% | -10% | 0% | -1% | 15% | -1% | -8% | -12% | 3% | -50% | -10% | -5% | -4% |
| | | 99% | 9% | 27% | 0% | 6% | 8% | -14% | -32% | 22% | -33% | -5% | -8% | -11% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

For most of the year, outflow from Hungry Horse Dam would differ from that of the No Action Alternative due to the *Slightly Deeper Draft for Hydropower* measure, which drafts the reservoir deeper starting in January for increased hydropower generation.

- The greatest increase in outflows would occur in January. There would be an increase of 2.8 kcfs in the median average monthly flow that month, at a time when the reservoir would typically be releasing 3 to 4 kcfs in the No Action Alternative to meet the Columbia Falls minimum flow.
- In February, average monthly outflow at the 25 percent exceedance level would increase by 2.0 kcfs, again due to the *Slightly Deeper Draft for Hydropower* measure.
- In March and April, the average monthly outflow would be lower. This is because by the end of February, the *Slightly Deeper Draft for Hydropower* measure would generally have the reservoir 8 to 12 feet lower than for the No Action Alternative. Consequently, less drafting would be needed in March and April to meet reservoir elevation objectives in the spring (notably the April 10 elevation objective). The median value of the monthly average outflow in March and April decrease by 0.2 and 0.9 kcfs, respectively. At the higher flow levels (the 25 percent and 1 percent exceedance levels), the decreases would be greater.
- The late spring and early summer would also have lower outflows. The monthly average outflow in June and July would decrease by 1.6 and 0.3 kcfs, respectively.

Throughout the year, the *Ramping Rates for Safety* measure would allow for less restrictive ramping rates, meaning that changes in outflow from Hungry Horse Dam (increases or decreases) could be greater in magnitude than for the No Action Alternative. This measure would not discernibly alter the monthly average outflow, but could change the outflow for a few days following a sharp rise or drop in flow. It should be noted that the HEC-ResSim hydroregulation modeling does not incorporate hourly, daily, or weekly load shaping at dams, including Hungry Horse Dam.

**Columbia Falls Flow**

Under MO2, the *Ramping Rates for Safety*, *Slightly Deeper Draft for Hydropower*, and *Sliding Scale at Libby and Hungry Horse* measures would affect flows at Columbia Falls. The change in average monthly flow at Columbia Falls throughout the water year, as compared to the No Action Alternative, is presented in Table 3-22.

**Table 3-22. Columbia Falls Monthly Average Flow for Multiple Objective Alternative 2 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| NAA | Ave. mo. outflow (kcfs) | 1% | 8.9 | 14.4 | 14.8 | 11.0 | 14.2 | 17.4 | 30.5 | 38.0 | 43.2 | 23.9 | 8.8 | 8.7 |

| | | 99% | -4% | 0% | 0% | -1% | -2% | -3% | -11% | -1% | -15% | -2% | -5% | -3% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

**Lake Pend Oreille Elevation**

Under MO2, there are no measures that would have a direct effect on the level of Lake Pend Oreille. The operational changes at Hungry Horse Dam from the *Slightly Deeper Draft for Hydropower* and *Sliding Scale at Libby and Hungry Horse* measures would translate downstream (as flow changes) and pass through Lake Pend Oreille. The flow changes would not impact the annual peak reservoir levels and would not change the timing of refill or drawdown.

Thus, there would not be any noticeable difference in the level of Lake Pend Oreille as compared to the No Action Alternative.

### Albeni Falls Outflow

Under MO2, the flow changes caused by the *Slightly Deeper Draft for Hydropower* and *Sliding Scale at Libby and Hungry Horse* measures at Hungry Horse Dam would translate downstream and pass through Lake Pend Oreille, resulting in changed outflows from Albeni Falls Dam as compared to the No Action Alternative. This is seen in the Albeni Falls Dam outflow summary hydrograph in Figure 3-49. The most pronounced difference is seen during January and early February, when outflows would generally be higher due to the *Slightly Deeper Draft for Hydropower* measure.

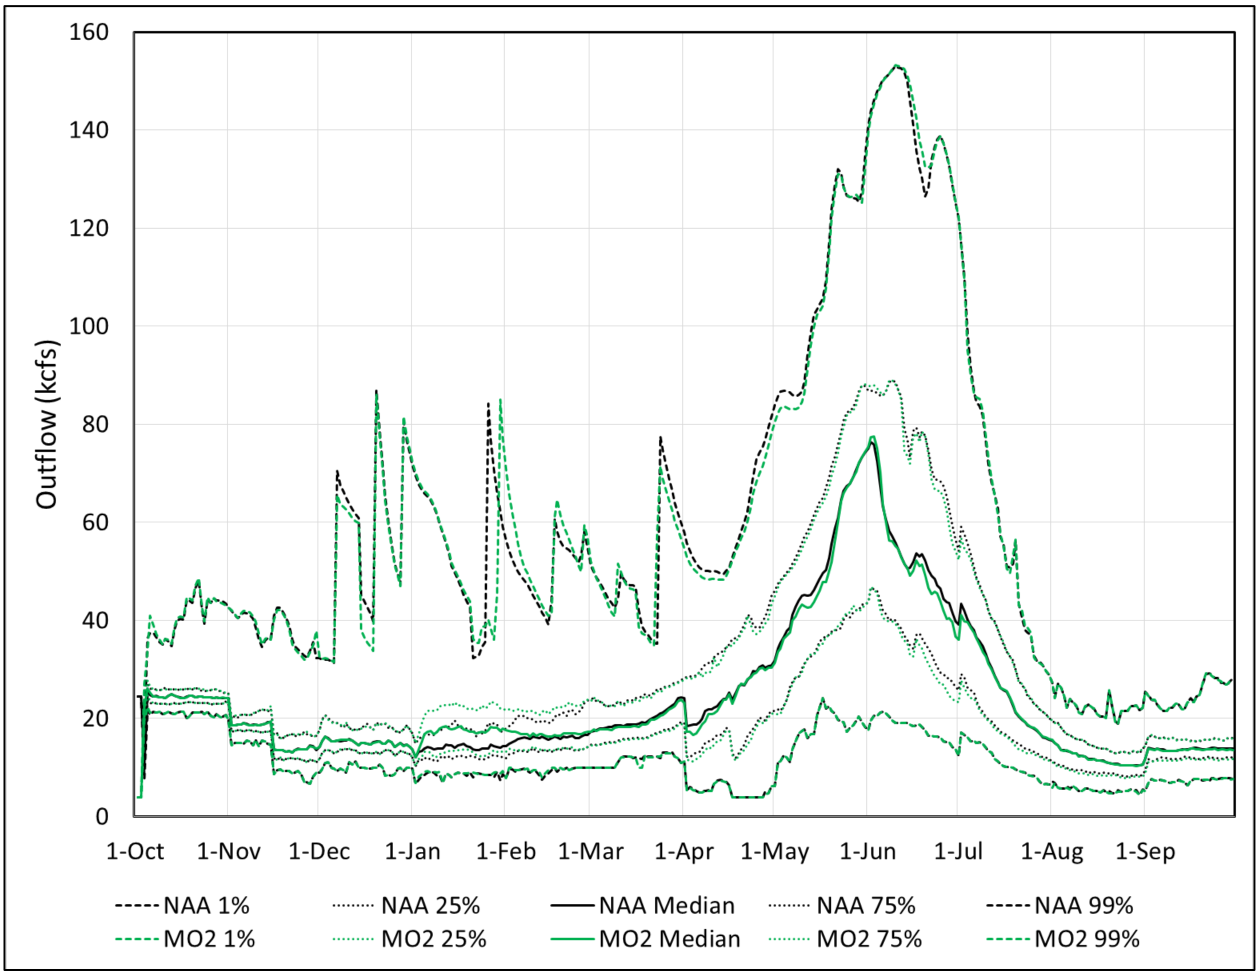

**Figure 3-49. Albeni Falls Dam Outflow Summary Hydrograph for Multiple Objective Alternative 2**

The *Slightly Deeper Draft for Hydropower* measure at Hungry Horse Dam, as well as the *Sliding Scale at Libby and Hungry Horse* measure, would affect the monthly average outflow from Albeni Falls Dam, but to a lesser degree than at Hungry Horse Dam or Columbia Falls. This is shown in Table 3-23.

**Table 3-23. Pend Oreille Basin Monthly Average Flows for Multiple Objective Alternative 2 (as change from No Action Alternative)**

| | Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| NAA (kcfs) | Hungry Horse | 1.9 | 2.0 | 2.4 | 2.6 | 2.7 | 2.7 | 5.4 | 5.7 | 4.3 | 3.4 | 2.7 | 2.7 |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

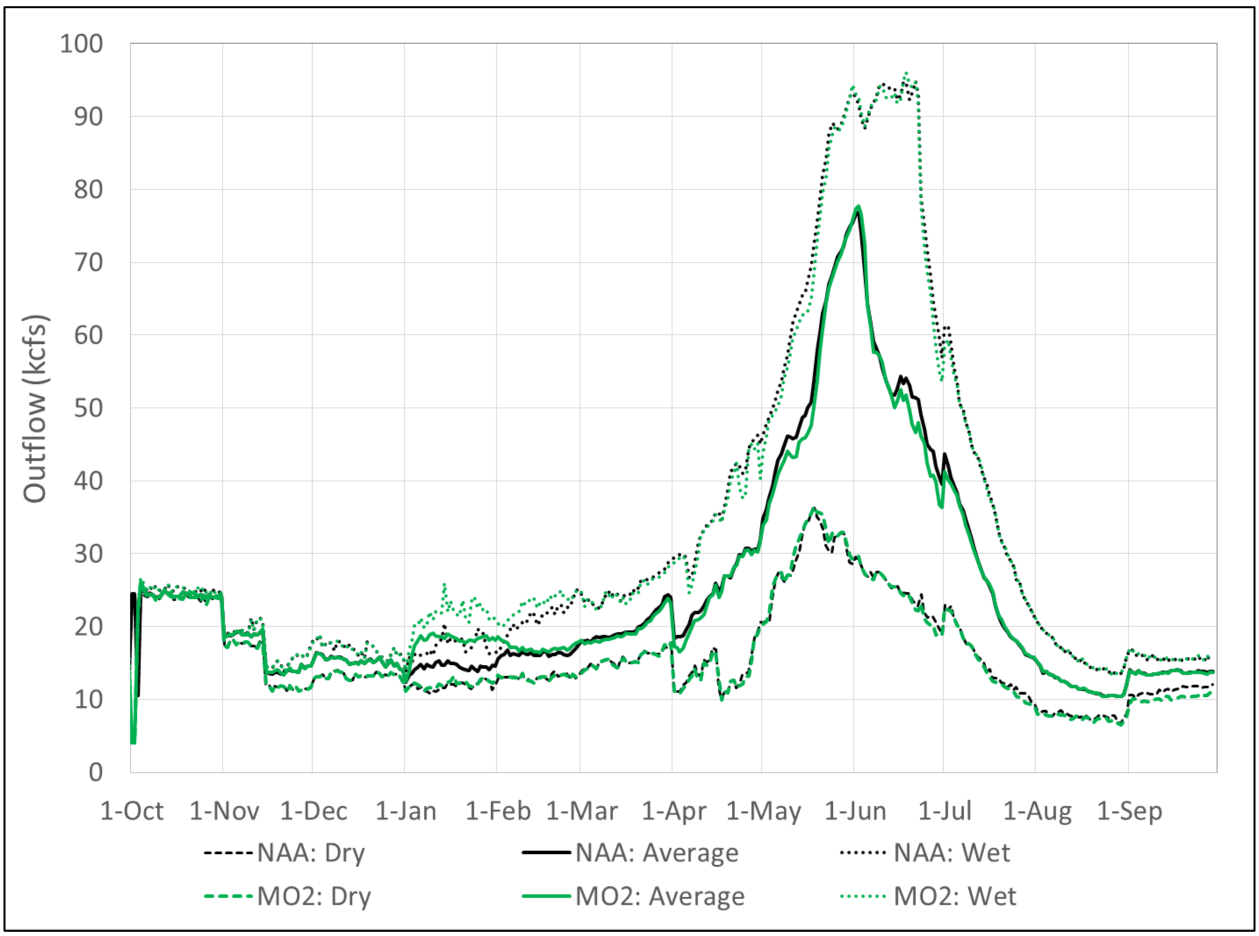

**Figure 3-50. Albeni Falls Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 2**

In January, the median value of the monthly average outflow from Albeni Falls Dam would be 3.2 kcfs higher than the No Action Alternative. In February, it would be 1.0 kcfs higher than the No Action Alternative. Following that, the months of March, April, May, and June would all have lower outflows. The January to February flow increases and the March to June flow decreases are all attributable to the *Slightly Deeper Draft for Hydropower* measure at Hungry Horse Dam.

The median outflow hydrographs shown in Figure 3-50 are useful for understanding how the Albeni Falls Dam outflow under MO2 would differ from the No Action Alternative in different types of years. Average and wet years would have higher outflows in January, attributable to the *Slightly Deeper Draft for Hydropower* measure at Hungry Horse Dam. Higher outflows would also occur through most of February in wet years, again attributable to the *Slightly Deeper Draft for Hydropower* measure.

### REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

#### Columbia River Flow Upstream of Grand Coulee Dam

Under MO2, the *Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, and *December Libby Target Elevation* measures would affect Columbia River flow upstream of Grand Coulee Dam. Figure 3-51 shows flows near RM 748 (just downstream of the U.S.-Canada border, about 151 river miles upstream of Grand Coulee Dam).

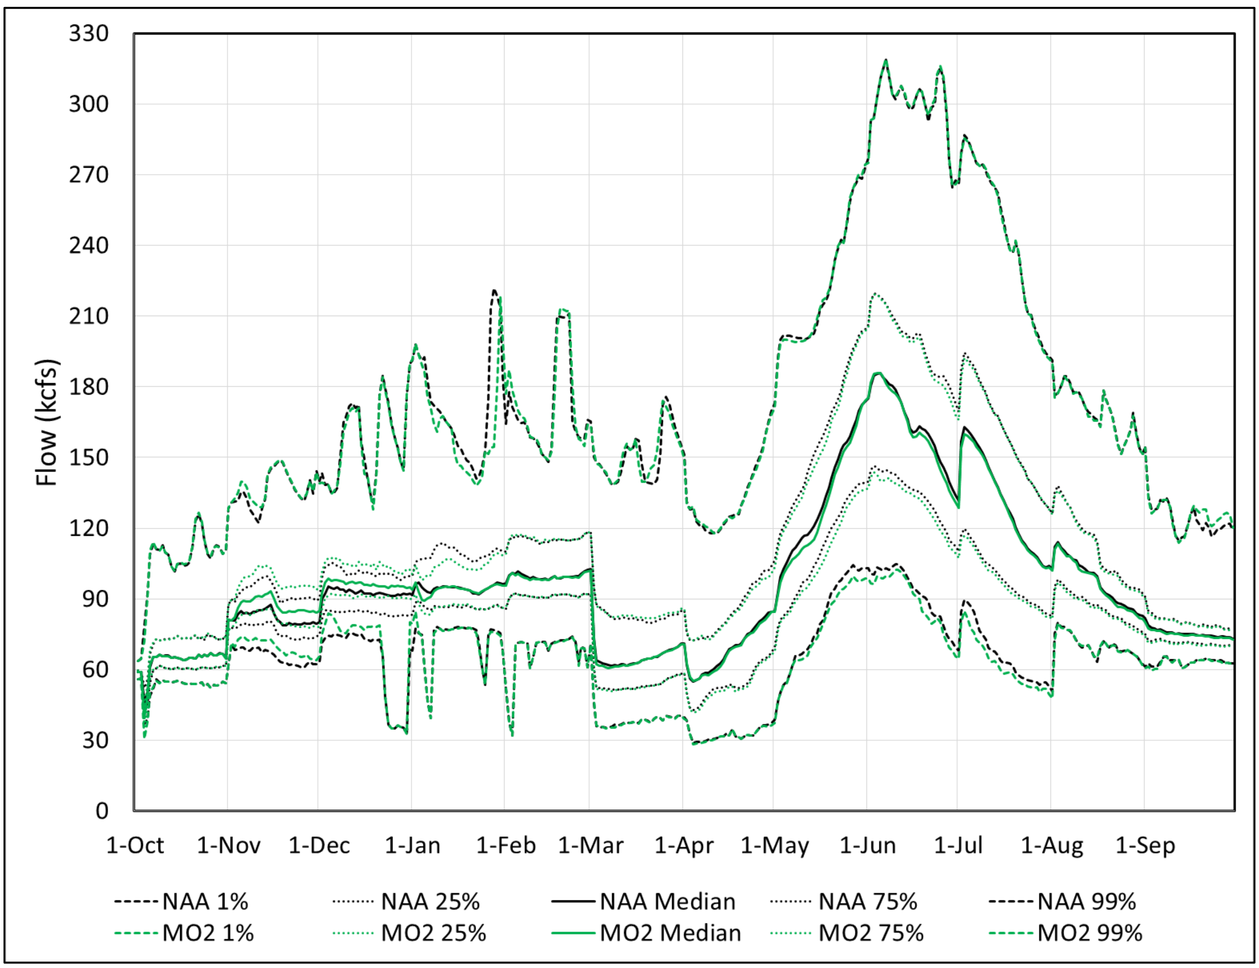

**Figure 3-51. Lake Roosevelt Inflow Summary Hydrograph for Multiple Objective Alternative 2**

Figure 3-51 characterizes the timing and magnitude of flow changes between the No Action Alternative and MO2 due to the combined effect of measures at Libby and Hungry Horse Dams. Changes in flow between MO2 and the No Action Alternative would be most noticeable in November, December, and January. In November, the median flow for MO2 would be about 5 kcfs higher than for the No Action Alternative, primarily due to the *Slightly Deeper Draft for Hydropower* measure at Libby Dam. In December, flow would be about 4 kcfs higher than for the No Action Alternative. This is primarily attributable to the combined effect of the *December Libby Target Elevation* and *Slightly Deeper Draft for Hydropower* measures at Libby Dam. In January, flows would generally be the same or lower due to the combined effect of flow changes at Libby and Hungry Horse Dams. Libby Dam would already have a lower reservoir elevation at the end of December, so less drafting would occur in January to reach its end of January FRM elevation. At the same time, Hungry Horse outflows in January would generally be higher due to power drafts at that project occurring as part of the *Slightly Deeper Draft for Hydropower* measure.

**Lake Roosevelt (Grand Coulee Dam Reservoir) Elevation**

Under MO2, the *Slightly Deeper Draft for Hydropower*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures would influence reservoir elevations at Lake Roosevelt.

In addition to the measures listed above, the *Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, and *December Libby Target Elevation* measures would affect the inflow to Grand Coulee Dam. The hydroregulation modeling performed for MO2 incorporates all of these measures, but because each measure was not evaluated in isolation from the others, drawing a direct linkage between a single measure and an effect is not always possible. The effects that would occur from a measure or combination of measures are identified and discussed to the extent possible.

Reservoir water levels in Lake Roosevelt under MO2 would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-52.

Under MO2, the reservoir elevation would be lower in October, December, January, and February in virtually all years, as compared to the No Action Alternative. During the remainder of the winter and through the early spring, the reservoir level would also generally be the same or lower than the No Action Alternative.

The lower reservoir elevations in October are primarily caused by the *Slightly Deeper Draft for Hydropower* measure, which includes a minimum elevation of 1,283 feet NGVD29 at the end of October. (In the No Action Alternative, the target elevation of 1,283 feet NGVD29 is for the end of September for resident fish considerations.) From mid-December through January, the median monthly reservoir elevation would be about 5 feet lower under MO2 than for the No Action Alternative. This is primarily due to the *Winter System FRM Space* measure, which would increase the space available at Grand Coulee Dam for FRM in the winter months when rain-induced floods may occur as well as the *Slightly Deeper Draft for Hydropower* measure, which drafts the project more deeply for hydropower in January of the wettest years. In February, the reservoir would be lower than the No Action Alternative, primarily due to the *Slightly Deeper Draft for Hydropower* and *Planned Draft Rate at Grand Coulee* measures. By March 1, the median reservoir levels for MO2 realign with those in the No Action Alternative and match almost exactly from May through August. However, the wetter water years and drier water years would generally continue having lower reservoir elevations through March, April, and into May.

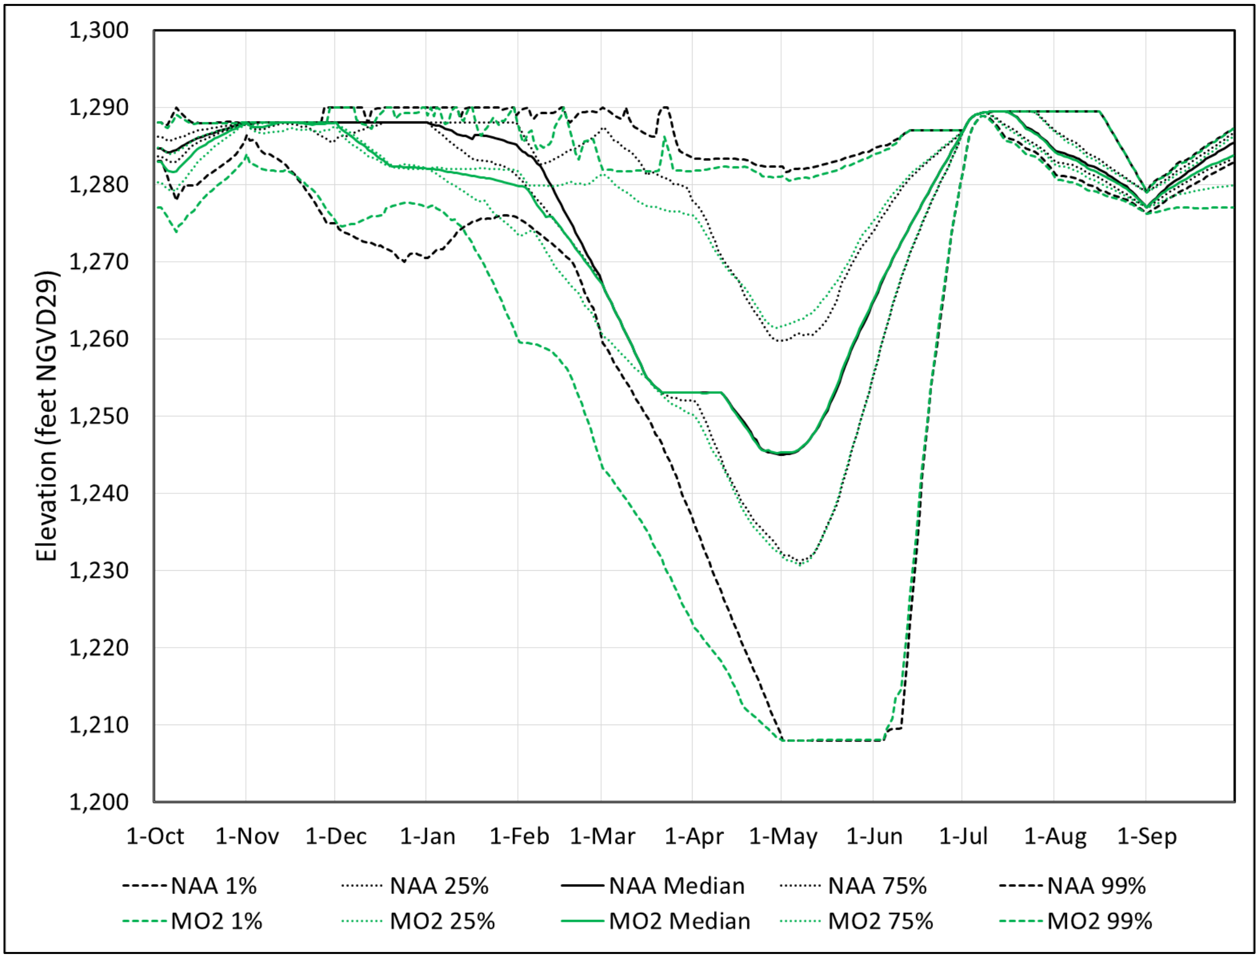

**Figure 3-52. Lake Roosevelt Summary Hydrograph for Multiple Objective Alternative 2**

Under MO2, the probability of drafting to very low reservoir elevations (elevation 1,222 feet NGVD29 or below) at Lake Roosevelt on April 30 would increase when compared to the No Action Alternative. This is due to an element in the *Update System FRM Calculation* measure which calls for the FRM space requirement at Grand Coulee Dam to increase as the water supply forecast increases. This is in contrast to the FRM space requirement at Grand Coulee Dam for the No Action Alternative, which has a “flat spot” at elevation 1,222.7 feet NGVD29 where the FRM space requirement does not increase right away with the runoff forecast over a certain range of runoff conditions.

The effects of MO2 on the April 30 level of Lake Roosevelt are summarized as follows:

- The chance of drawing the reservoir down to "empty" (elevation 1,208 feet NGVD29) on April 30 would be about 6 percent for MO2, as compared to about 5 percent for the No Action Alternative.
- The chance of drawing the reservoir down to elevation 1,222 feet NGVD29 or below on April 30 would be about 15 percent for MO2, as compared to about 8 percent for the No Action Alternative.

During the majority of the summer, reservoir elevations under MO2 would generally be the same as those for the No Action Alternative. However, beginning in September and continuing until the end of October, the reservoir would be lower under MO2 than the No Action Alternative, primarily due to the *Slightly Deeper Draft for Hydropower* measure.

Finally, Figure 3-53 shows median hydrographs for Lake Roosevelt in dry, average, and wet years. Figure 3-53 provides another way to picture the effects described above, this time categorized by water year type. In dry years, the level of Lake Roosevelt under MO2 would be lower than for the No Action Alternative from mid-November through mid-May. In average years it would be lower from December through February, and in wet years it would be lower from December through mid-May. In all water year types, the September and October reservoir elevations under MO2 would be lower than for the No Action Alternative.

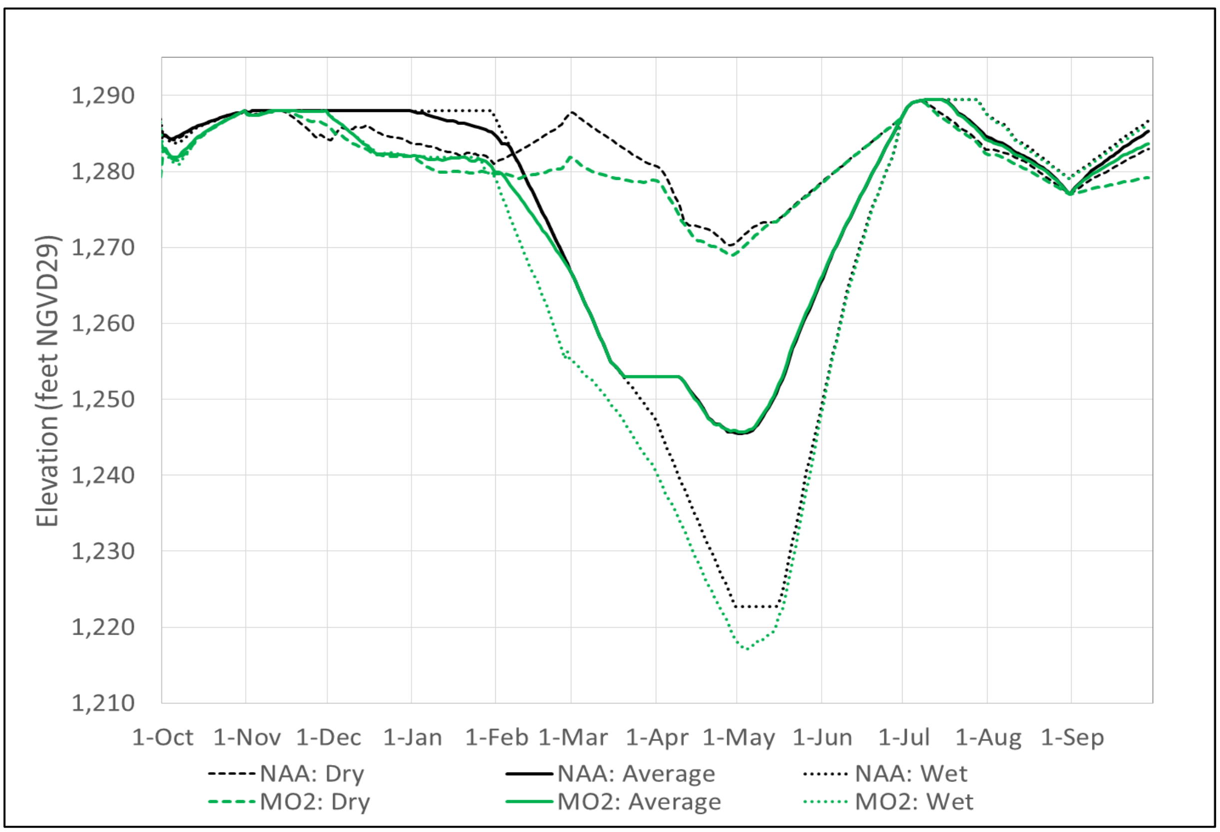

**Figure 3-53. Lake Roosevelt Water Year Type Hydrographs for Multiple Objective Alternative 2**

**Grand Coulee Dam Drum Gate Maintenance**

Drum gate maintenance at Grand Coulee Dam is planned to occur annually during March, April, and May, but is not conducted in all years. The reservoir must be at or below elevation 1,255 feet NGVD29 for 8 weeks to complete drum gate maintenance. Under MO2, the *Slightly Deeper Draft for Hydropower*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures would influence reservoir elevations during spring months.

The changes in elevations for MO2 that influence the decision to conduct drum gate maintenance would not change significantly relative to the No Action Alternative (April 30 FRM elevation targets and drum gate initiation methodology is discussed in more detail in Part 1 of Appendix B). The decision to conduct drum gate maintenance is based on the February water supply forecast and the resulting April 30 FRM elevation projection (April 30 FRM elevation target at or below 1,255 or 1,265 feet NGVD29 depending on how recently the maintenance has been conducted). This is not to say the spring elevations are the same for the two alternatives, but rather that there are a similar number of years that elevations would allow for drum gate maintenance. In both MO2 and the No Action Alternative, drum gate maintenance would be achievable in 65 percent of the years.

**Grand Coulee Dam Outflow**

Under MO2, the *Slightly Deeper Draft for Hydropower*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures would directly affect outflows from Grand Coulee Dam. In addition, MO2 also has measures at Libby Dam (*Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, and *December Libby Target Elevation*), and Hungry Horse Dam (*Slightly Deeper Draft for Hydropower* and *Sliding Scale at Libby and Hungry Horse*) which would affect inflows and outflows at Grand Coulee Dam. The outflows from Grand Coulee Dam would differ from the No Action Alternative depending on the time of year, as seen in the summary hydrograph in Figure 3-54.

The change in average monthly outflow throughout the water year is presented in Table 3-24.

Under MO2, changes in Grand Coulee outflow would come from several measures throughout the year. It is worth noting that MO2 does not have the water supply measures that are included in the other MOs (MO1, MO3, and MO4). Effects to outflow are described below, and where possible, the measure (or combination of measures) causing the effect is identified.

- Under MO2, outflows in October would be lower than the No Action Alternative due to the change in end of September and end of October draft targets from the Slightly Deeper Draft for Hydropower measure. The median October value of the monthly average discharge would be 4.8 kcfs less than the No Action Alternative.
- In November, the median value of the monthly average outflow would increase by 2.0 kcfs. This is primarily due to the *Slightly Deeper Draft for Hydropower* measure.

- In December, the median value of the monthly average outflow would increase by 10.9 kcfs. This is primarily attributable to the measure for the *Winter System FRM Space* and *Slightly Deeper Draft for Hydropower* measures.
- In January, February, and March, the median values of the monthly average outflow would decrease by 1.2, 3.0, and 5.2 kcfs, respectively due to the *Slightly Deeper Draft for Hydropower* and *Planned Draft Rate at Grand Coulee* measures.
- In April, May, and June, the median values of the monthly average outflow would decrease by 2.5, 4.1, and 2.0 kcfs, respectively due mostly to changes in inflow, but in part to measures at Grand Coulee in April. However, the highest monthly average flows for June (at the 1 percent exceedance level) would increase by 3.6 kcfs.
- Monthly average outflows in July and August would be 0.8 and 1.0 kcfs lower, respectively, than for the No Action Alternative due to changes in inflow.
- In September, outflows would generally be greater than the No Action Alternative. The median value of the monthly average outflow would increase by 2.6 kcfs. This is primarily due to the change in the end of September target elevation from the *Slightly Deeper Draft for Hydropower* measure.
- The *Grand Coulee Maintenance Operations* measure would not impact reservoir elevations or total outflows, but would reduce the hydraulic capacity through the power plants, resulting in additional spill and an increase in TDG in some situations.

Finally, Figure 3-55 shows median hydrographs for Grand Coulee Dam outflow in dry, average, and wet years. MO2 and the No Action Alternative are shown. The figure provides another way to picture the effects described above, this time categorized by water year type.

**Table 3-24. Grand Coulee Dam Monthly Average Outflow for Multiple Objective Alternative 2 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

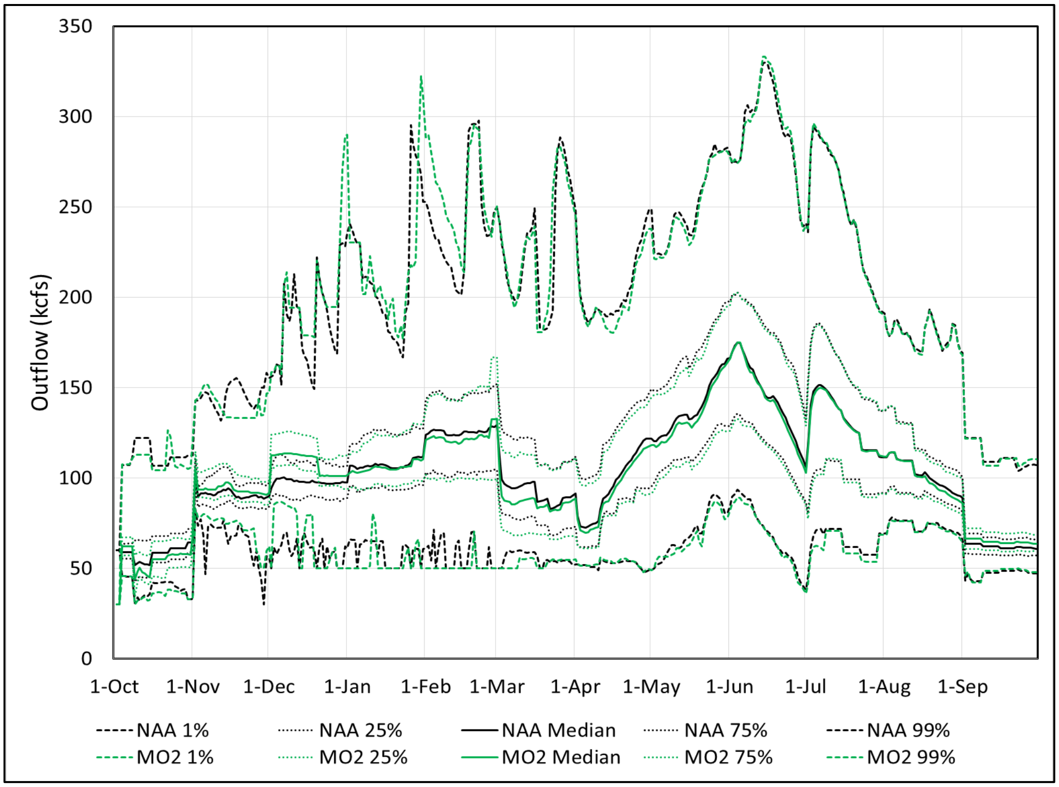

**Figure 3-54. Grand Coulee Dam Outflow Summary Hydrograph for Multiple Objective Alternative 2**

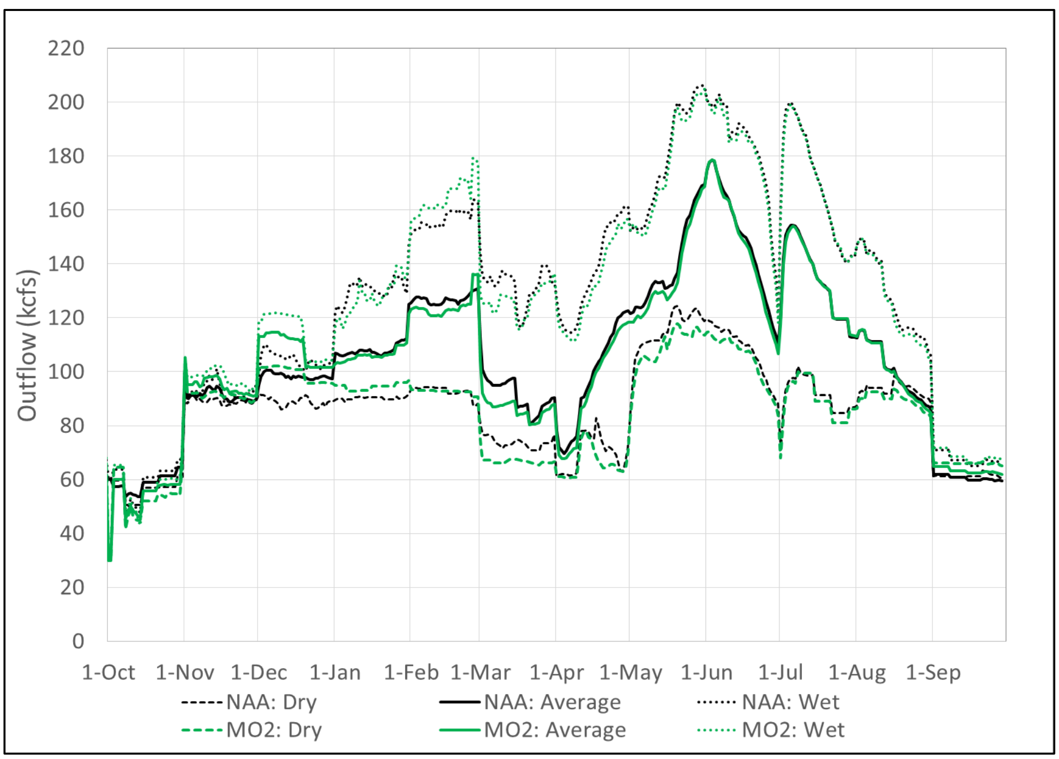

**Figure 3-55. Grand Coulee Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 2**

### Middle Columbia River below Grand Coulee Dam

Under MO2, the pattern of flow changes in the middle Columbia River would be similar to those described for Grand Coulee Dam outflow, with the changes occurring for the same reasons as described for Grand Coulee Dam outflow. The reservoir elevation at Chief Joseph Dam would not change from the No Action Alternative.

Table 3-25 shows changes in the median values of monthly average flows at locations in the middle Columbia River.

**Table 3-25. Middle Columbia River Monthly Average Flows for Multiple Objective Alternative 2 (as change from No Action Alternative)**

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Dworshak Dam

Under MO2, the *Slightly Deeper Draft for Hydropower* measure would have a direct effect on Dworshak Dam operations. Reservoir water levels would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-56.

In MO2, the *Slightly Deeper Draft for Hydropower* measure would allow for additional hydropower generation and hydropower flexibility by drafting to reservoir elevations lower than required for FRM purposes. This measure would affect reservoir levels beginning in

January of each year, with elevations consistently lower than the No Action Alternative through June.

Under the No Action Alternative, Dworshak Reservoir refills to within 0.5 foot of the normal full reservoir elevation of 1,600 feet NGVD29 in about 80 percent of years. Under MO2, ResSim modeling assumptions did not represent the intended operations and instead showed the reservoir would have a decreased refill probability, refilling to within 0.5 foot of the normal full reservoir elevation in about 48 percent of years. It is likely that in real-time operations, the refill probability for Dworshak Reservoir under MO2 would be higher than shown in modeled results and more closely aligned with the No Action Alternative. Integrating the *Slightly Deeper Draft for Hydropower* measure at Dworshak Reservoir with model refill logic yielded lower peak reservoir elevations than for the No Action Alternative. MO2 does not delay the start of summer draft until July 7 like the No Action Alternative does, which also contributes to the reduced peak reservoir elevations in MO2.

Another way to picture how Dworshak Reservoir levels under MO2 would differ from the No Action Alternative is shown in median hydrographs for dry, average, and wet years (Figure 3-57). The most notable differences in Figure 3-57 are seen in January through June.

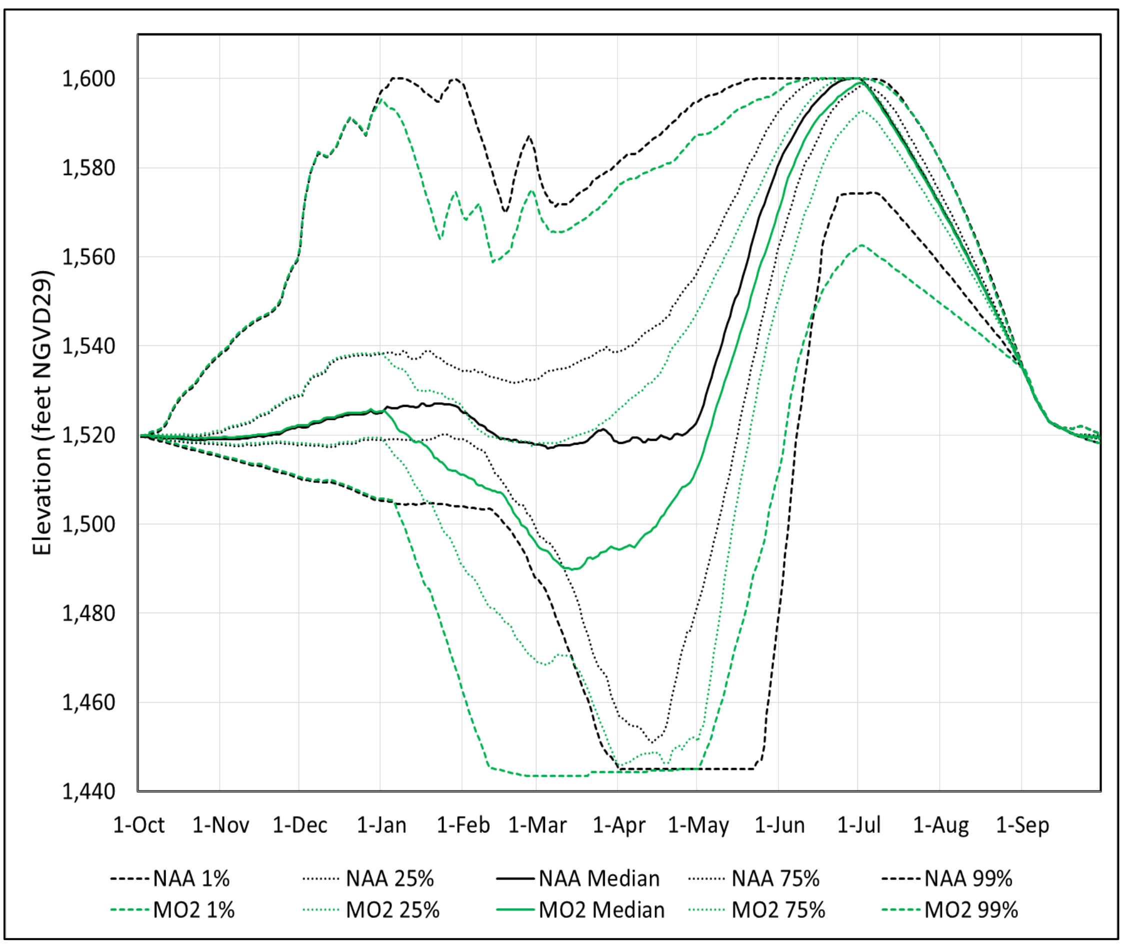

**Figure 3-56. Dworshak Reservoir Summary Hydrograph for Multiple Objective Alternative 2**

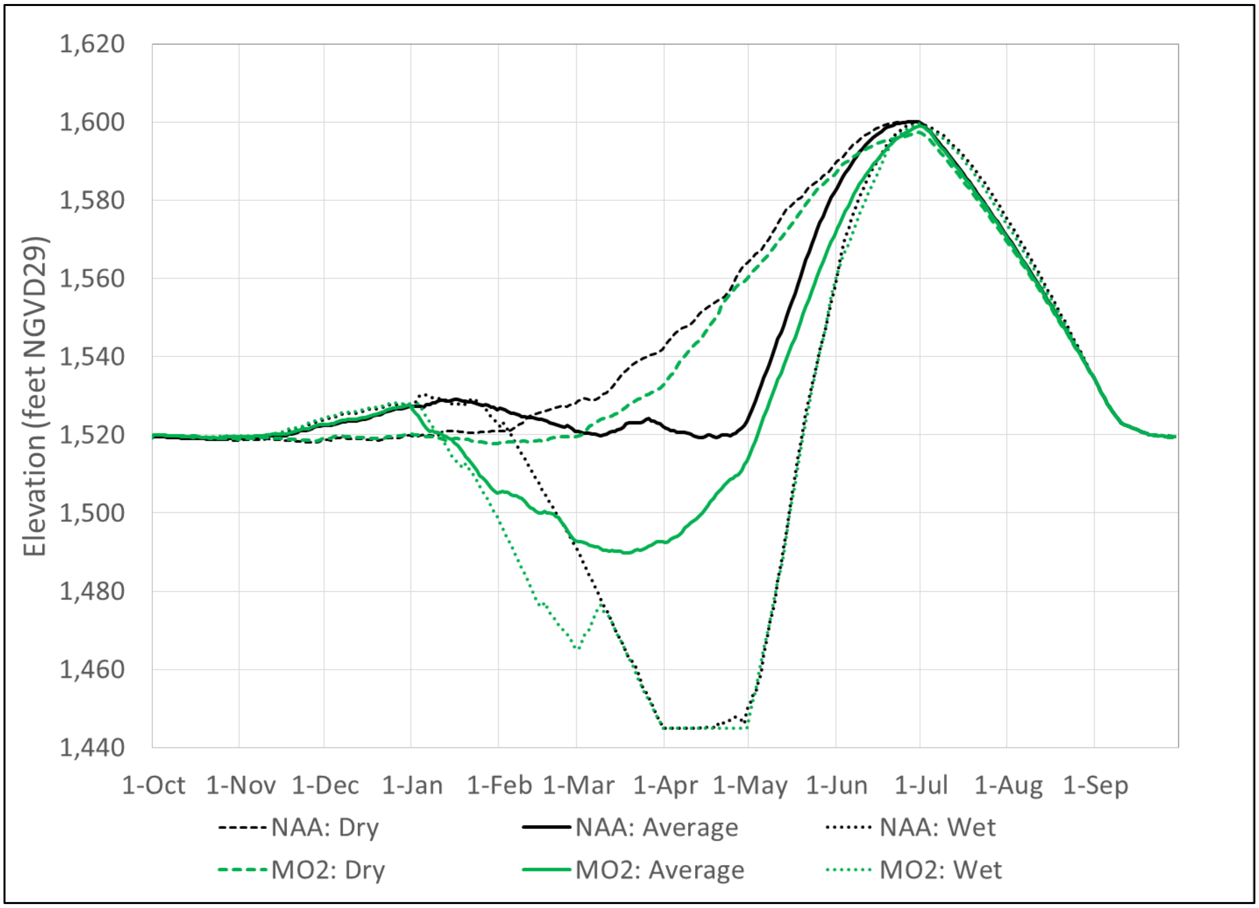

**Figure 3-57. Dworshak Reservoir Water Year Type Hydrographs for Multiple Objective Alternative 2**

**Dworshak Dam Outflow**

Under MO2, the *Slightly Deeper Draft for Hydropower* measure would have a direct effect on Dworshak Dam outflows. The *Ramping Rates for Safety* measure, calling for less restrictive ramping rates, could result in greater hourly or daily outflow changes at Dworshak Dam as well as the other CRS dams. The outflows would differ from the No Action Alternative from January through August. Figure 3-58 shows median hydrographs for Dworshak Dam outflow in dry, average, and wet years.

The change in average monthly outflow is characterized in Table 3-26.

The months of January through August would all have changes in outflow as compared to the No Action Alternative. The changes in outflow are attributable to the *Slightly Deeper Draft for Hydropower* measure. Due to the deeper than intended drafting in ResSim in the spring, the intended flows would likely be lower in the spring and higher in the summer than the modeled values.

- In January, outflows would increase. The median value of the monthly average outflow would increase by 6.6 kcfs.

- In February, outflows would increase for all but the highest flows. The median value of the monthly average outflow would increase by 2.0 kcfs.
- In March, outflows would decrease. The median value of the monthly average outflow would decrease by 1.5 kcfs.
- The outflow in April would decrease. The median value of the monthly average outflow would decrease by 1.9 kcfs.
- In May, outflows would increase for all but the highest flows. The median value of the monthly average outflow would increase by 1.0 kcfs.
- In June, outflows would decrease for all but the highest flows. The median value of the monthly average outflow would decrease by 2.2 kcfs.
- In July, outflows would decrease. The median value of the monthly average outflow would decrease by 0.2 kcfs.
- In August, the median value of the monthly average outflow would decrease by 0.4 kcfs. The lowest outflows (at the 99 percent exceedance level) would decrease by 3.2 kcfs.

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO2 flows lower than the No Action Alternative flows; green shading denotes MO2 flows higher than the No Action Alternative flows.

### Lower Snake River Reservoir Elevations

Under MO2, the reservoir elevations at the four lower Snake River dams would differ from those of the No Action Alternative due to the *Full Range Reservoir Operations* measure, which calls for operating within the full reservoir operating range throughout the year, instead of reducing the normal operating range in the MOP season, April through August. The normal operating ranges for each of the four projects are described below, along with a description of the change from No Action Alternative:

- Lower Granite Dam would use the normal operating range of 733.0 to 738.0 feet NGVD29 year-round. This is a 4.0-foot elevation range increase and a 4.0-foot increase in the upper elevation from April through August compared to the No Action Alternative.
- Little Goose Dam would use the normal operating range of 633.0 to 638.0 feet NGVD29 year round. This is a 4.0-foot elevation range increase and a 4.0-foot increase in the upper elevation from April through August compared to the No Action Alternative.
- Lower Monumental Dam would use the normal operating range of 537.0 to 540.0 feet NGVD29 year round. This is a 2.0-foot elevation range increase and a 2.0-foot increase in the upper elevation from April through August compared to the No Action Alternative.
- Ice Harbor Dam would use the normal operating range of 437.0 to 440.0 feet NGVD29 year round. This is a 2.0-foot elevation range increase and a 2.0-foot increase in the upper elevation from April through August compared to the No Action Alternative.

### Clearwater River below Dworshak Dam and the Lower Snake River

Under MO2, the pattern of outflow changes from Dworshak Dam from January through August would continue downstream. While the percent changes in flow from the No Action Alternative would be pronounced in the Clearwater River system, they would become diluted as the Clearwater River merges with the Snake River near Lewiston, Idaho. This is seen in Table 3-27, which shows changes in median values of monthly average flows. All changes are attributable to the *Slightly Deeper Draft for Hydropower* measure in MO2.

**Table 3-27. Lower Snake Basin Monthly Average Flows for Multiple Objective Alternative 2 (as change from No Action Alternative)**

## REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

### Lower Columbia River Reservoir Elevations

Under MO2, there would be no changes to the reservoir elevations at McNary Dam, The Dalles Dam, or Bonneville Dam. At John Day Dam, the *John Day Full Pool* measure calls for operating the reservoir in a range that goes up to 266.5 feet NGVD29 year round, except as needed for FRM. When operation is needed for FRM, the full operating range (257.0 to 268.0 feet NGVD29) may be used, as is the case for the No Action Alternative. The operating elevation range changes as compared to No Action Alternative are described below:

- January 1 to March 14: Compared to the No Action Alternative (262.0 and 265.0 feet NGVD29), the overall range and maximum elevation is increased by 1.5 feet.
- March 15 to April 9 and October 1 to November 14: Compared to the No Action Alternative (262.5 and 265.0 feet NGVD29), the overall range and maximum elevation is increased by 1.5 feet.

- April 10 to September 30: Compared to the No Action Alternative (262.5 and 264.0 feet NGVD29), the overall range and maximum elevation is increased by 2.5 feet.

The operating range for John Day Dam for Multi Objective Alternative 2 is shown in Figure 3-59. The No Action Alternative operating range is shown for comparison purposes.

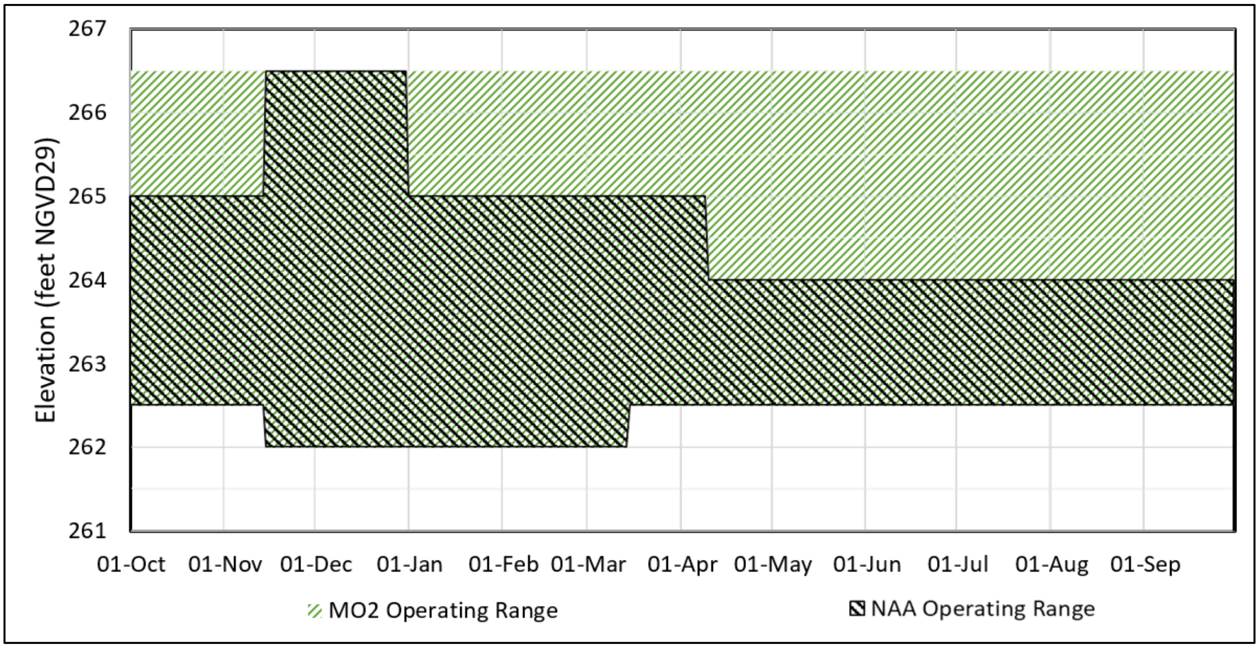

**Figure 3-59. John Day Dam Operating Range for Multiple Objective Alternative 2**

Note: John Day may be operated between 257 feet and 268 feet NGVD29 for FRM purposes. These limits are not shown on this figure in order to show greater detail in the vertical scale.

**Lower Columbia River Flows**

Under MO2, the *Slightly Deeper Draft for Hydropower*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Winter System FRM Space* measures would cause changes in flow patterns in the lower Columbia River.

At McNary Dam, the outflows under MO2 would differ from the No Action Alternative to various extents through the water year. The magnitude and timing of differences in flow are displayed in the summary hydrograph, Figure 3-60.

In addition to the daily outflow values depicted in Figure 3-60, the monthly average outflows from McNary Dam that would occur under MO2 were compared to those for the No Action Alternative, as shown in Table 3-28.

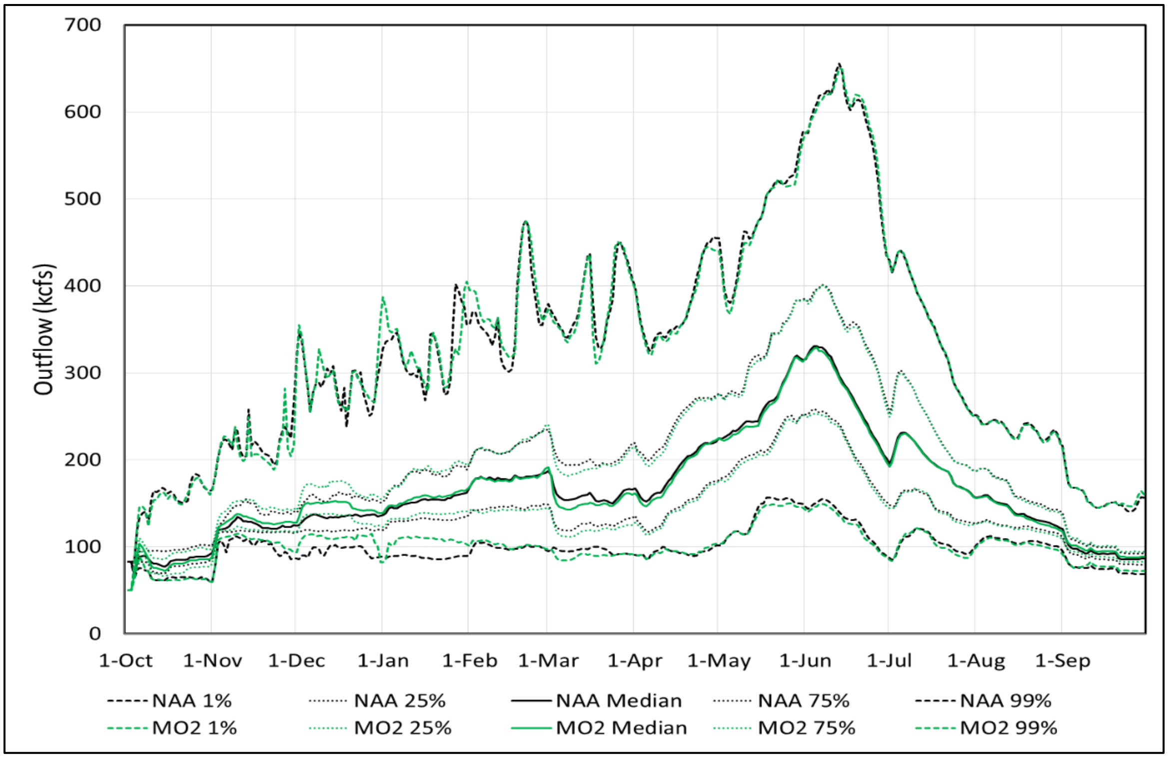

**Figure 3-60. McNary Dam Outflow Summary Hydrograph for Multiple Objective Alternative 2**

Conclusions from this comparison are below:

- In November, the median value of the monthly average outflow would increase by 4.1 kcfs. A combination of measures would cause this, with the *Slightly Deeper Draft for Hydropower* measure being the main reason for the flow increases.
- In December and January, the median value of the monthly average outflow would increase by 10.8 and 4.7 kcfs, respectively. A combination of measures would cause these flow increases, with *Slightly Deeper Draft for Hydropower* and *Winter System FRM Space* being the measures primarily responsible for the change.
- In March through June, the median value of the monthly average outflow would decrease by 6.4, 4.7, 3.6, and 3.2 kcfs, respectively. A combination of measures would cause this, with the *Slightly Deeper Draft for Hydropower* measure, which shifts some system flows from the spring months into the winter months, being one of them.
- In September, the median value of the monthly average outflow would increase by 2.7 kcfs. In October, it would decrease by 3.9 kcfs. These changes are due to the *Slightly Deeper Draft for Hydropower* measure changing the end of September draft target at Grand Coulee Dam.

Finally, median hydrographs for McNary Dam outflow in dry, average, and wet years are shown in Figure 3-61. The figure provides another way to picture the effects described above, this time categorized by water year type. Higher outflows would occur in November and December for all water year types. In January, the dry and average years would continue to have higher outflows. In March outflows would decrease for all water year types.

The effects on McNary Dam outflow from MO2 would occur similarly, and for the same reasons, at John Day Dam, The Dalles Dam, and Bonneville Dam. Along the lower Columbia River, the median value of the average monthly flow for MO2 would be higher than the No Action Alternative in some months (for example, November through January), and lower in others (for example, March through June). The flow change patterns seen at the confluence of the Columbia and Snake Rivers continue downstream to other locations as can be seen in Table 3-29.

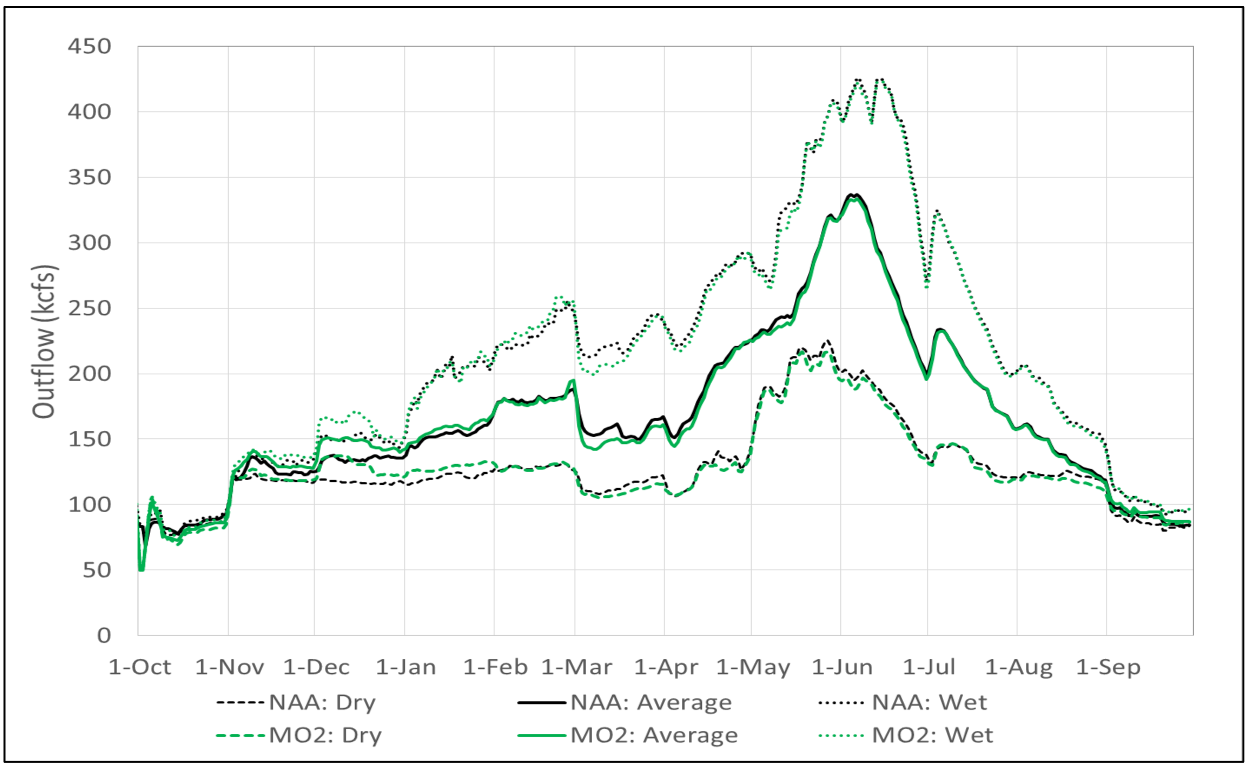

**Figure 3-61. McNary Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 2**

## SUMMARY OF EFFECTS

Under MO2, the largest changes in water levels occur at Libby, Hungry Horse, Grand Coulee, and Dworshak Dams. Lake Koocanusa water levels are substantially lower in most years from November through June, but can be higher in the drawdown period starting in January in larger forecast years, and reservoir levels are slightly higher in the later summer months. Water levels in Hungry Horse Reservoir are lower from January through June in most years, and lower pool levels in the rest of the year are less common. Lake Roosevelt water levels are lower in December through March and at the end of September. Dworshak Reservoir is drawn deeper in January, and it stays lower through July due to impacts to refill by assumptions not representing the intended operation.

The largest impacts to river flow occur immediately below Libby, Hungry Horse, Grand Coulee, and Dworshak Dams, and total flow changes are largest below Grand Coulee Dam. Changes in Libby outflow vary greatly across the year; November and December releases are much higher, otherwise flows are lower, particularly in January and May. Hungry Horse outflow is notably higher in January and February most years, and lower the rest of the year, particularly in May and June. These flow changes carry through the Flathead and Pend Oreille River Basins downstream. Flow in the Columbia River below Grand Coulee is higher in November and December, lower in the spring, and then slightly higher in September followed by lower October flows. Dworshak outflow is higher in January and February and lower March through June. With the exception of December, which can be more than 10 percent higher in lower water years, changes in average monthly flow through the lower Columbia River are within 5 percent of No Action Alternative for all months for most years.

### *3.2.4.6 Multiple Objective Alternative 3*

As the effects of MO3 are presented, they will be displayed along with the No Action Alternative to illuminate the timing and magnitude of differences in water conditions between it and the No Action Alternative. Similar to previous sections, the operational measure (or measures) from MO3 which would result in changes from the No Action Alternative, are identified to the extent possible.

It should be noted that the *Ramping Rates for Safety* measure in MO3 would allow for less restrictive ramping rates at all CRS projects, meaning that changes in outflow could be greater in magnitude than for the No Action Alternative. This measure was implemented to the extent possible in the hydroregulation modeling (ramping rates restrictions at Libby and Hungry Horse Dams were relaxed, approximated by doubling the restrictions) but it is not reflected in modeling at the other CRS projects. Effects on power generation and transmission are discussed in Section 3.7 of this EIS.

#### REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS

#### Lake Koocanusa (Libby Dam Reservoir) Elevation

Under MO3, the *Ramping Rates for Safety*, *Sliding Scale at Libby and Hungry Horse*, Modified Draft at Libby, and *December Libby Target Elevation* measures would have a direct effect on Libby Dam operations.

Reservoir water levels in Lake Koocanusa would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-62.

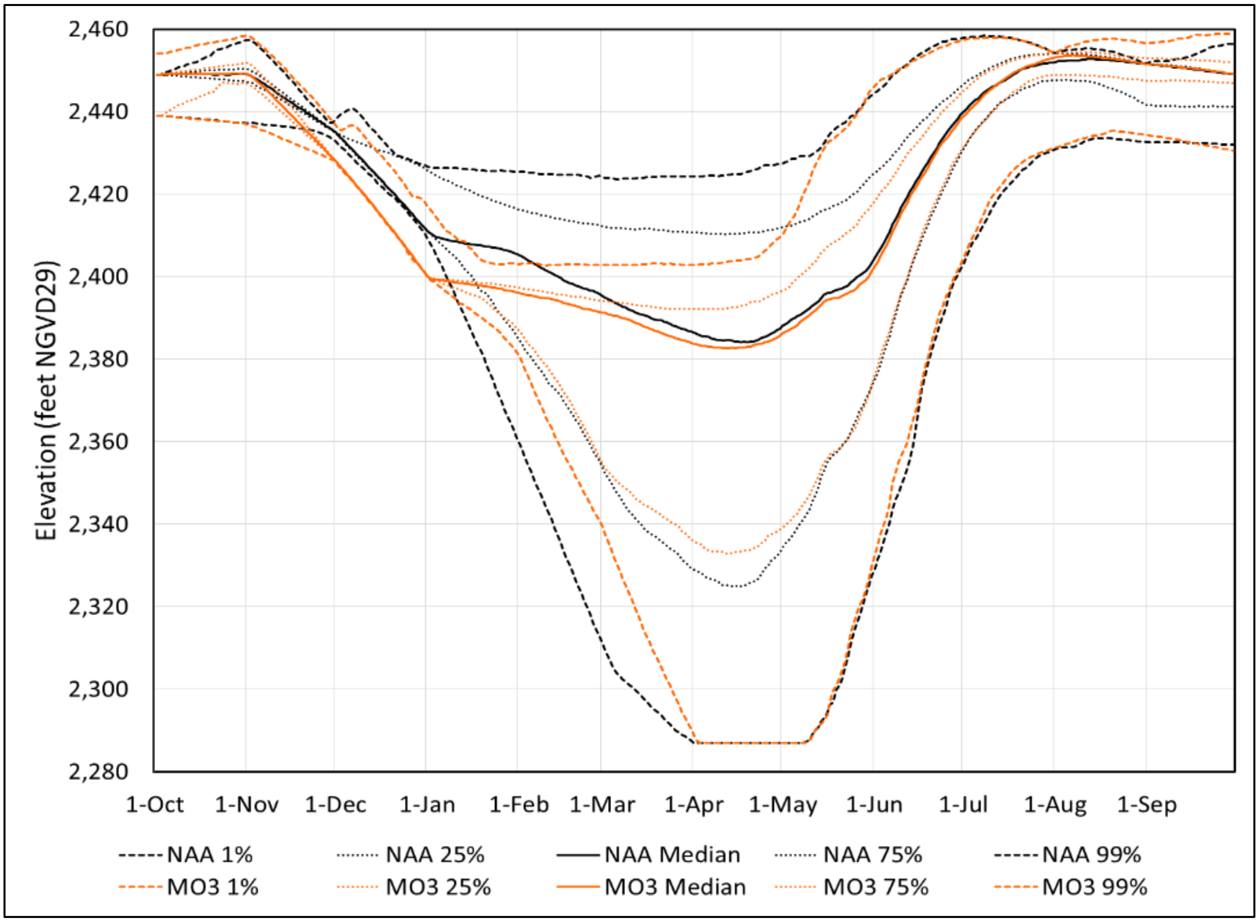

**Figure 3-62. Lake Koocanusa Summary Hydrograph for Multiple Objective Alternative 3**

MO3 would generally have the same end-of-October reservoir elevation as the No Action Alternative. However, over the course of November and December the reservoir elevations for MO3 would be lower than for the No Action Alternative due to the *December Libby Target Elevation* measure, resulting in an end-of-December elevation of 2,400 feet NGVD29 in most years.

Through the remaining winter months and into the early spring, reservoir levels would generally continue to be lower under MO3 than they would be for the No Action Alternative, though this is not always the case as seen in the 99 percent exceedance and 75 percent exceedance lines. The reservoir elevations that would occur in the winter and early spring are driven by the prolonged effect of the lower end of December elevation (from the *December Libby Target Elevation* measure) or the drafts called for by the *Modified Draft at Libby* measure (or both). It should be noted that MO3 targets a reservoir elevation of 2,400 feet NGVD29 at the end of December (*December Libby Target Elevation* measure), but uses draft targets in January, February and March set by an SRD (*Modified Draft at Libby* measure) designed to accommodate an end-of-December elevation of 2,420 (NGVD29). The result of this combination of measures is that in higher water supply years the reservoir is not drafted as deeply in January through March as would be desired to achieve April FRM draft targets while striving for relatively stable outflow.

By April or May, the reservoir would generally begin refilling. The modified refill operation called for in the *Modified Draft at Libby* measure would generally improve the probability of refilling the reservoir, though in the driest years the reservoir would have less success in refilling (as compared to the No Action Alternative) due to the lower winter and early spring reservoir elevations that would occur. Overall, MO3 would have a 44 percent chance of the reservoir reaching elevation 2,454 feet NGVD29 or higher (within 5 feet of the full pool elevation of 2,459 feet NGVD29) by July 31, as compared to a 39 percent chance for the No Action Alternative. The peak reservoir elevation would usually be achieved in July or early August.

During the months of August and September, the reservoir elevation for MO3 would generally be about 1 to 4 feet higher than for the No Action Alternative. The reason for this is the *Modified Draft at Libby* measure, which tends to increase the peak refill elevation, and the *Sliding Scale at Libby and Hungry Horse* measure which calls for a sliding scale end-of-September target elevation that would be dependent on the Libby Dam water supply forecast, rather than the system-wide water supply forecast at The Dalles. The *Sliding Scale at Libby and Hungry Horse* measure targets a higher elevation than the No Action Alternative in the wettest 25 percent of years.

As already discussed, the timing of and extent to which the reservoir elevation for MO3 would differ from the No Action Alternative would vary throughout the year. It is helpful to examine the changes that would occur based on the water year type, as shown in the median hydrographs for dry, average, and wet years in Figure 3-63. Dry years would see the most pronounced difference, with lower reservoir elevations beginning in November and December, and continuing through the winter and early spring, when they would be 20 to 25 feet lower than under the No Action Alternative. Average years would also have lower reservoir elevations, with the difference being most pronounced in the late fall and early winter months. Wet years would also differ, having lower reservoir elevations in November and December, and similar or higher elevations through the remainder of the water year.

Finally, the three panels in Figure 3-64 show monthly elevation duration curves for July, August, and September, respectively. The curve for MO3 is plotted along with the curve for the No Action Alternative in each month. For July, the MO3 curve is virtually identical to the No Action Alternative. In August and September, the reservoir elevation under MO3 would tend to be the same or higher than the No Action Alternative. The higher elevations in August are due to the *Modified Draft at Libby* and the *Sliding Scale at Libby and Hungry Horse* measures. In September, they are due to the *Sliding Scale at Libby and Hungry Horse* measure, which has fewer years drafting to 2,439 feet NGVD29 than the No Action Alternative due to the change in forecast location, and the wettest years only needing a draft to 2,454 feet NGVD29.

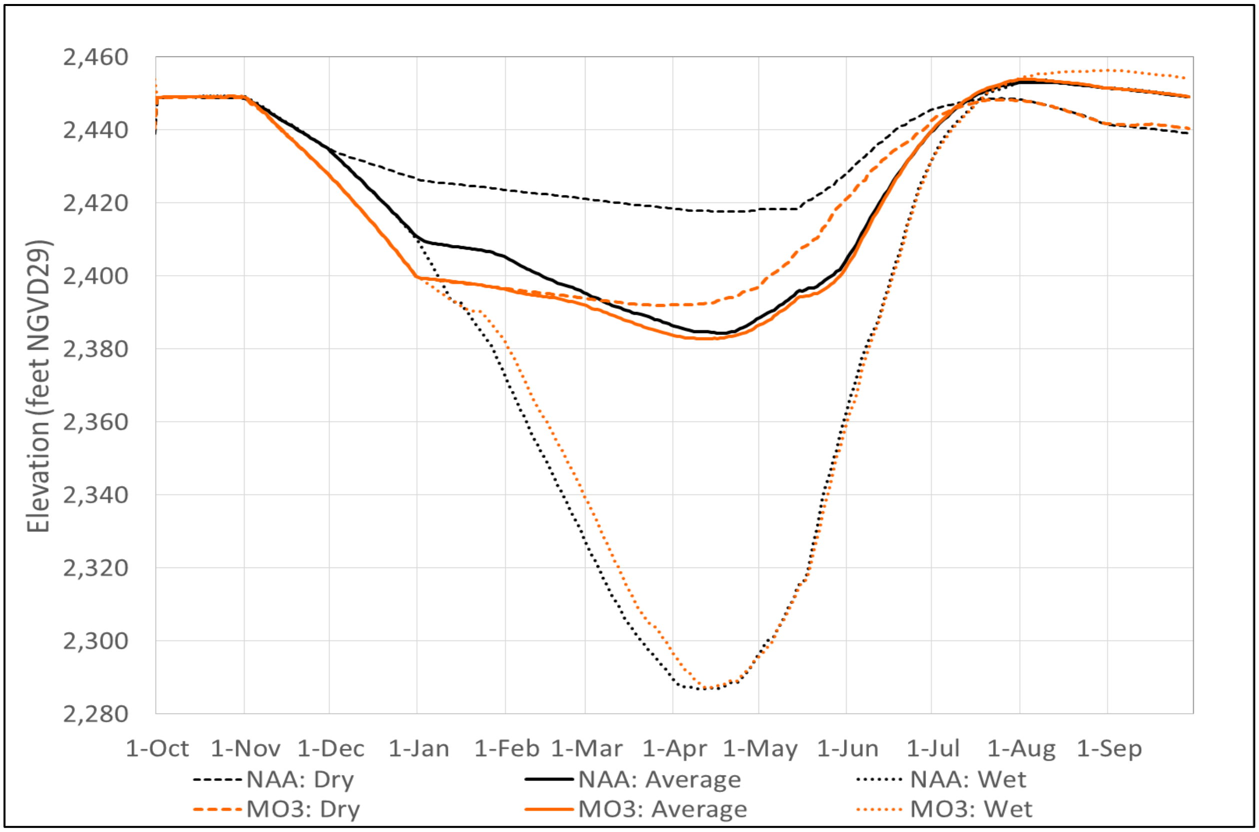

**Figure 3-63. Lake Koocanusa Water Year Type Hydrographs for Multiple Objective Alternative 3**

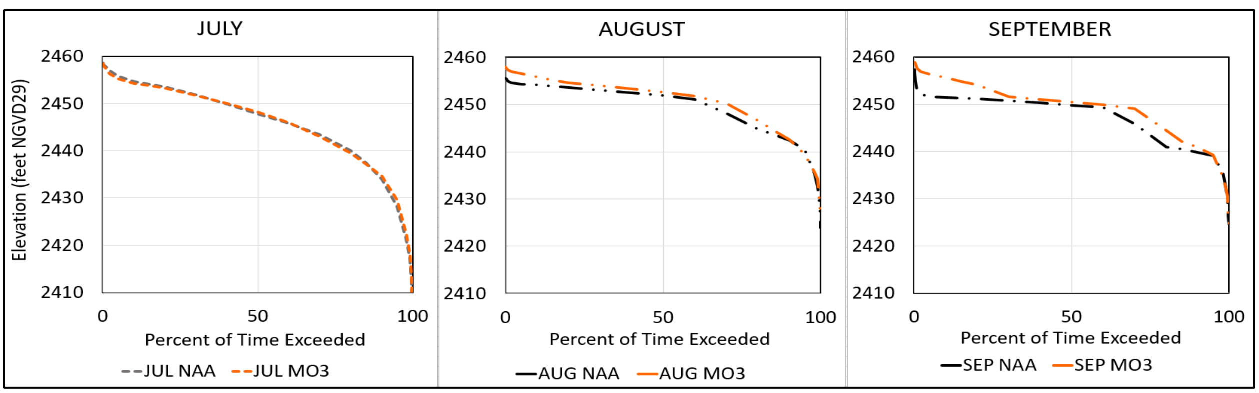

**Figure 3-64. Lake Koocanusa Summer Elevations for Multiple Objective Alternative 3**

**Libby Dam Outflow**

Under MO3, the *Ramping Rates for Safety*, *Sliding Scale at Libby and Hungry Horse*, Modified Draft at Libby, and the *December Libby Target Elevation* measures would have a direct effect on Libby Dam outflow. The change in outflows from the No Action Alternative varies throughout the year. Figure 3-65 shows median hydrographs for Libby Dam outflow in dry, average, and wet years.

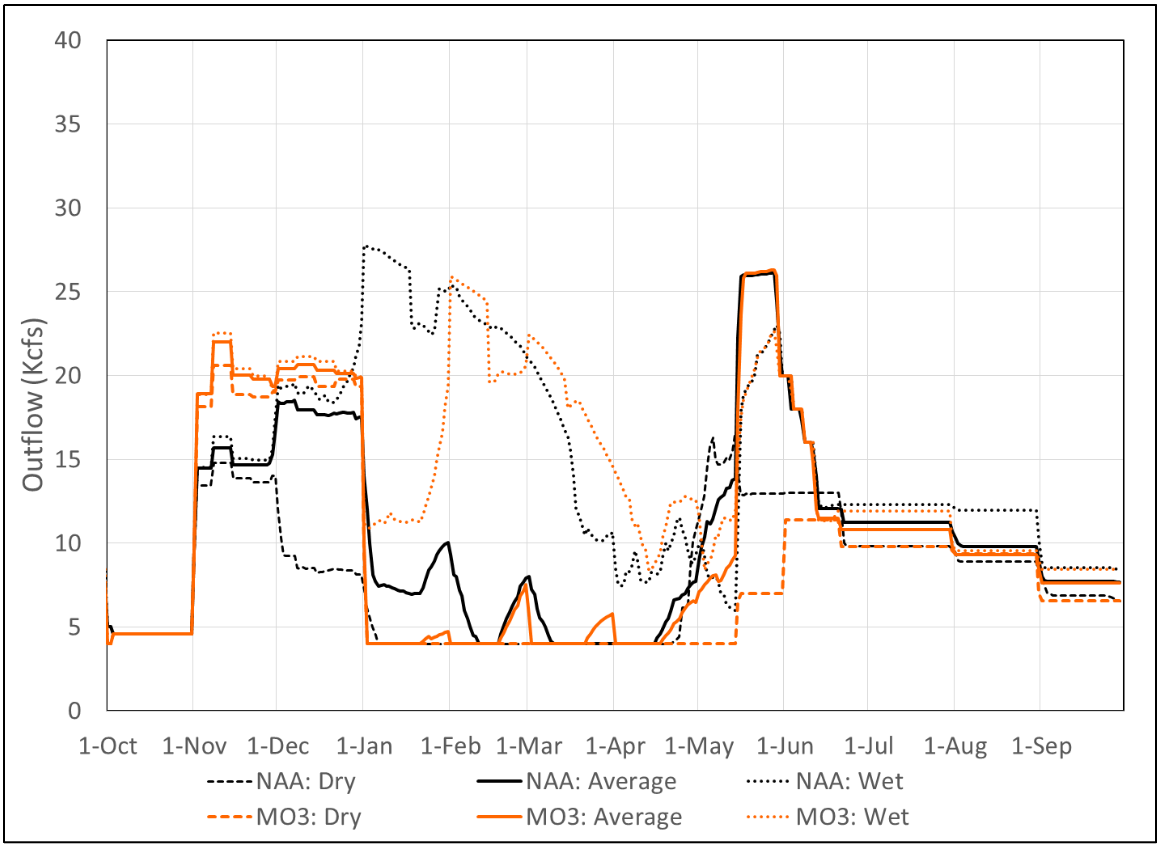

**Figure 3-65. Libby Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 3**

Throughout the year, the *Ramping Rates for Safety* measure would allow for less restrictive ramping rates, meaning that changes in outflow from Libby Dam (increases or decreases) could be greater in magnitude than for the No Action Alternative. This measure would not discernibly alter the monthly average outflow, but could change the outflow for a few days following a sharp rise or drop in flow. It should be noted that the HEC-ResSim hydroregulation modeling does not incorporate hourly, daily, or weekly load shaping at dams, including Libby Dam.

The change in average monthly outflow throughout the water year is presented in Table 3-30.

Average outflow from Libby Dam under MO3 would differ from the No Action Alternative:

- In November and December, the monthly average outflows would increase. At the median level, the increase in November would be 4.9 kcfs and the increase in December would be 2.4 kcfs. The December increases would be most pronounced in the lowest water supply forecast years, with increases of 9.6 and 10.7 kcfs, respectively, at the 75 percent and 99 percent exceedance levels. The outflow increases are caused by the reservoir drafting to elevation 2,400 feet NGVD29 in most years for hydropower, the result of the *December Libby Target Elevation* measure.
- In January through March, monthly average outflows would generally be the same or lower than the No Action Alternative. At the median level, they would decrease by 3.7, 1.4, and

0.6 kcfs, respectively. The lower outflow in January, and to a lesser extent in February and March of some years, is due to the way the *December Libby Target Elevation* measure combines with the *Modified Draft at Libby* measure.

- Overall, April and May median monthly average outflows would decrease by 1.8 and 1.1 kcfs, respectively, from the No Action Alternative. These changes are related to the VarQ update in the *Modified Draft at Libby* measure that would account for future volume releases and refill the reservoir more aggressively. During dry years, the larger decrease is from being drafted deeper in December for hydropower as part of the *December Libby Target Elevation* measure.
- In June and July, monthly average outflows would generally be lower than the No Action Alternative. At the median level, they would decrease by 0.7 and 0.8 kcfs, respectively. However, the very highest releases under MO3 would be greater than those for the No Action Alternative.
- In August and September, monthly average outflows would be lower than the No Action Alternative. At the median level, they would decrease by 0.9 and 0.4 kcfs, respectively. The *Sliding Scale at Libby and Hungry Horse* measure, calling for a sliding scale end-of-September target elevation based on the Libby Dam water supply forecast and a higher elevation target in the wettest 25 percent of years, contributes to this along with the improved refill from the *Modified Draft at Libby* measure.

**Table 3-30. Libby Dam Monthly Average Outflow for Multiple Objective Alternative 3 (as change from No Action Alternative)**

### Bonners Ferry Flow

Under MO3, the *Ramping Rates for Safety*, *Sliding Scale at Libby and Hungry Horse*, Modified Draft at Libby, and *December Libby Target Elevation* measures would affect flows at Bonners Ferry. In general, the flows would differ from the No Action Alternative in much the same way as at Libby Dam, and for the same reasons. The change in average monthly flow at Bonners Ferry throughout the water year is presented in Table 3-31.

**Table 3-31. Bonners Ferry Monthly Average Flow for Multiple Objective Alternative 3 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO3 flows lower than the No Action Alternative flows; green shading denotes MO3 flows higher than the No Action Alternative flows.

### Hungry Horse Reservoir Elevation

Under MO3, the *Ramping Rates for Safety*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would have a direct effect on Hungry Horse Dam operations.

Reservoir water levels would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-66.

The water year would begin with the reservoir levels for MO3 being lower than those for the No Action Alternative. This is because the operations associated with the *Hungry Horse Additional Water Supply* measure would leave the reservoir at a lower elevation on September 30 than under the No Action Alternative, and the condition would carry over to the following water year. It should be noted that when MO3 was modeled, the initial Hungry Horse Reservoir levels at the start of each water year were erroneously set lower than intended. A subsequent sensitivity analysis revealed that this initialization error primarily affected results in the fall and winter. In the summary hydrograph, Figure 3-66, the median and higher elevations should have water levels 1 to 3 feet higher than shown from October through May. Below the median, the results should be 5 to 10 feet higher from October through February.

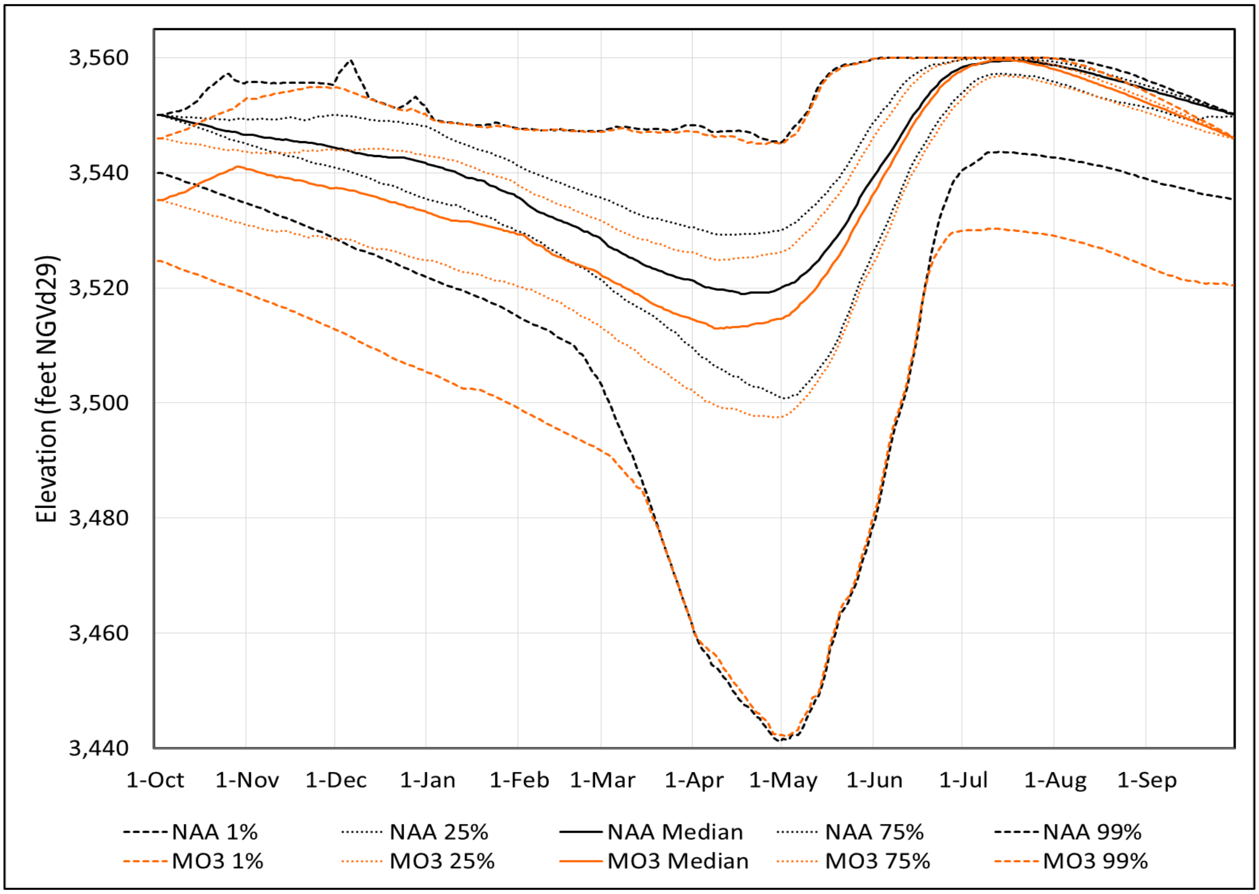

**Figure 3-66. Hungry Horse Reservoir Summary Hydrograph for Multiple Objective Alternative 3**

This initialization error had little effect downstream from Hungry Horse Dam. Hungry Horse Dam's modeled releases were up to 1 kcfs lower than they should have been, but by the time flow reaches Flathead Lake the MO3 results have little error.

Overall, reservoir elevations under MO3 would be lower than for the No Action Alternative. At the median level, reservoir elevations would be about 4 feet lower in November through April and 0 to 2 feet lower in May through August. By the end of September, reservoir levels under MO3 would typically be 4 feet lower than the No Action Alternative. The *Sliding Scale at Libby and Hungry Horse* measure results in reducing the draft requirements in some years, by setting a higher elevation target for summer flow augmentation than the No Action Alternative.

Water levels at Hungry Horse Reservoir under MO3 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-67.

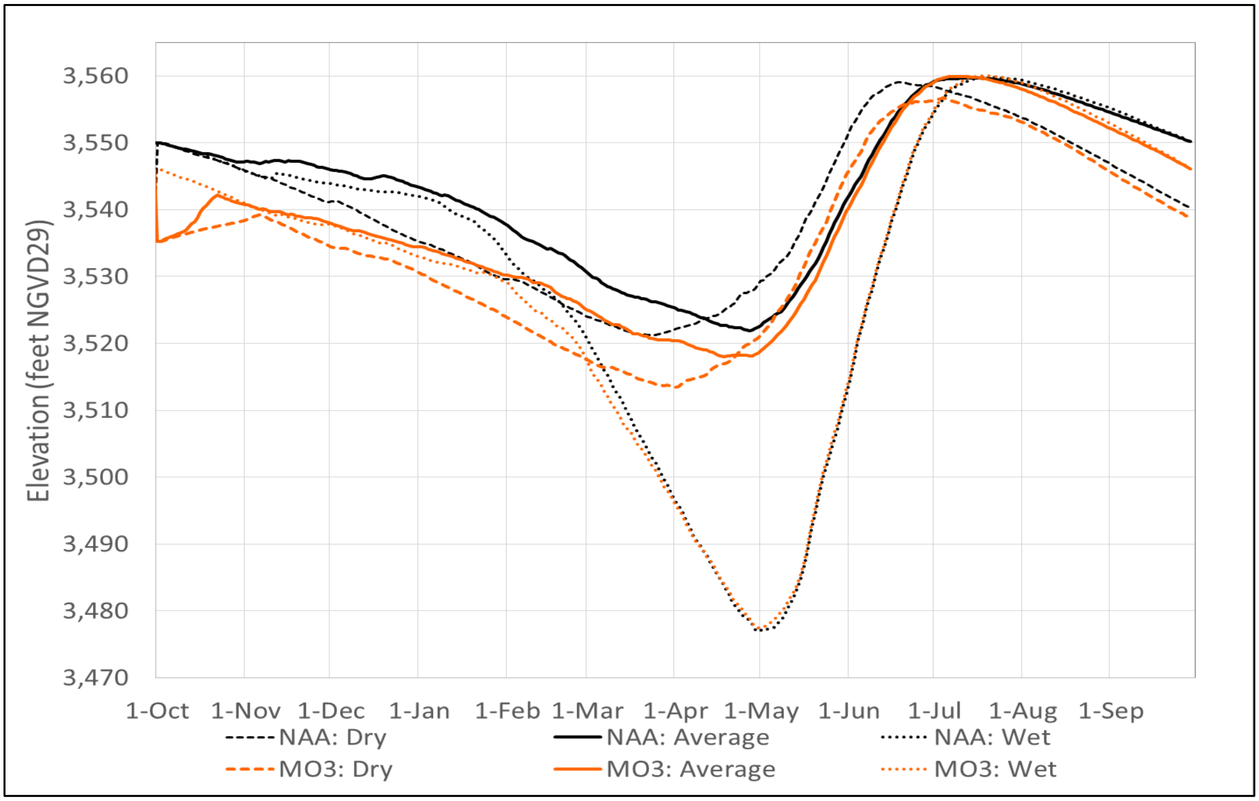

**Figure 3-67. Hungry Horse Reservoir Water Year Type Hydrographs for Multiple Objective Alternative 3**

Finally, the three panels in Figure 3-68 show Hungry Horse Reservoir elevation duration curves for the months of July, August, and September, respectively. While other months have larger differences, these three are shown because of interest in summer reservoir elevations. In general, the reservoir levels under MO3 would be lower than for the No Action Alternative, with August and September having the most difference. For instance, the daily reservoir elevation in September would be above elevation 3,550 feet NGVD29 about 30 percent of the time under MO3, whereas it would be above that elevation about 71 percent of the time under the No Action Alternative.

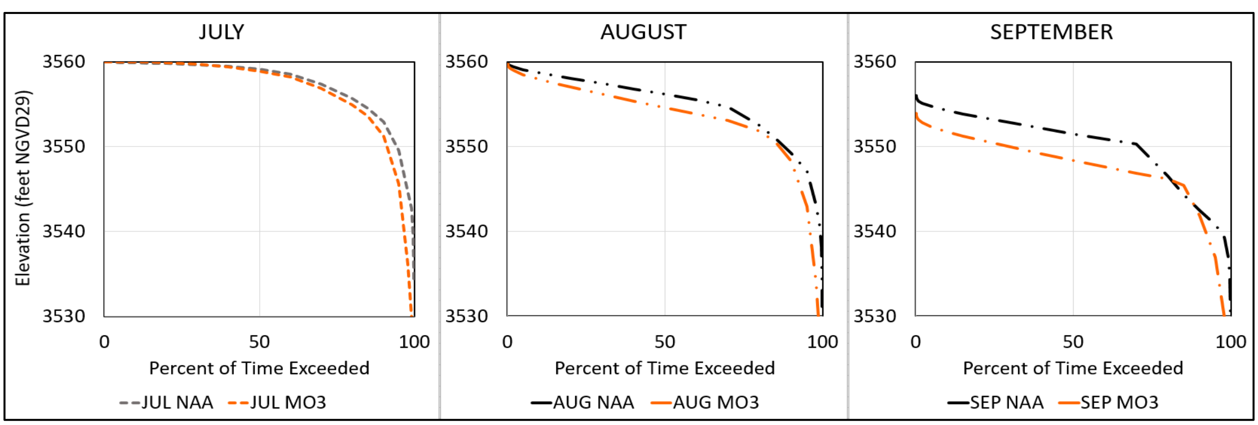

**Figure 3-68. Hungry Horse Reservoir Summer Elevations for Multiple Objective Alternative 3**

**Hungry Horse Dam Outflow**

Under MO3, the *Ramping Rates for Safety*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would have a direct effect on Hungry Horse Dam outflows. The outflows would differ from the No Action Alternative depending on the time of year. Figure 3-69 shows median hydrographs for Hungry Horse Dam outflow in dry, average, and wet years.

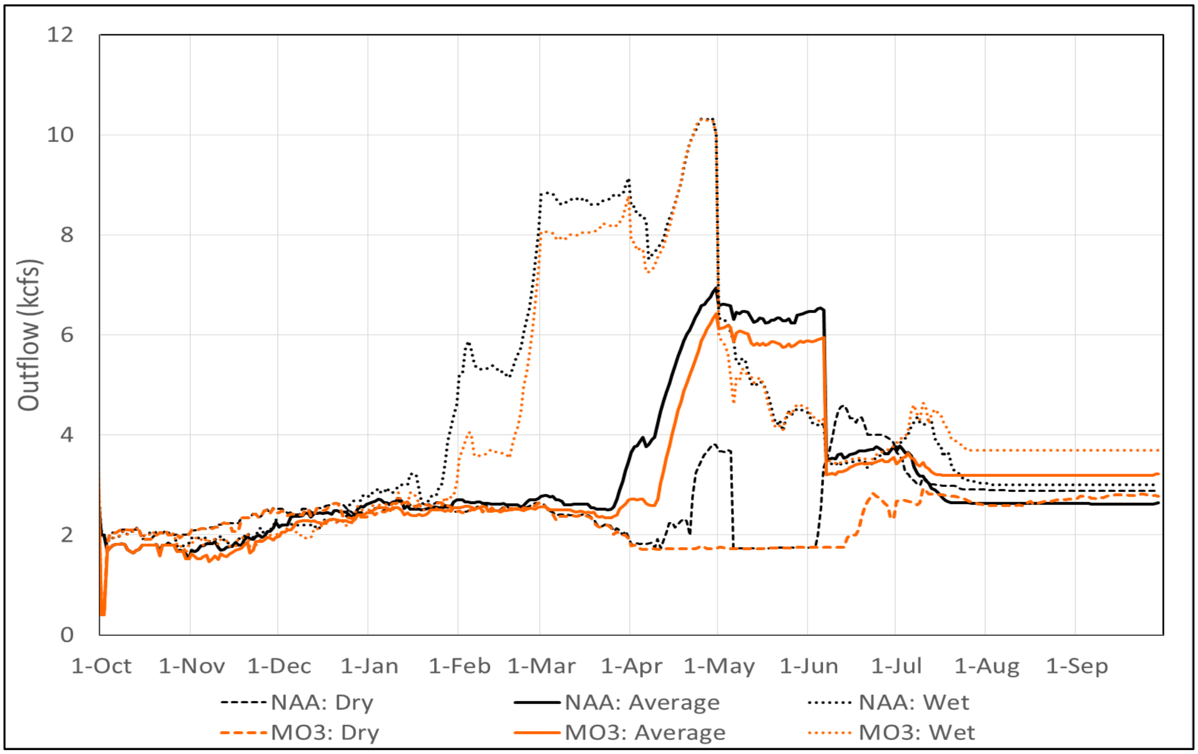

**Figure 3-69. Hungry Horse Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 3**

The change in average monthly outflow from Hungry Horse Dam throughout the water year is presented in Table 3-32.

**Table 3-32. Hungry Horse Dam Monthly Average Outflow for Multiple Objective Alternative 3 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

| | | 99% | -39% | -29% | -32% | -17% | -12% | -7% | -3% | -1% | -3% | -3% | 12% | 17% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO3 flows lower than the No Action Alternative flows; green shading denotes MO3 flows higher than the No Action Alternative flows.

Average outflow from Hungry Horse Dam would differ from the No Action Alternative:

- In August and September, the median value of the monthly average outflow would increase as compared to the No Action Alternative. The measures driving these changes are the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures.
- After September and through the spring, reservoir outflows would generally be lower than for the No Action Alternative. The lower outflows would occur because the reservoir would be drafted deeper at the end of September, and so would begin the water year at a lower elevation than under the No Action Alternative.

While the initial Hungry Horse Reservoir levels at the start of each water year were erroneously set lower than intended, the effects of this initialization on Hungry Horse discharge are smaller than the effects on reservoir elevation. The results in Table 3-31 are close to what would be expected for MO3. Winter flows would be lower than for the No Action Alternative, with flows at the 1 percent exceedance level being the most underpredicted (the underprediction ranges from 0.2 to 0.9 kcfs at the 1 percent exceedance level). By May and June, the underprediction in flows from the initialization error is just 0.1 to 0.2 kcfs for most water year types. Moving downstream through the system, flow effects from initialization have less and less of an effect as the total river flows become larger and larger.

Throughout the year, the *Ramping Rates for Safety* measure would allow for less restrictive ramping rates, meaning that changes in outflow from Hungry Horse Dam (increases or decreases) could be greater in magnitude than for the No Action Alternative. This measure would not discernibly alter the monthly average outflow, but could change the outflow for a few days following a sharp rise or drop in flow. It should be noted that the HEC-ResSim hydroregulation modeling does not incorporate hourly, daily, or weekly load shaping at dams, including Hungry Horse Dam.

### Columbia Falls Flow

Under MO3, the *Ramping Rates for Safety*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would affect flows at Columbia Falls. Compared to the No Action Alternative, there would be increased flow in August and September in virtually all years, while other months of the year would have flows similar to or less than those under the No Action Alternative, while still meeting minimum flow requirements. The change in average monthly flow at Columbia Falls throughout the water year, as compared to the No Action Alternative, is presented in Table 3-33.

**Table 3-33. Columbia Falls Monthly Average Flow for Multiple Objective Alternative 3 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

| | | 75% | -2% | 0% | 0% | 0% | 0% | -2% | -8% | -3% | -3% | 0% | 6% | 8% |
| | | 99% | -3% | 0% | 0% | 0% | 0% | 0% | -8% | -3% | -4% | -5% | 1% | 9% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO3 flows lower than the No Action Alternative flows; green shading denotes MO3 flows higher than the No Action Alternative flows.

### Lake Pend Oreille Elevation

Under MO3, there are no measures that would have a direct effect on the level of Lake Pend Oreille. The operational changes at Hungry Horse Dam from the *Sliding Scale at Libby and Hungry Horse* and *Hungry Horse Additional Water Supply* measures would translate downstream (as flow changes) and pass through Lake Pend Oreille. The flow changes would not impact the annual peak reservoir levels and would not change the timing of refill or drawdown.

Thus, there would not be any noticeable difference in the level of Lake Pend Oreille as compared to the No Action Alternative.

**Albeni Falls Outflow**

Under MO3, the *Sliding Scale at Libby and Hungry Horse* and *Hungry Horse Additional Water Supply* measures would affect the monthly average outflow from Albeni Falls Dam, but to a lesser degree than at Hungry Horse Dam or Columbia Falls. This is seen in Table 3-34.

**Table 3-34. Pend Oreille Basin Monthly Average Flows for Multiple Objective Alternative 3 (as change from No Action Alternative)**

**REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS**

**Columbia River flow upstream of Grand Coulee Dam**

Under MO3, the *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, and *Hungry Horse Additional Water Supply* measures would affect Columbia River flow upstream of Grand Coulee Dam. A summary hydrograph of flows near RM 748 (just downstream of the U.S.-Canada border, about 151 river miles upstream of Grand Coulee Dam) is shown in Figure 3-70.

Figure 3-70 characterizes the timing and magnitude of flow changes between the No Action Alternative and MO3 due to the combined effect of measures at Libby and Hungry Horse Dams. Changes in flow between MO3 and the No Action Alternative would be noticeable in many months. In November and December, flows for MO3 would generally be higher, primarily due to the hydropower draft in in the *December Libby Target Elevation* measure at Libby Dam. In January, and again from May through July, MO3's flows would generally be the same or lower.

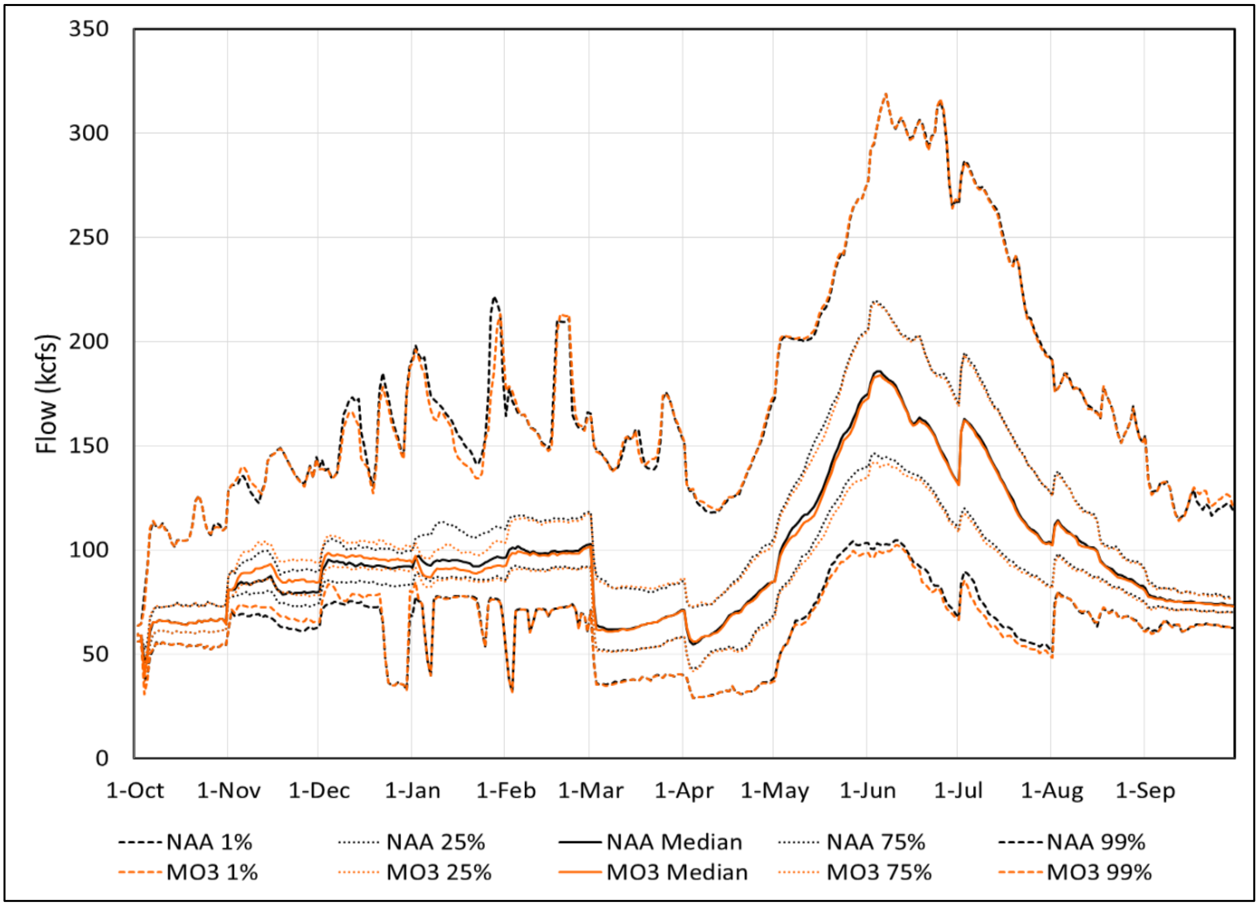

**Figure 3-70. Lake Roosevelt Inflow Summary Hydrograph for Multiple Objective Alternative 3**

### Lake Roosevelt (Grand Coulee Dam Reservoir) Elevation

Under MO3, the *Update System FRM Calculation* and *Planned Draft Rate at Grand Coulee* measures relate directly to Grand Coulee Dam and would influence reservoir elevations at Lake Roosevelt.

In addition, the *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, and *Hungry Horse Additional Water Supply* measures would affect the inflow to Grand Coulee Dam. It is worth noting that MO3 does not have a measure calling for winter FRM space at Grand Coulee Dam, whereas MO1, MO2, and MO4 all do have the *Winter System FRM Space* measure. The hydroregulation modeling performed for MO3 incorporates all of these measures, but because each measure was not evaluated in isolation from the others, drawing a direct linkage between a single measure and an effect is not always possible. The effects that would occur from a measure or combination of measures are identified and discussed to the extent possible.

Reservoir water levels in Lake Roosevelt under MO3 would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-71.

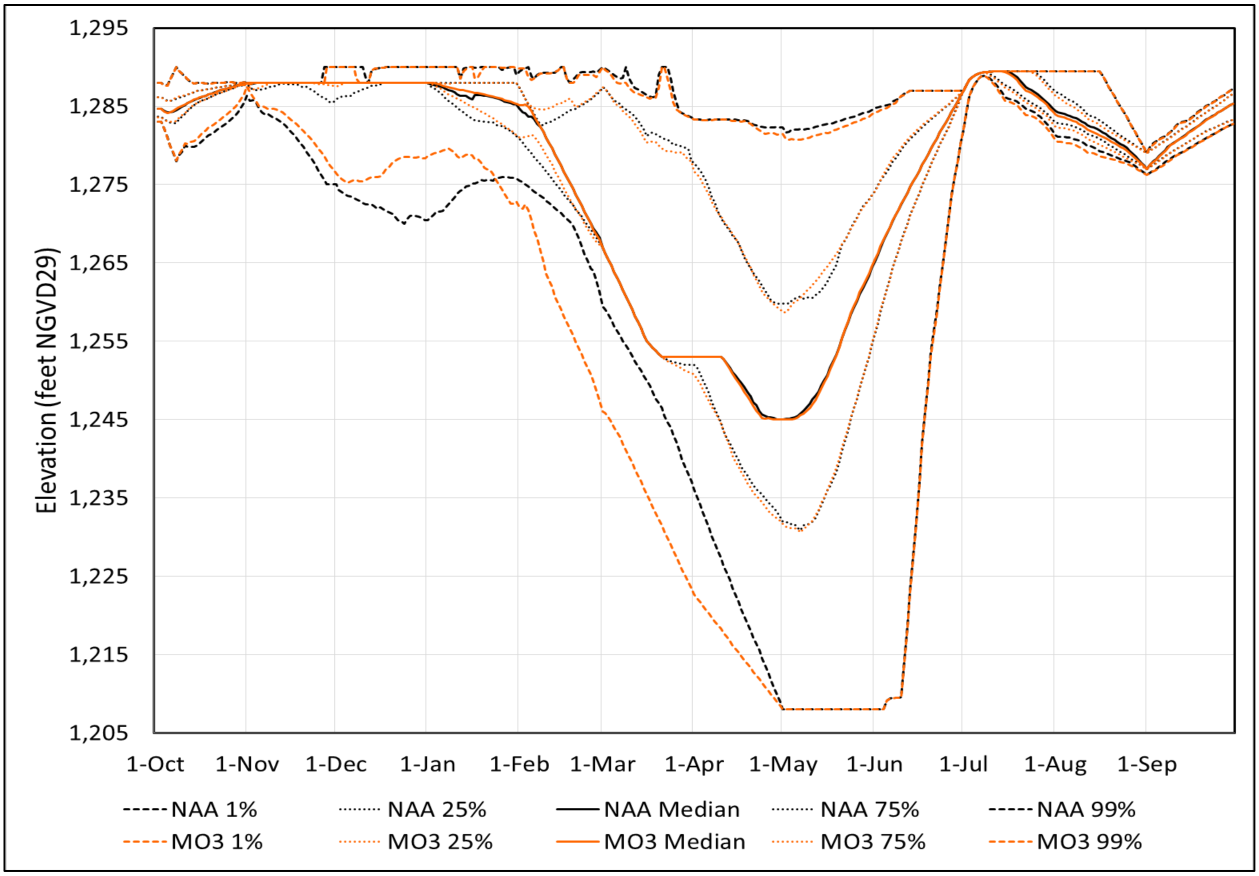

**Figure 3-71. Lake Roosevelt Summary Hydrograph for Multiple Objective Alternative 3**

Under MO3, the elevation of Lake Roosevelt throughout the year would be similar to the No Action Alternative, with a few exceptions as shown in Figure 3-71. In years with large water supply forecasts issued in the winter months, the reservoir elevation would be lower in the winter and early spring primarily due to the *Planned Draft Rate at Grand Coulee* and *Update System FRM Calculation* measures. These measures work together to achieve FRM space requirements at Grand Coulee Dam based on water supply conditions. The *Update System FRM Calculation* measure determines how much space is needed at Grand Coulee Dam, given the amount of space available elsewhere in the system; the *Planned Draft Rate at Grand Coulee* measure determines how early to start drafting the reservoir to achieve that space. The *Update System FRM Calculation* measure would also have an influence on reservoir elevations in the winter and spring months. *Grand Coulee Maintenance Operations* and *Lake Roosevelt Additional Water Supply* measures would not have an effect on the reservoir elevation, but would affect outflow from the dam, including the amount of outflow that would occur as spill.

MO3 has a similar probability of drafting to very low reservoir elevations (elevation 1,222 feet NGVD29 or below) at Lake Roosevelt on April 30 as the No Action Alternative. This is because the FRM space requirement at Grand Coulee Dam defined in the *Update System FRM Calculation* measure retains a "flat spot" at elevation 1,222.7 feet NGVD29, similar to the No Action Alternative.

Finally, median hydrographs for Lake Roosevelt elevation in dry, average, and wet years are shown in Figure 3-72. The figure provides another way to picture the effects of MO3, this time categorized by water year type. Presented this way, it can be seen that in dry years, Lake Roosevelt's elevation from mid-November through early February would be higher under MO3 than the No Action Alternative. From mid-November through the end of December, this is caused by higher inflows to Grand Coulee Dam, rather than a change in operations at Grand Coulee Dam itself.

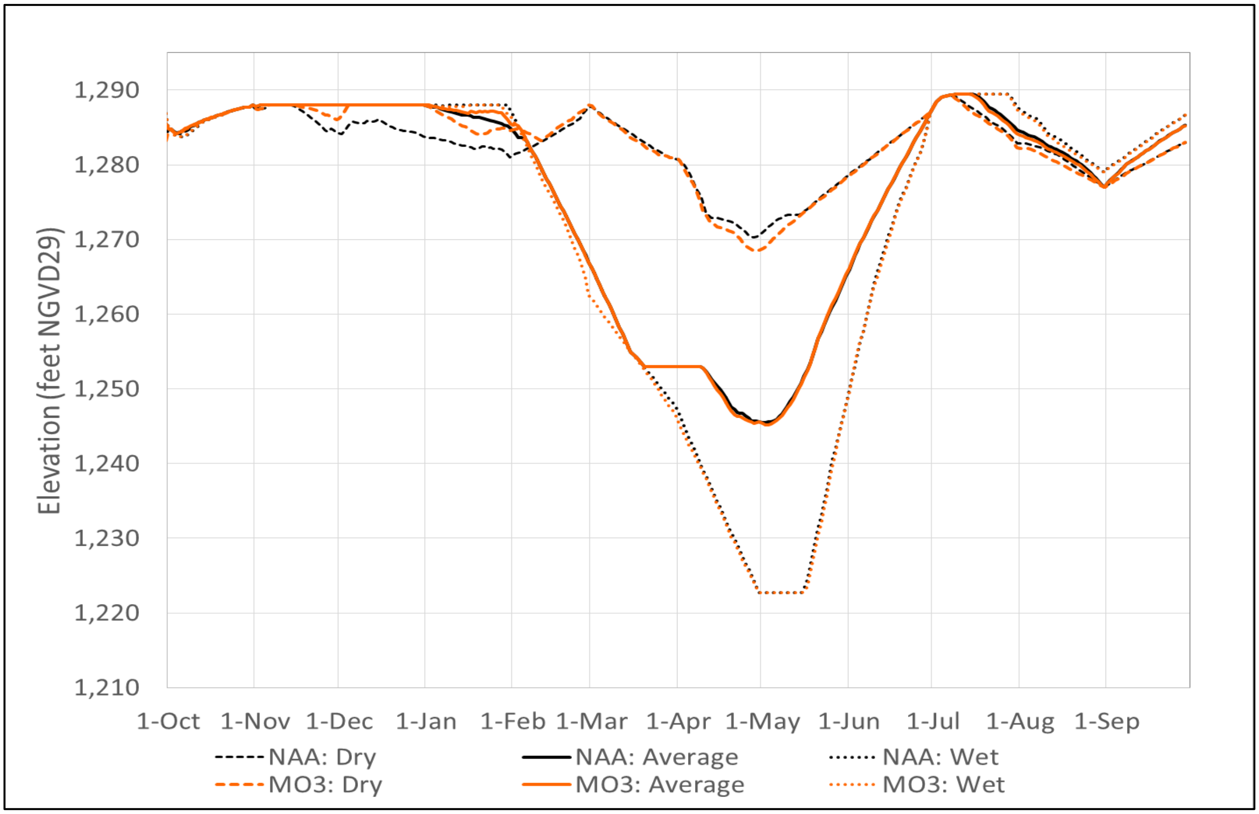

**Figure 3-72. Lake Roosevelt Water Year Type Hydrographs for Multiple Objective Alternative 3**

**Grand Coulee Dam Drum Gate Maintenance**

Drum gate maintenance at Grand Coulee Dam is planned to occur annually during March, April, and May, but is not conducted in all years. The reservoir must be at or below elevation 1,255 feet NGVD29 for 8 weeks to complete drum gate maintenance. Under MO3, the *Update System FRM Calculation*, and *Planned Draft Rate at Grand Coulee* measures would influence reservoir elevations during spring months.

The changes in elevations for MO3 that influence the decision to conduct drum gate maintenance would not change significantly relative to the No Action Alternative (April 30 FRM elevation targets and drum gate initiation methodology is discussed in more detail in Part 1 of Appendix B). The decision to conduct drum gate maintenance is based on the February water supply forecast and the resulting April 30 FRM elevation projection (April 30 FRM elevation target at or below 1,255 or 1,265 feet NGVD29 depending on how recently the maintenance has been conducted). This is not to say the spring elevations are the same for the two alternatives but rather there are a similar number of years that elevations would allow for drum gate maintenance. In both MO3 and the No Action Alternative, drum gate maintenance would be achievable in 65 percent of the years.

**Grand Coulee Dam Outflow**

Under MO3, the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Lake Roosevelt Additional Water Supply* measures would directly affect outflows from Grand Coulee Dam. In addition, the *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation* and *Hungry Horse Additional Water Supply* measures would affect inflows and outflows at Grand Coulee Dam. The outflows from Grand Coulee Dam would differ from the No Action Alternative depending on the time of year, as seen in the summary hydrograph, Figure 3-73.

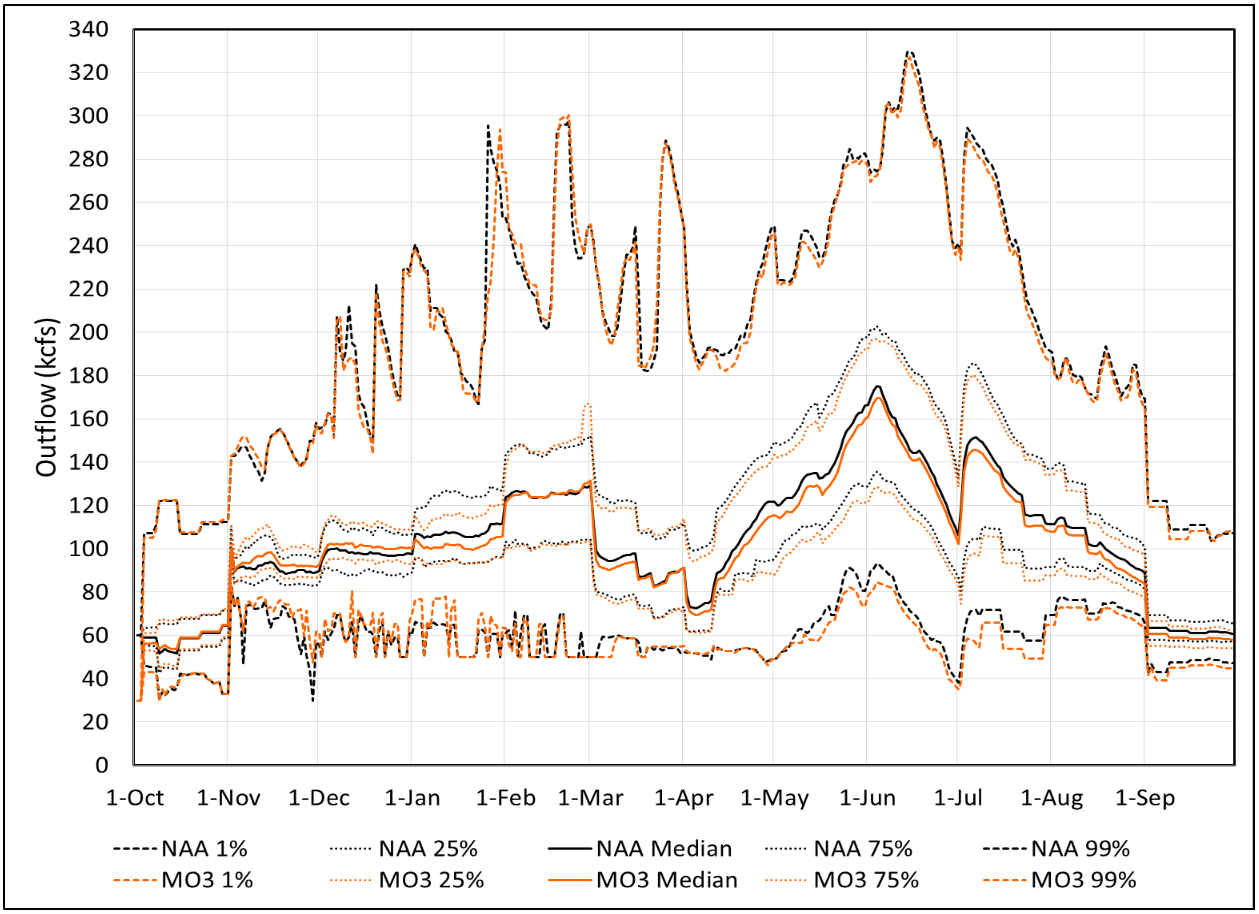

**Figure 3-73. Grand Coulee Dam Outflow Summary Hydrograph for Multiple Objective Alternative 3**

The change in average monthly outflow throughout the water year is presented in Table 3-35.

**Table 3-35. Grand Coulee Dam Monthly Average Outflow for Multiple Objective Alternative 3 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| NAA | Ave. mo. outflow (kcfs) | 1% | 94 | 130 | 174 | 190 | 213 | 186 | 191 | 231 | 275 | 247 | 175 | 111 |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO3 flows lower than the No Action Alternative flows; green shading denotes MO3 flows higher than the No Action Alternative flows.

Under MO3, the *Lake Roosevelt Additional Water Supply* measure calls for an increased volume of water to be pumped from Lake Roosevelt into Banks Lake, which would directly affect Grand Coulee Dam outflows. Because several other measures in MO3 would also affect Grand Coulee Dam's outflow, the effects of MO3 are described below, identifying the measure (or combination of measures) responsible for the change where possible.

- In November, the median value of the monthly average outflow would increase by 2.2 kcfs. This is due to the hydropower draft in the *December Libby Target Elevation* measure.
- In December, the median value of the monthly average outflow would increase by 3.7 kcfs. This is again attributable to the *December Libby Target Elevation* measure. However, for the highest flows (1 percent exceedance levels), the monthly average outflow would decrease.
- In January, the median value of the monthly average outflow would decrease by 5.4 kcfs. At other exceedance levels, there would be flow changes of greater magnitude, some higher than the No Action Alternative and some lower. The outflow decrease is primarily caused by reduced outflow from Libby Dam.
- In February, the median value of the monthly average outflow would be similar to the No Action Alternative (0.1 kcfs modeled increase). However, other exceedance levels would have changes of greater magnitude, some higher than the No Action Alternative and some lower.
- In March, the median value of the monthly average outflow would decrease by 2.3 kcfs due to outflow changes from Libby and Hungry Horse Dams and the additional water supply

from Lake Roosevelt. In March the measure *Lake Roosevelt Additional Water Supply* would reduce flows approximately 0.6 kcfs.

- In April the volume of water to be pumped from Lake Roosevelt into Banks Lake as a result of the *Lake Roosevelt Additional Water Supply* measure would increase. The April through September period would have the greatest total pumping volumes, as well as the greatest additional pumping volumes as called for in the *Lake Roosevelt Additional Water Supply* measure.
- In April, May, and June, the monthly average outflows would consistently be lower. At the median level, they would decrease by 4.8, 6.7, and 4.8 kcfs, respectively. These changes are largely due to the *Lake Roosevelt Additional Water Supply* measure and changes to inflows from projects upstream (Libby and Hungry Horse Dams), though other measures also have an influence. In April, May and June the measure *Lake Roosevelt Additional Water Supply* would reduce flows approximately 3.2, 3.2, and 3.0 kcfs respectively.
- In July, August, and September, monthly average outflows would also be consistently lower. At the median level, the monthly average outflow for July, August, and September would be reduced by 4.6, 3.9, and 3.2 kcfs, respectively. These changes are predominantly due to the *Lake Roosevelt Additional Water Supply* measure. The *Lake Roosevelt Additional Water Supply* measure would decrease flows by 4.2, 2.6, and 2.5 kcfs in July, August, and September respectively.
- The *Grand Coulee Maintenance Operations* measure would not impact reservoir elevations or total outflows, but would reduce the hydraulic capacity through the power plants, resulting in additional spill and an increase in TDG in some situations.

Finally, median hydrographs for Grand Coulee Dam outflow in dry, average, and wet years are shown in Figure 3-74. MO3 and the No Action Alternative are shown. The figure provides another way to picture the effects described above, this time categorized by water year type.

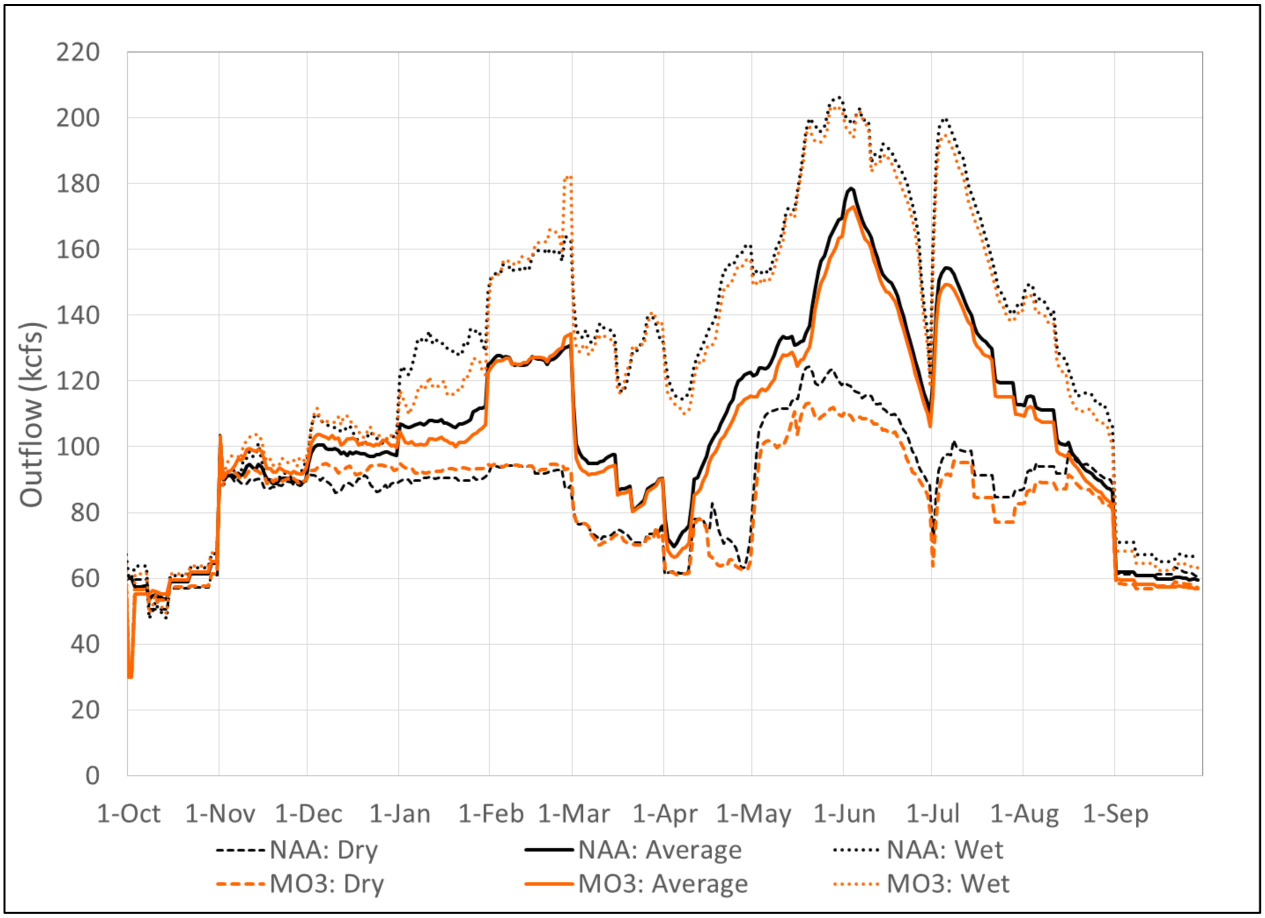

**Figure 3-74. Grand Coulee Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 3**

**Middle Columbia River below Grand Coulee Dam**

Under MO3, the pattern of flow changes in the middle Columbia River would be similar to those described for Grand Coulee Dam outflow, with the changes occurring for the same reasons as described for Grand Coulee Dam outflow. An additional measure, *Chief Joseph Dam Project Additional Water Supply*, calls for an increase in water diversion (at a maximum rate of 0.05 kcfs) from the Columbia River for the Chief Joseph Dam. The total flow impact from the *Chief Joseph Dam Project Additional Water Supply* measure is 9.6 kaf annually, which is significantly smaller than the impacts from the *Lake Roosevelt Additional Water Supply* measure that reduces flows an additional 1.1 Maf annually. For perspective, the flow change for the *Chief Joseph Dam Project Additional Water Supply* measure is two orders of magnitude smaller than that for the *Lake Roosevelt Additional Water Supply* measure. The reservoir elevation at Chief Joseph Dam would not change from the No Action Alternative.

Table 3-36 shows changes in the median values of monthly average flows at locations in the middle Columbia River.

**Table 3-36. Middle Columbia River Monthly Average Flows for Multiple Objective Alternative 3 (as change from No Action Alternative)**

| | Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO3 flows lower than the No Action Alternative flows; green shading denotes MO3 flows higher than the No Action Alternative flows.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Dworshak Dam

MO3 does not have any operational measures that would directly affect Dworshak Reservoir elevations or Dworshak Dam outflows. Given this, the effects would be the same as those for the No Action Alternative, though the *Ramping Rates for Safety* measure, which allows for less restrictive ramping rates, could result in greater hourly or daily outflow changes at Dworshak Dam, as well as the other CRS dams.

### Clearwater and Snake Rivers below Dworshak Dam

Under MO3, the *Breach Snake Embankments* measure calls for the breaching of the four lower Snake River dams by removing earthen embankments and adjacent structures. This measure would result in dramatic changes in hydraulic conditions (water level, depth, channel width, velocity, etc.) and seasonal water level dynamics in the lower Snake River from several miles above the confluence of the Snake with the Clearwater River near Lewiston, Idaho, to the location of Ice Harbor Dam. Changes to flow amounts would be minor since the four lower Snake River dams are run-of-river projects, not storage projects. Compared to the No Action Alternative where transitions to or from MOP operations occur in late March and early September, MO3 would result in monthly average flow changes below Ice Harbor Dam of -0.9 kcfs in the March and +1.3 kcfs in September. The latter can result in and up to 8 percent increase in average monthly September flow in low water years.

Also, changes in irrigation withdrawals were not included in the Reservoir Operations model but are discussed in Section 3.12, the Water Supply section of this EIS. It is expected that irrigation withdrawals from the lower Snake River reach could be decreased by over 200 KAF through the irrigation season, and this would translate to a small (less than 1 kcfs) but sometimes noticeable increase in total Snake River flows compared to the No Action Alternative from April 1 to October 15. The increase in Snake River flow below Ice Harbor would typically be less than 1 percent, but could be as large as 4 percent in late summer during dry years, and the flow change downstream in the Columbia would be negligible. These changes would be in addition to the reported changes described in Table 3-35.

The H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*) also contains greater detail on expected water conditions than the information presented here.

Figure 3-75 shows a comparison of water surface profiles for the lower Snake River reaches (from McNary Dam to beyond Lewiston, Idaho). The water surface profile for MO3 generally follows the slope of the riverbed, whereas the water surface profile for the No Action Alternative appears as a stair step, due to the presence of the dams and the reservoirs they impound. The *Breach Snake Embankments* measure would cause the depth of water in the river to be as much as 100 feet less at locations just upstream of the four lower Snake River dam sites. Seasonal fluctuations in water level would increase from less than 5 feet under the No Action Alternative to 10 to 15 feet (typical) under MO3.

Under MO3, changes in river width would also occur. The average decrease in width would be about 500 feet, but the change could be as much as a half mile in some locations. The decrease in width would generally be the most pronounced in locations closest to the dams, although this is not the case with Little Goose Reservoir, which has the widest section a few miles upstream from the dam, near RM 75.

Other changes in river hydraulics include dramatic increases in average and minimum hydraulic grade (slope) and increases in average and minimum velocity. Without the reservoirs, the water particle travel time through the reach could be reduced by an order of magnitude. These changes are described in greater detail in the H&H Appendix (Appendix B, Part 1, *H&H Data Analysis*). The River Mechanics section of this EIS (Section 3.3, *River Mechanics*) presents information on the changes in river hydraulics that would occur as a result of this measure, including sediment transport and channel morphology. Further details are also provided in the River Mechanics Appendix (Appendix C), which describes the channel conditions that would be expected several years following dam breach, after fluvial processes have had time to move accumulated sediment and allow for the river channel to reach a relatively stable, equilibrium state. Changes in hydrologic routing through the reach would be minor.

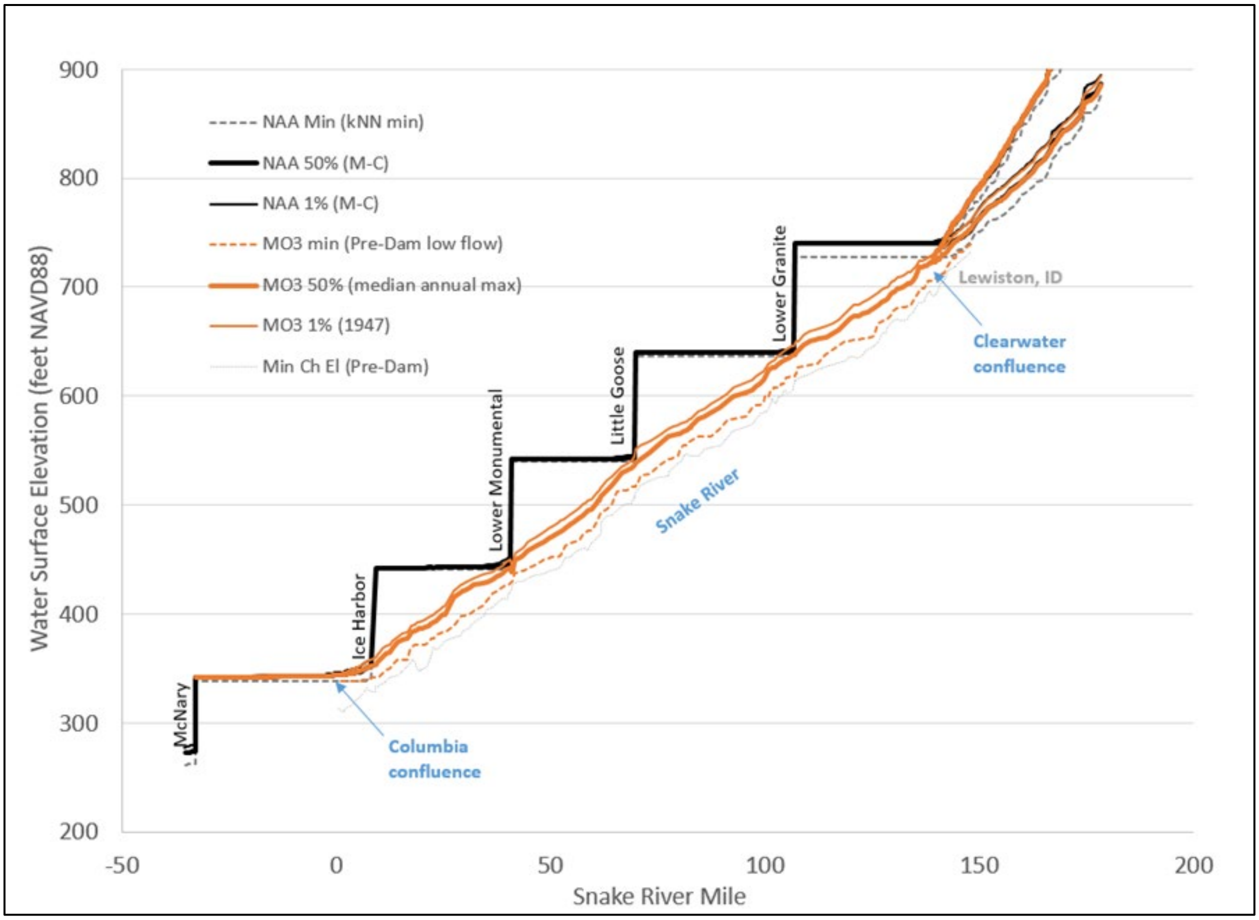

**Figure 3-75. Lower Snake River Water Surface Profiles for Multiple Objective Alternative 3**

## REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

### Lower Columbia River Reservoir Elevations

Under MO3, there would be no changes to the reservoir elevations at McNary Dam, The Dalles Dam, or Bonneville Dam. At John Day Dam, the *John Day Full Pool* measure calls for operating the reservoir in a range between 262.5 feet NGVD29 and 266.5 feet NGVD29 year round, except as needed for FRM. When operation is needed for FRM, the full operating range (257.0 to 268.0 feet NGVD29) may be used, as is the case for the No Action Alternative. The operating elevation range changes and changes in elevation maximum and minimum elevations as compared to No Action Alternative are described below:

- January 1 to March 14: Compared to the No Action Alternative (262.0 and 265.0 feet NGVD29), the minimum and maximum elevations are increased by 0.5 foot and 1.5 feet, respectively, increasing the overall range from 3.0 to 4.0 feet.
- March 15 to April 9 and October 1 to November 14: Compared to the No Action Alternative (262.5 and 265.0 feet NGVD29), the overall range and maximum elevation is increased by 1.5 feet.

- April 10 to September 30: Compared to the No Action Alternative (262.5 and 264.0 feet NGVD29), the overall range and maximum elevation is increased by 2.5 feet.
- November 15 to December 31: Compared to the No Action Alternative (262.0 and 266.5 feet NGVD29), the minimum elevation is decreased by 0.5 foot, as is the overall operating range.

The operating range for John Day Dam for Multi Objective Alternative 3 is shown in Figure 3-76. The No Action Alternative operating range is shown for comparison purposes.

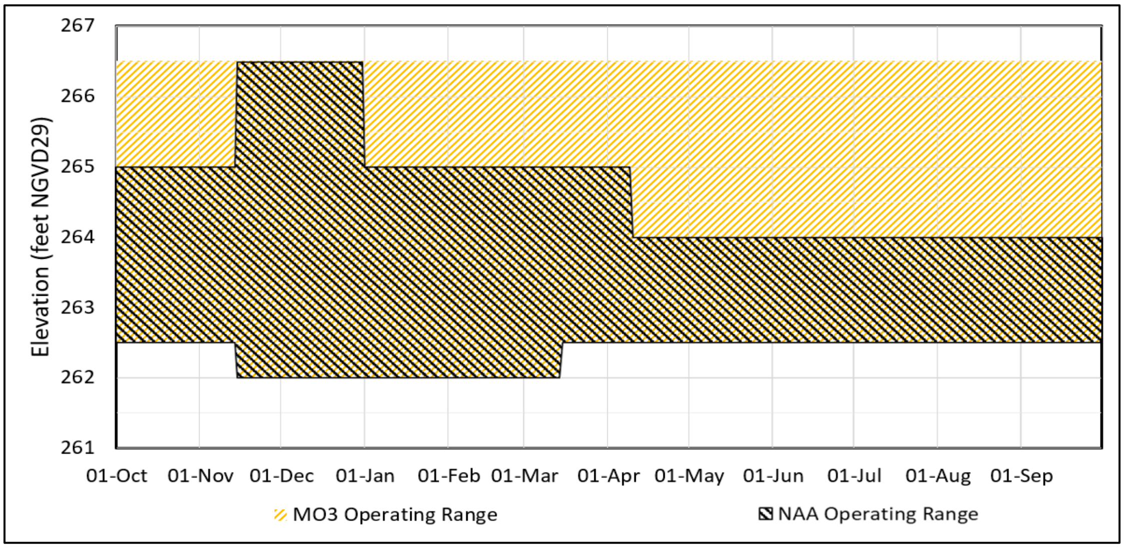

**Figure 3-76. John Day Dam Operating Range for Multiple Objective Alternative 3**

Note: John Day may be operated between 257 feet and 268 feet NGVD29 for FRM purposes. These limits are not shown on this figure in order to show greater detail in the vertical scale.

**Lower Columbia River Flows**

Under MO3, the *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *John Day Full Pool, Lake Roosevelt Additional Water Supply*, *Hungry Horse Additional Water Supply*, and *Chief Joseph Dam Project Additional Water Supply* measures would cause changes in flow patterns in the lower Columbia River.

At McNary Dam, the outflows under MO3 would differ from the No Action Alternative to various extents through the water year. The magnitude and timing of differences in flow are displayed in the summary hydrograph, Figure 3-77.

In addition to the daily outflow values depicted in Figure 3-77, the monthly average outflows from McNary Dam that would occur under MO3 were compared to those for the No Action Alternative, as shown in Table 3-37.

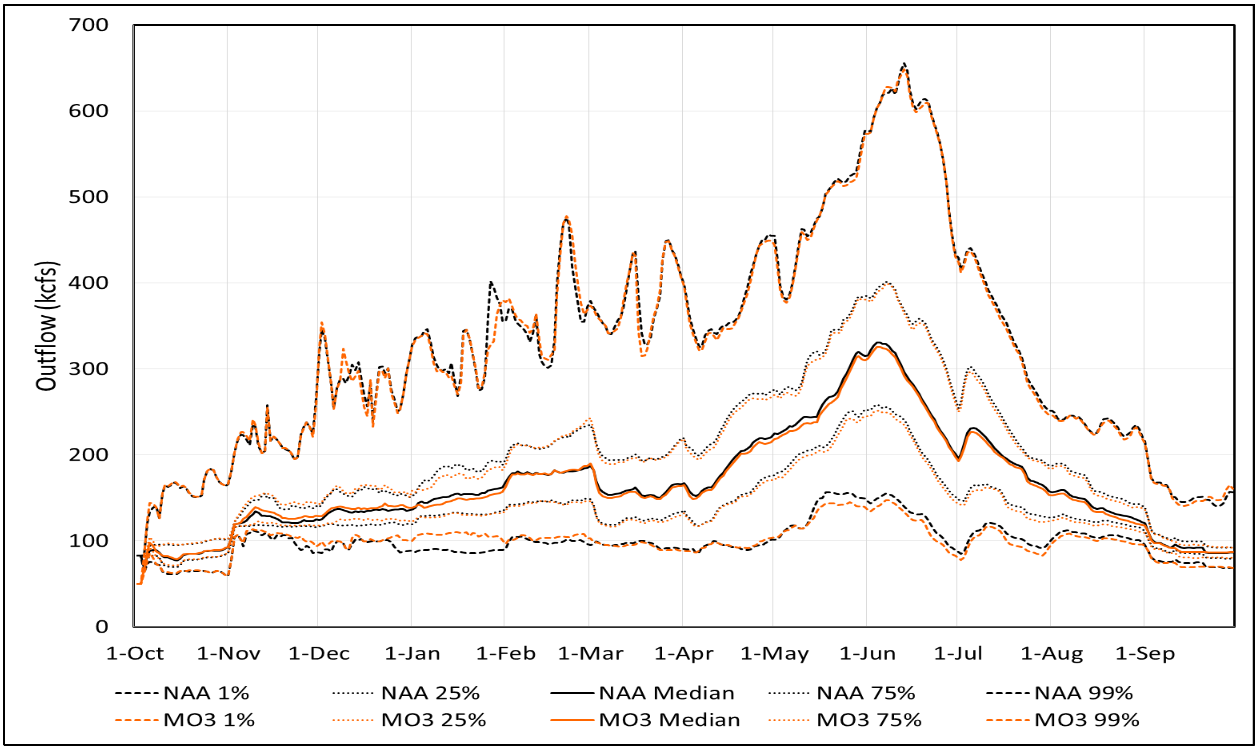

**Figure 3-77. McNary Dam Outflow Summary Hydrograph for Multiple Objective Alternative 3**

Conclusions from this comparison are as follows:

- In November and December, the median value of monthly average outflow would increase by 4.1 and 3.3 kcfs, respectively. There would be increases for most other exceedance values as well. The *December Libby Target Elevation* measure, which drafts Libby Dam to elevation 2,400 feet NGVD at the end of December for hydropower, is the main reason for these flow increases.
- In January, the median value of the monthly average outflow would decrease by 4.5 kcfs. The degree to which flows would increase or decrease in January varies depending on the flow exceedance level.
- In February, the median value of the monthly average outflow would increase by 0.7 kcfs. Again, the degree to which flows would increase or decrease depends on the flow exceedance level.
- From March through October, monthly average outflow would generally be less than the No Action Alternative at all flow levels.

Finally, median hydrographs for McNary Dam outflow in dry, average, and wet years are shown in Figure 3-78. MO3 and the No Action Alternative results are shown. The figure provides another way to picture the effects described above, this time categorized by water year type. For dry water years, it shows that flows in December and January would generally be higher, and flows from March through September would generally be lower.

Along the lower Columbia River, the median value of the average monthly flow for MO3 would be higher than the No Action Alternative in some months (for example, November and December), and lower in others (for example, January and March through September). The flow change patterns seen at the confluence of the Columbia and Snake Rivers continue downstream to other locations. This is seen in Table 3-38.

**Table 3-37. McNary Dam Monthly Average Outflow for Multiple Objective Alternative 3 (as change from No Action Alternative)**

**SUMMARY OF EFFECTS**

Under MO3, the largest changes in water levels occur at Libby, Grand Coulee, and the four lower Snake River dams. Lake Koocanusa water levels are substantially lower in most years from November through June, but can be higher in the drawdown period starting in January in larger forecast years, and reservoir levels are slightly higher in the later summer months. Lower Snake River dams are breached, and the four reservoirs in series are converted to a free-flowing river with water levels up to 80 feet lower and channel width up to 2,500 feet narrower. Smaller but notable water level changes occur at Hungry Horse Reservoir where additional water demands in the summer months result in slightly lower reservoir levels most of the year, and increased forebay operating flexibility at John Day Dam results in slightly higher typical and maximum water levels in April and May. Lake Roosevelt water levels are similar to the No Action Alternative in most years, and there are no changes at Dworshak Dam.

The largest impacts to river flow occur immediately below Libby and Grand Coulee Dams, and total flow changes are largest below Grand Coulee Dam. November and December releases from Libby Dam are much higher, otherwise flows are lower, particularly in January and May. Outflow from Grand Coulee is lower in the spring and summer months due to additional pumping to Banks Lake. Changes in Lake Roosevelt inflow, notably higher November and

December flows and lower January flows, stem from changes at Libby Dam and continue past Grand Coulee Dam downstream through the Columbia River. Changes in average monthly flow through the lower Columbia River are within 3 percent of the Not Action Alternative for all months for most years.

### *3.2.4.7 Multiple Objective Alternative 4*

As the effects of MO4 are presented, they will be displayed along with the No Action Alternative to illuminate the timing and magnitude of differences in water conditions between it and the No Action Alternative. Similar to previous sections, the operational measure (or measures) from MO4 which would result in changes from the No Action Alternative are identified to the extent possible.

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Lake Koocanusa (Libby Dam Reservoir) Elevation**

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, and *Winter Stage for Riparian* measures would have a direct effect on Libby Dam operations.

Reservoir water levels in Lake Koocanusa would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-79.

The water year would begin with the reservoir levels for MO4 being different (generally lower, but sometimes higher) than those for the No Action Alternative. This is because the operations that would occur from June through September under MO4 would leave the reservoir at a different elevation on September 30 than under the No Action Alternative, and the condition would carry over to the following water year. The *McNary Flow Target* measure, which aims to support higher flows at McNary Dam by releasing water stored at Libby Dam (as well as Hungry Horse, Albeni Falls, and Grand Coulee Dams) would release up to an additional 534 kaf of water from Libby Dam between May and the end of September in the years when it is triggered. The *Sliding Scale at Libby and Hungry Horse* measure, which calls for a sliding scale end-of-September target reservoir elevation dependent on the Libby Dam water supply forecast, targets a higher elevation than the No Action Alternative in the wettest 25 percent of years. The combined effect of the *McNary Flow Target* and *Sliding Scale at Libby and Hungry Horse* measures, then, would result in a wider range of reservoir elevations on October 1 than for the No Action Alternative. This is seen in Figure 3-79 with the range between the 99 percent exceedance line and the 1 percent exceedance line spanning from 2,425 to 2,454 feet NGVD29.

MO4 would have the same end-of-November target reservoir elevation as the No Action Alternative. Over the course of December, the reservoir elevation under MO4 would differ from the No Action Alternative due to the *December Libby Target Elevation* measure, which calls for an end-of-December target elevation of 2,420 feet NGVD29 in all years. In most years, this would make the reservoir elevation on December 31 higher than the No Action Alternative;

however, in about the driest 30 percent of forecast years (those forecasted to have an April to August runoff volume of 5.67 Maf or less), the reservoir elevation on December 31 would be lower than for the No Action Alternative.

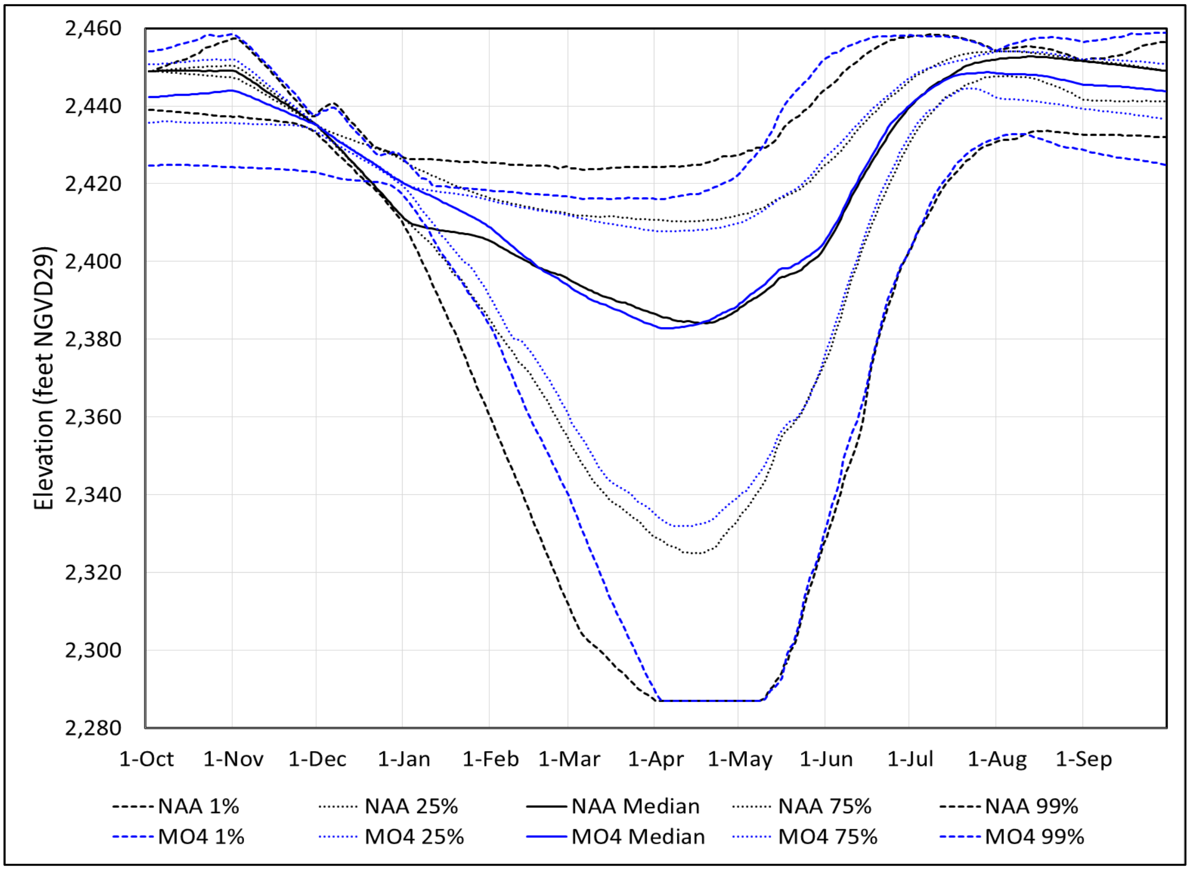

**Figure 3-79. Lake Koocanusa Summary Hydrograph for Multiple Objective Alternative 4**

From December 31 through mid-February, reservoir levels would generally be higher under MO4 than they would be for the No Action Alternative, though for the driest forecast years, the reservoir would be lower.

The *Modified Draft at Libby* measure would begin influencing reservoir elevations after December 31, and its effects are best understood by looking at the spring, when the lowest reservoir elevation typically occurs. While the *Sliding Scale at Libby and Hungry Horse* measure would generally delay the lowering of the reservoir, it is the *Modified Draft at Libby* measure that would cause the spring reservoir elevation to be lower than the No Action Alternative when the seasonal water supply forecast is less than 6.9 Maf at Libby Dam. This is not the case for all years, though, as demonstrated by the 75 percent exceedance lines for MO4 and the No Action Alternative. There, the case is the opposite; the reservoir elevation under MO4 would be higher than that for the No Action Alternative through about the first half of spring.

In years when the *Winter Stage for Riparian* measure would be in effect, it would have a direct effect on Libby Dam operations at various times between the months of November and March.

The modified releases would typically only occur for short durations of time while attempting to limit water levels at Bonners Ferry. In these cases, there would be little noticeable effect on the reservoir elevation at Libby Dam. In years when local flows are high, operations for the *Winter Stage for Riparian* measure would last longer and result in slightly higher elevations in November and December.

The *Modified Draft at Libby* measure would result in a general increased likelihood of reservoir refill in all water year types through June. In July, the refilling of the reservoir at Libby Dam would be affected by the *McNary Flow Target* measure in the drier-than-normal years when the *McNary Flow Target* measure is triggered, resulting in generally lower reservoir elevations in July than for the No Action Alternative. In the years when the *McNary Flow Target* measure would not be triggered, refilling of the reservoir would generally continue into July, similar to the No Action Alternative. Overall, there would be a 36 percent chance of the reservoir reaching elevation 2,454 feet NGVD29 or higher by July 31 under MO4, as compared to a 39 percent chance under the No Action Alternative. (The reservoir elevation of 2,454 feet NGVD is often used when discussing reservoir refill, as it is within 5 feet of the full pool elevation of 2,459 feet NGVD29.)

Reservoir water levels in Lake Koocanusa under MO4 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-80.

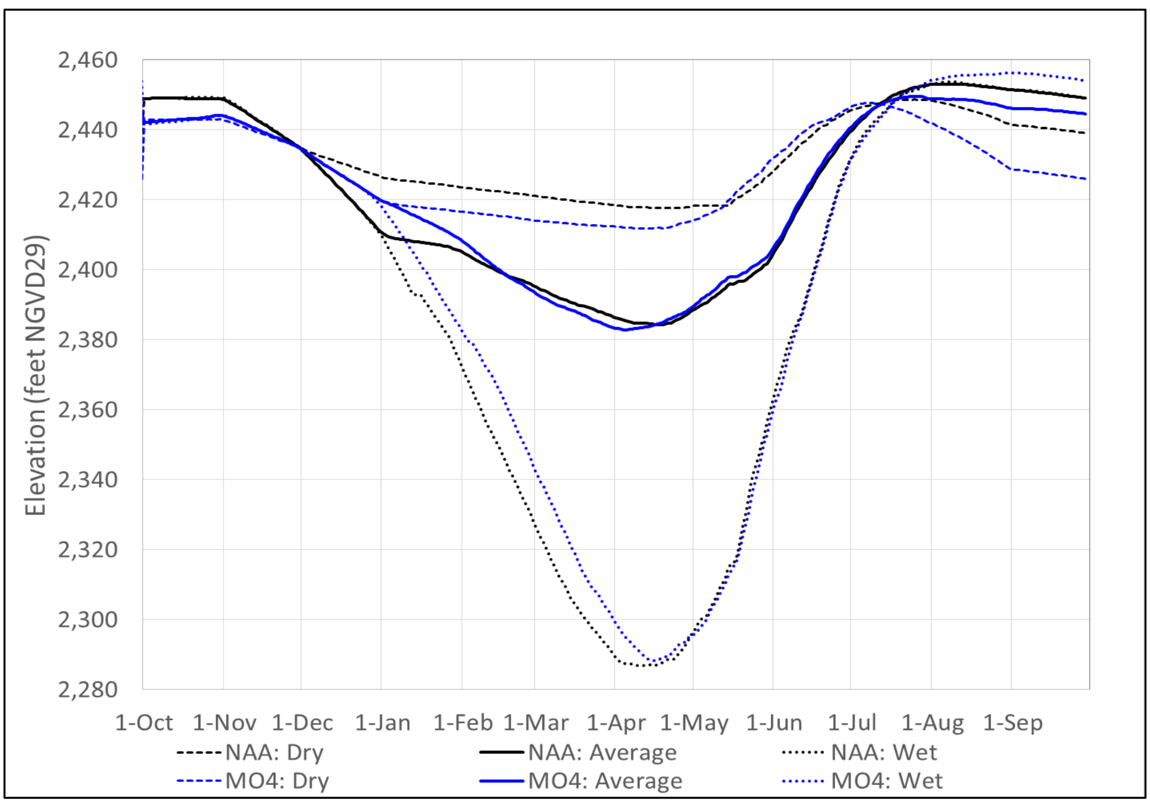

**Figure 3-80. Lake Koocanusa Water Year Type Hydrographs for Multiple Objective Alternative 4**

Finally, the three panels in Figure 3-81 show monthly elevation duration curves for July, August, and September, respectively. The curve for MO4 is plotted along with the curve for the No Action Alternative in each month. In July, reservoir elevations under MO4 would tend to be lower than the No Action Alternative by a slight amount. (It would be above elevation 2,446.5 feet NGVD29 50 percent of the time for MO4, whereas it would be above elevation 2,447.9 NGVD29 50 percent of the time for the No Action Alternative.) In August and September, reservoir elevations would usually be lower under MO4 than with the No Action Alternative due to the *McNary Flow Target* measure. However, about 30 percent of the time, it would be higher in those months under MO4, due to the absence of the *McNary Flow Target* measure being triggered while the *Sliding Scale at Libby and Hungry Horse* measure would continue to be in effect with an end-of-September target elevation.

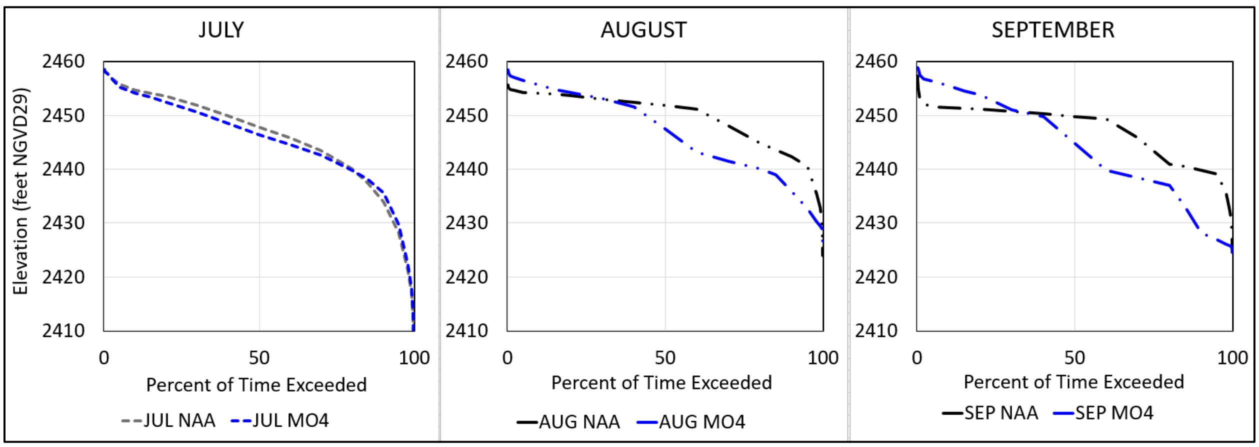

**Figure 3-81. Lake Koocanusa Summer Elevations for Multiple Objective Alternative 4**

### Libby Dam Outflow

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, and the *Winter Stage for Riparian* measures would have a direct effect on Libby Dam outflows. The outflows would differ from the No Action Alternative in a variety of ways throughout the year. Figure 3-82 shows median hydrographs for Libby Dam outflow in dry, average, and wet years.

The change in average monthly outflow throughout the water year is presented in Table 3-39.

Average outflow from Libby Dam under MO4 would differ from the No Action Alternative:

- In December, the median value of the monthly average outflow would decrease by 4.7 kcfs due to the *December Libby Target Elevation* measure. The flows at the 25 percent and 1 percent exceedance levels (higher flows) would also decrease, while the flows at the 75 percent exceedance level would increase.
- In January, February and March the median value of the monthly average outflow would increase by 1.6, 3.3, and 1.6 kcfs, respectively. These outflow increases are caused by the reservoir being lowered at a faster rate under MO4 than the No Action Alternative for many

years, caused by the *December Libby Target Elevation* measure as well as the *Modified Draft at Libby* measure.

- In April and May, the median value of the monthly average outflow would decrease by 1.4 and 0.8 kcfs, respectively. Both of these reductions are related to the VarQ update in the *Modified Draft at Libby* measure that would account for future volume releases and refill the reservoir more aggressively.
- In June and July, the overall median value of the monthly average outflow would increase by 0.6 and 2.9 kcfs, respectively. The increase in outflows occurs during dry and medium years due primarily to the *McNary Flow Target* measure. The increasing shape of July outflow stems from the HEC-ResSim model logic that adjusts Libby Reservoir draft targets to meet the McNary Dam flow targets. If this measure was implemented, reservoir regulators would strive to create smoother outflows in July and August by making the rise less pronounced by spreading it out over a longer time.
- In August median value of the monthly average outflow would increase by 0.2 kcfs, and in September it would decrease by 0.1 kcfs.

### Kootenai River below Libby Dam

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby, December Libby Target Elevation*, and *Winter Stage for Riparian* measures would affect flows at Bonners Ferry. In general, the flows would differ from the No Action Alternative in much the same way as at Libby Dam, and for the same reasons. The change in average monthly flow at Bonners Ferry throughout the water year is presented in Table 3-40.

The *Winter Stage for Riparian* measure in MO4 would change outflows from Libby Dam in a manner designed to aid survival of riparian vegetation along the Kootenai River. The measure would specifically try to limit river stages at Bonners Ferry to elevation 1,753 feet NGVD29 or below, between the months of November and March in certain years. The stage may exceed 1,753 feet NGVD29 in years where the Libby Dam water supply forecast exceeds 6.9 Maf or local flows downstream of the dam cause the stage to exceed 1,753 feet NGVD29 while Libby Dam has reduced outflows to only 9 kcfs. Table 3-41 presents the change in median monthly river stage at various locations along an approximately 100-mile-long stretch of the Kootenai River, from RM 202 down to RM 103 at the U.S.-Canada border. The results presented are not solely the effect of the *Winter Stage for Riparian* measure. Rather, they represent the combined effect of five measures: the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft Rate at Libby*, *December Libby Target Elevation*, and *Winter Stage for Riparian* measures.

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows lower than the No Action Alternative flows; green shading denotes MO4 flows higher than the No Action Alternative flows.

**Table 3-41. Kootenai River stage for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | Changes in Median Monthly River Stage (feet) | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Kootenai River Location | Oct | Nov | Dec | Jan | Feb | Mar | Apr | May | Jun | Jul | Aug | Sep |
| RM 202 | 0.0 | -1.2 | -1.4 | 0.4 | 1.3 | 1.1 | -0.3 | -0.8 | 0.3 | 0.8 | 0.1 | 0.0 |
| RM 169 | 0.0 | -1.1 | -1.5 | 0.3 | 1.1 | 0.7 | -0.2 | -0.9 | 0.3 | 0.9 | 0.1 | 0.0 |
| RM 150 (Bonners Ferry) | 0.0 | -0.9 | -1.3 | 0.4 | 1.2 | 0.8 | -0.3 | -1.0 | 0.0 | 1.3 | 0.1 | 0.0 |
| RM 140 | 0.0 | -0.6 | -1.0 | 0.3 | 0.8 | 0.6 | -0.3 | -1.0 | -0.1 | 1.2 | 0.1 | 0.0 |
| RM 103 (US-Can Border) | 0.0 | -0.3 | -0.4 | 0.1 | 0.2 | 0.3 | -0.1 | -0.6 | -0.1 | 0.7 | 0.0 | 0.0 |

Note: Orange shading denotes MO4 stages lower than the No Action Alternative stages; green shading denotes MO4 stages higher than the No Action Alternative stages.

The decrease in median monthly outflow from Libby Dam in November and December translate to decreases in water levels of just over a foot in the free-flowing reach below Libby Dam. At Bonners Ferry, the decreases in median average monthly outflow for November and December are 0.9 foot and 1.3 feet. Below Bonners Ferry, the decrease in stage is smaller but is still a few tenths of a foot at RM 103 near the U.S.-Canada border.

While the above table presents general information on when river stages would tend to be higher or lower throughout the year, it does not show the extent to which river stages would be above elevation 1,753 feet NGVD29 from November through March. That information is presented in Table 3-42.

**Table 3-42. Percentage of Days Kootenai River Stage Would be Above 1,753 feet NGVD29 at the Bonners Ferry Gage**

| | November | December | January | February | March |
|---|---|---|---|---|---|
| NAA | 10.0% | 12.8% | 20.7% | 17.9% | 5.4% |
| MO4 | 9.9% | 4.4% | 14.9% | 20.5% | 8.0% |
| Change | -0.1% | -8.4% | -5.8% | 2.6% | 2.6% |

Note: Results reflect modeling of all years, not just those when the *Winter Stage for Riparian* measure would be in effect.

Under MO4, the months of December and January would have fewer days exceeding elevation 1,753 feet NGVD29, while February and March would have more days exceeding that stage. Considering the entire 5-month period from November through March, there would be an overall decrease in days where the river stage would be above elevation 1,753 feet NGVD29. Further discussion of the effects from this measure are contained in Section 3.6.3, which covers environmental consequences to vegetation, wetland, and wildlife resources. It is worth noting that the *Winter Stage for Riparian* measure would not be in effect for years when the water supply forecast at Libby Dam is greater than 6.9 Maf.

**Hungry Horse Reservoir Elevation**

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would have a direct effect on Hungry Horse Dam operations.

Reservoir water levels would differ from the No Action Alternative, as shown in Figure 3-83.

The water year would begin with the reservoir levels for MO4 being lower than those for the No Action Alternative. This is because the operations associated with the *McNary Flow Target* and *Hungry Horse Additional Water Supply* measures would leave the reservoir at a lower elevation on September 30 than under the No Action Alternative, and the condition would carry over to the following water year.

The *McNary Flow Target* measure would release up to 232 kaf of water from Hungry Horse Dam in the years when it is triggered, the *Hungry Horse Additional Water Supply* measure would draft up to 90 kaf of stored water, and the *Sliding Scale at Libby and Hungry Horse* measure would generally tend to lessen the summer draft. The *Sliding Scale at Libby and Hungry Horse* measure results in reducing the draft requirements in some years, by setting a higher elevation target for summer flow augmentation than the No Action Alternative. However, its combination with the other measures would result in lower summer elevations. The overall effect, then, would be a lower reservoir elevation on October 1 than for the No Action Alternative. This is seen in Figure 3-83 with the range between the 99 percent exceedance line and the 1 percent exceedance line spanning from 3,525 feet NGVD29 to 3,546 feet NGVD29.

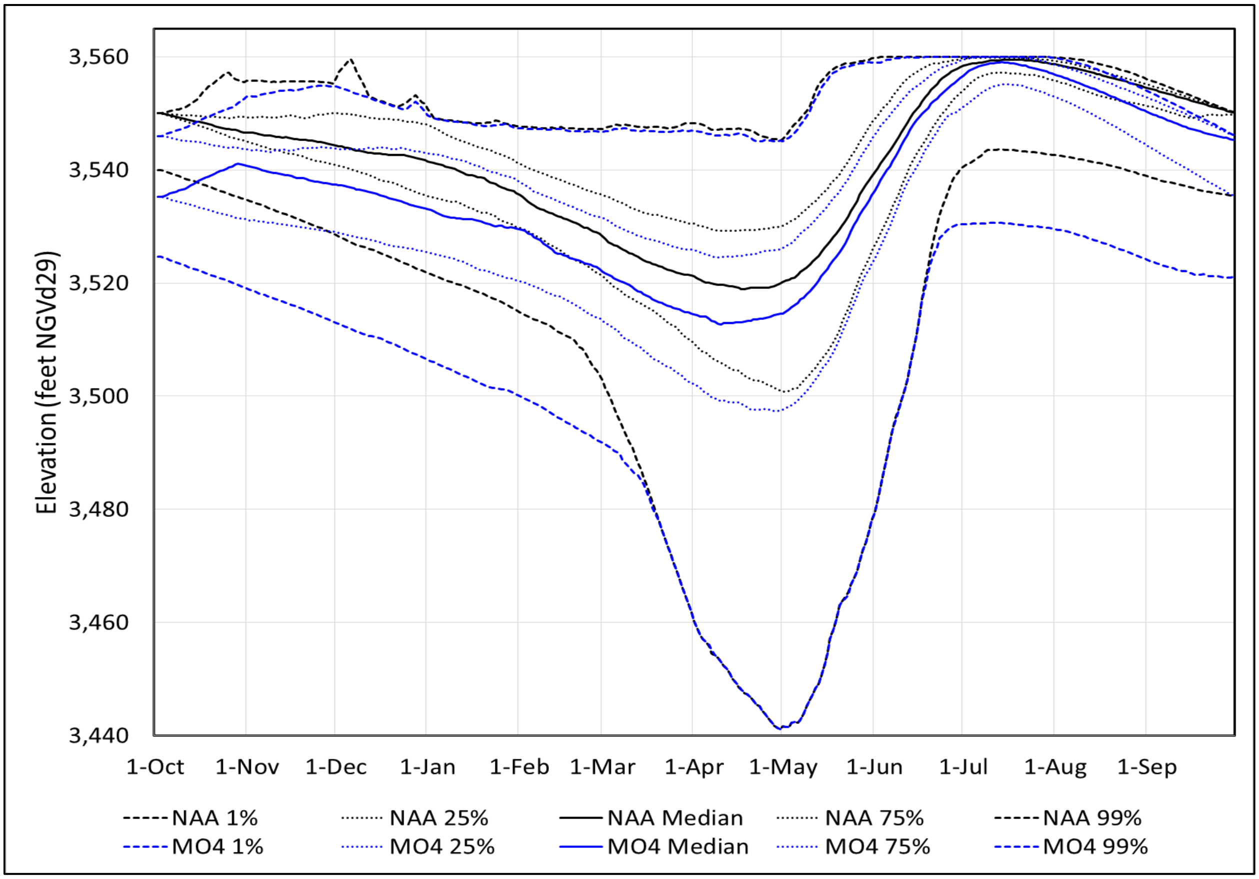

**Figure 3-83. Hungry Horse Reservoir Summary Hydrograph for Multiple Objective Alternative 4**

Reservoir elevations under MO4 would be lower than for the No Action Alternative. The greatest difference would occur in the months of September through April (about 5 to 9 feet difference) and the least difference would occur in May through August (about 2 to 4 feet difference). The most pronounced differences in reservoir elevation between MO4 and the No Action Alternative would occur when one dry water year is followed by another dry water year. In these instances, reservoir levels under MO4 could be more than 15 feet lower than for the No Action Alternative.

Water levels at Hungry Horse Reservoir under MO4 would differ from the No Action Alternative to varying extents, depending on the water year type. Median hydrographs of the reservoir level for dry, average, and wet years are shown in Figure 3-84.

Finally, the three panels in Figure 3-85 show Hungry Horse Reservoir elevation duration curves for the months of July, August, and September, respectively. While other months also have differences, these three are shown because of interest in summer reservoir elevations, and due to carryover impacts on winter elevation and spring flows. In general, the reservoir level in the summer months would be lower for MO4 than for the No Action Alternative. For instance, the daily reservoir elevation in September would be above elevation 3,550 feet NGVD29 only about

20 percent of the time under MO4, whereas it would be above that elevation about 70 percent of the time under the No Action Alternative.

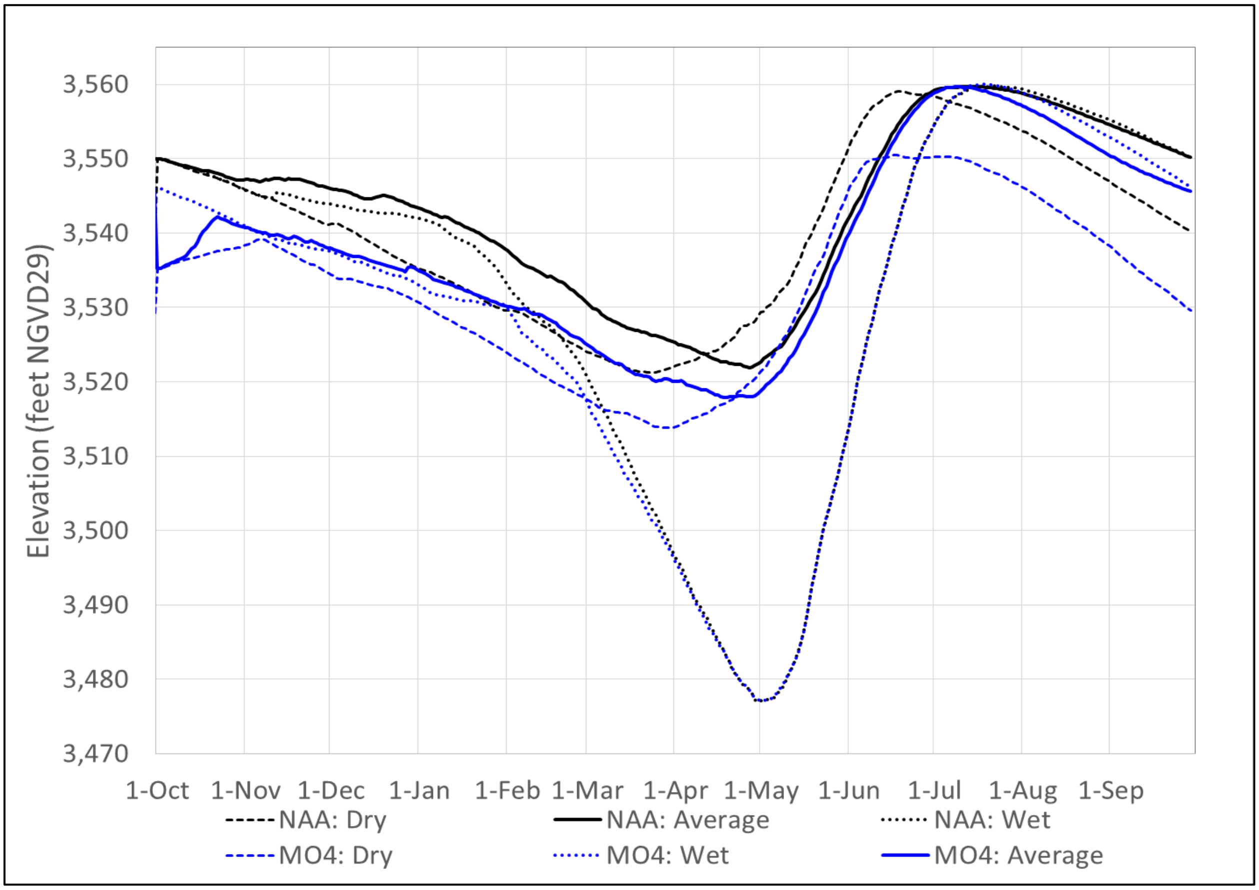

**Figure 3-84. Hungry Horse Reservoir Water Year Type Hydrographs for Multiple Objective Alternative 4**

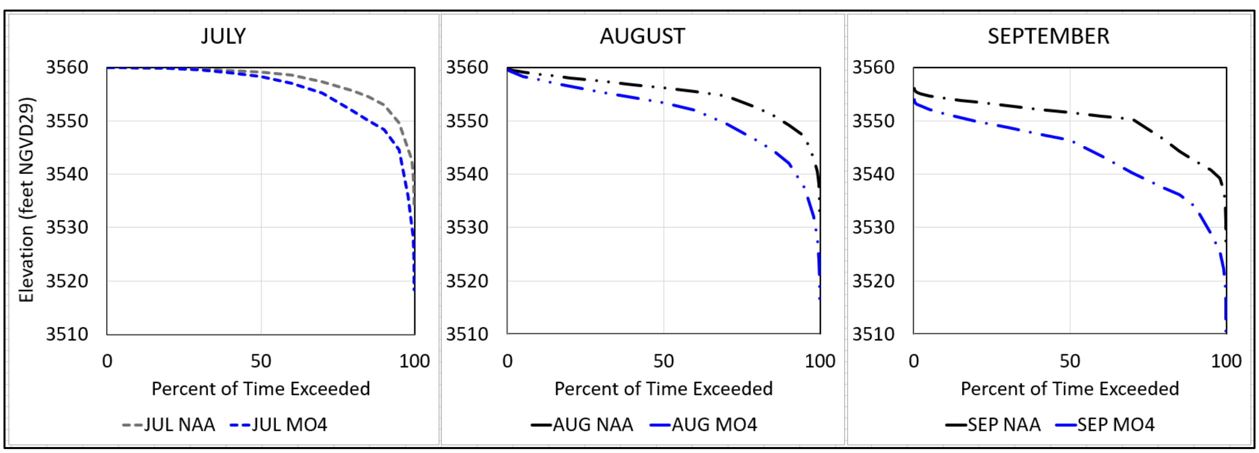

**Figure 3-85. Hungry Horse Reservoir Summer Elevations for Multiple Objective Alternative 4**

**Hungry Horse Dam Outflow**

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would have a direct effect on Hungry Horse Dam outflows. The outflows would differ from the No Action Alternative depending on the time of year. Figure 3-86 shows median hydrographs for Hungry Horse Dam outflow in dry, average, and wet years.

The change in average monthly outflow from Hungry Horse Dam throughout the water year is presented in Table 3-43.

Average outflow from Hungry Horse Dam would differ from the No Action Alternative:

- In July, August, and September the median value of the monthly average outflow would increase by 0.4, 1.0, and 1.0 kcfs, respectively, as compared to the No Action Alternative. The measures driving these changes are the *McNary Flow Target* and *Hungry Horse Additional Water Supply* measures. While the *Sliding Scale at Libby and Hungry Horse* measure would have a minor influence on flows in August and September (in isolation, it would tend to slightly reduce outflows), the overall effect of MO4 is to increase outflows in the summer. (The table above shows August and September flows 23 percent to 37 percent greater than the No Action Alternative.)
- After September and through the spring, reservoir outflows would generally be lower than for the No Action Alternative. This is because the reservoir would be in a deeply drafted state at the end of September. Outflows would either be supporting minimum flows in the Flathead River system (the same being true of the No Action Alternative), or they would be reduced in an attempt to fill back to normal winter elevations when minimum flows are already being met. The decrease in the median monthly average outflow would range from 0.1 kcfs to 0.8 kcfs during the October through April timeframe.
- May and June would continue to show a reduction in outflow. The median value of the monthly average outflow would decrease by 0.3 and 0.2 kcfs, respectively.

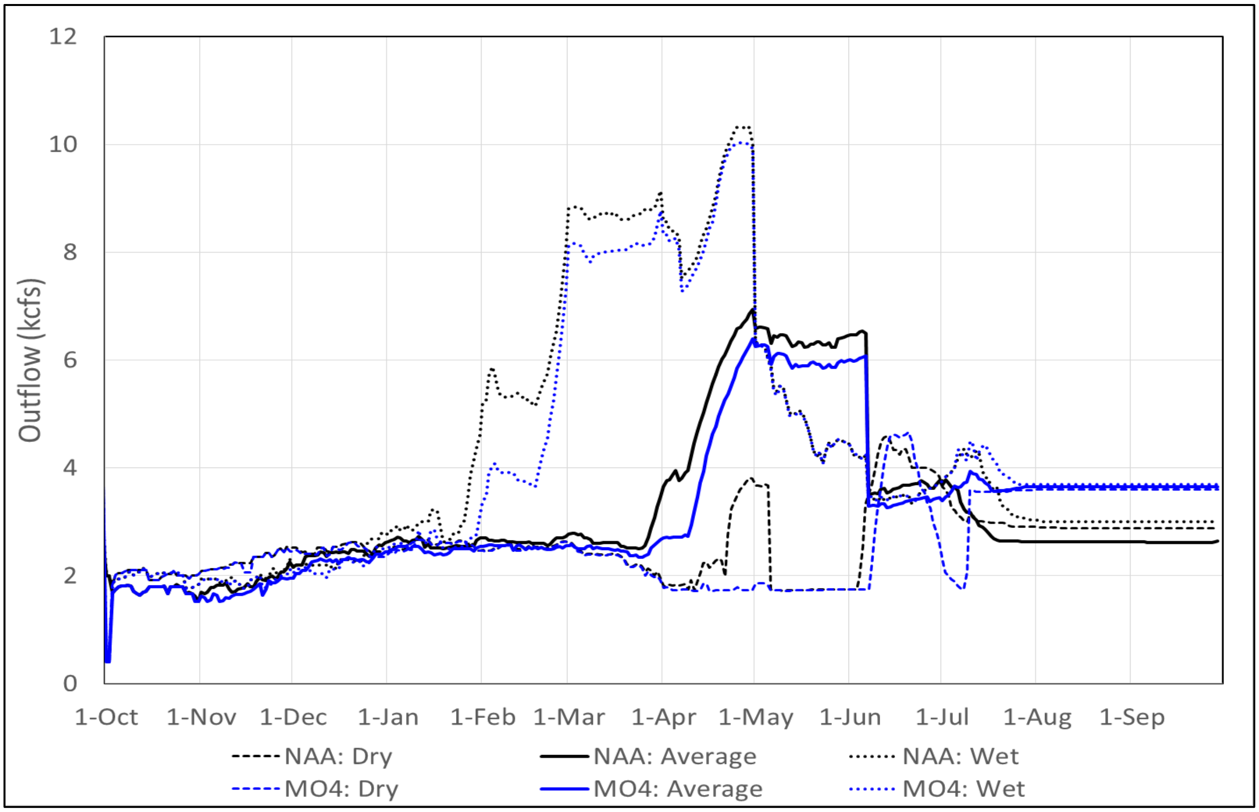

**Figure 3-86. Hungry Horse Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 4**

**Table 3-43. Hungry Horse Dam Monthly Average Outflow for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows lower than the No Action Alternative flows; green shading denotes MO4 flows higher than the No Action Alternative flows.

### Columbia Falls Flow

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, and *Hungry Horse Additional Water Supply* measures would affect flows at Columbia Falls. Compared to the No Action Alternative, there would be increased flow in July, August, and September in virtually all years, while the other months of the year would generally have flows less than those under the No Action Alternative, while still meeting minimum flow requirements. The change in average monthly flow at Columbia Falls throughout the water year, as compared to the No Action Alternative, is presented in Table 3-44.

**Table 3-44. Columbia Falls Monthly Average Flow for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

| | | 99% | -3% | 0% | 0% | 0% | 0% | 0% | -8% | -2% | -1% | 7% | 13% | 14% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows lower than the No Action Alternative flows; green shading denotes MO4 flows higher than the No Action Alternative flows.

### Lake Pend Oreille Elevation

Under MO4, the *McNary Flow Target* measure would have a direct effect on the level of Lake Pend Oreille. Lake levels would differ from the No Action Alternative during the months of May through September in years with drier-than-normal conditions. This is shown in Figure 3-87.

The *McNary Flow Target* measure, which aims to support higher flows at McNary Dam by releasing water stored at Albeni Falls Dam (as well as Libby, Hungry Horse, and Grand Coulee Dams) would release up to 234 kaf of water from Lake Pend Oreille in years when the measure is triggered. A release of 234 kaf corresponds to a reduction in water level at Lake Pend Oreille of approximately 2.6 feet below the typical summer elevation. In the years when the *McNary Flow Target* measure is not triggered, there would not be any noticeable difference in the level of Lake Pend Oreille as compared to the No Action Alternative.

The lower lake levels that would result from the *McNary Flow Target* measure are reflected in the 99 percent and 75 percent exceedance lines for MO4 beginning in May (99 percent exceedance level) and beginning in June (75 percent exceedance level).

Figure 3-88 demonstrates the timing and magnitude of how the level of Lake Pend Oreille would change under MO4. The figure shows median hydrographs for the lake level in dry, average, and wet years. As expected, the summer lake levels in dry years would be lower than they would be for the No Action Alternative.

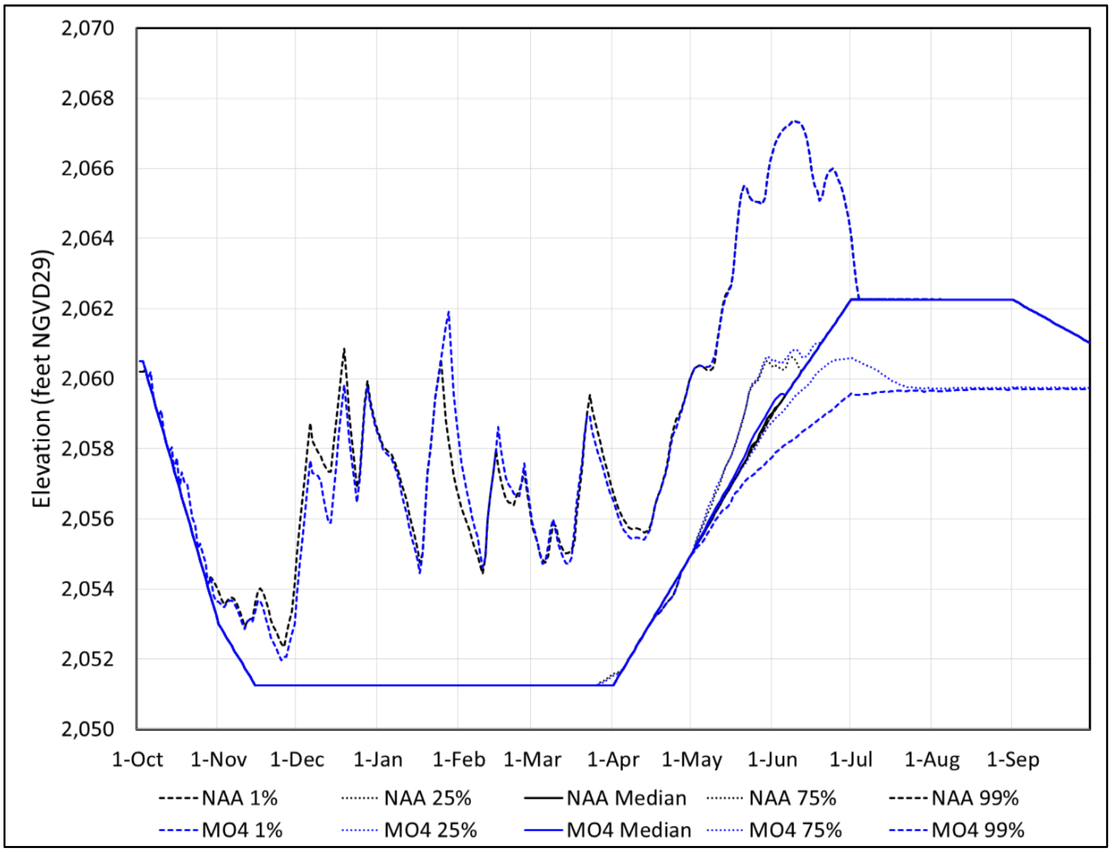

**Figure 3-87. Lake Pend Oreille Summary Hydrograph for Multiple Objective Alternative 4**

Finally, elevation duration curves are useful for understanding how lake levels under MO4 would differ from the No Action Alternative. The four panels in Figure 3-89 show monthly elevation duration curves for June, July, August, and September, respectively. Looking at the July and August panels, it is seen that under MO4, the lake level would be lower than the No Action Alternative about half of the time, when the *McNary Flow Target* measure is triggered. The expectation for summer lake levels to be lower than the No Action Alternative about half the time, is an important point that is not otherwise seen in either the summary hydrograph (Figure 3-87) or the median hydrographs (Figure 3-88) for dry/average/wet years.

2957 

2958 **Figure 3-88. Lake Pend Oreille Water Year Type Hydrographs for Multiple Objective**
2959 **Alternative 4**

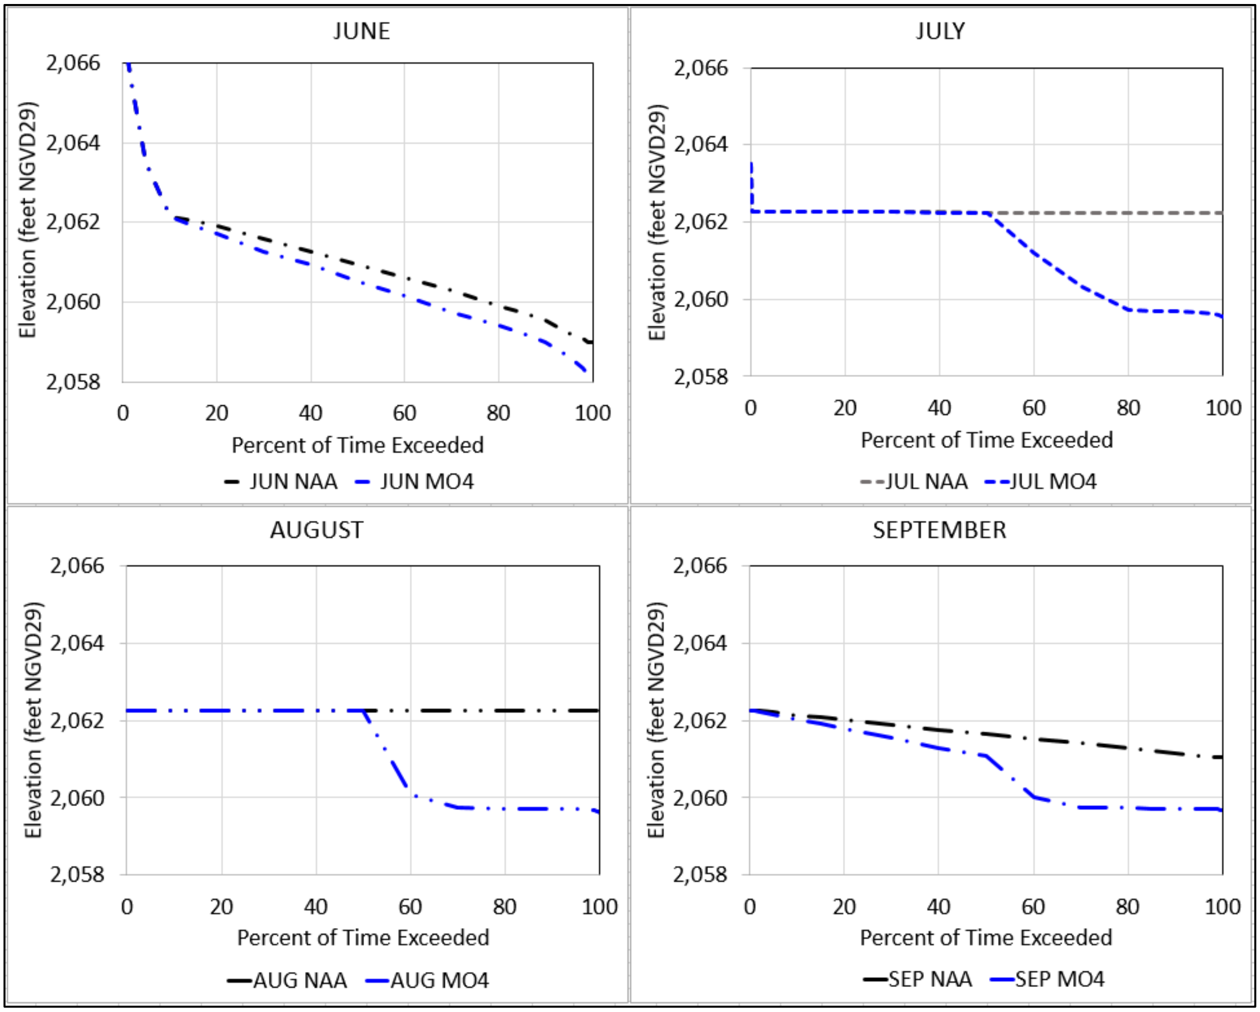

**Figure 3-89. Lake Pend Oreille Summer Elevations for Multiple Objective Alternative 4**

Note: The typical summer elevation range for Lake Pend Oreille in the No Action Alternative is 2,062.0 to 2,062.5 feet NVGD29. It is represented as 2,062.25 feet NGVD29 in the HEC-ResSim model, so appears as 2,062.25 feet NGVD29 in the panels above.

### Albeni Falls Outflow

Under MO4, the *McNary Flow Target* measure would directly affect Albeni Falls Dam outflow. An indirect influence would come from the *Sliding Scale at Libby and Hungry Horse* and the *Hungry Horse Additional Water Supply* measures. The outflows would differ from the No Action Alternative as seen in Figure 3-90.

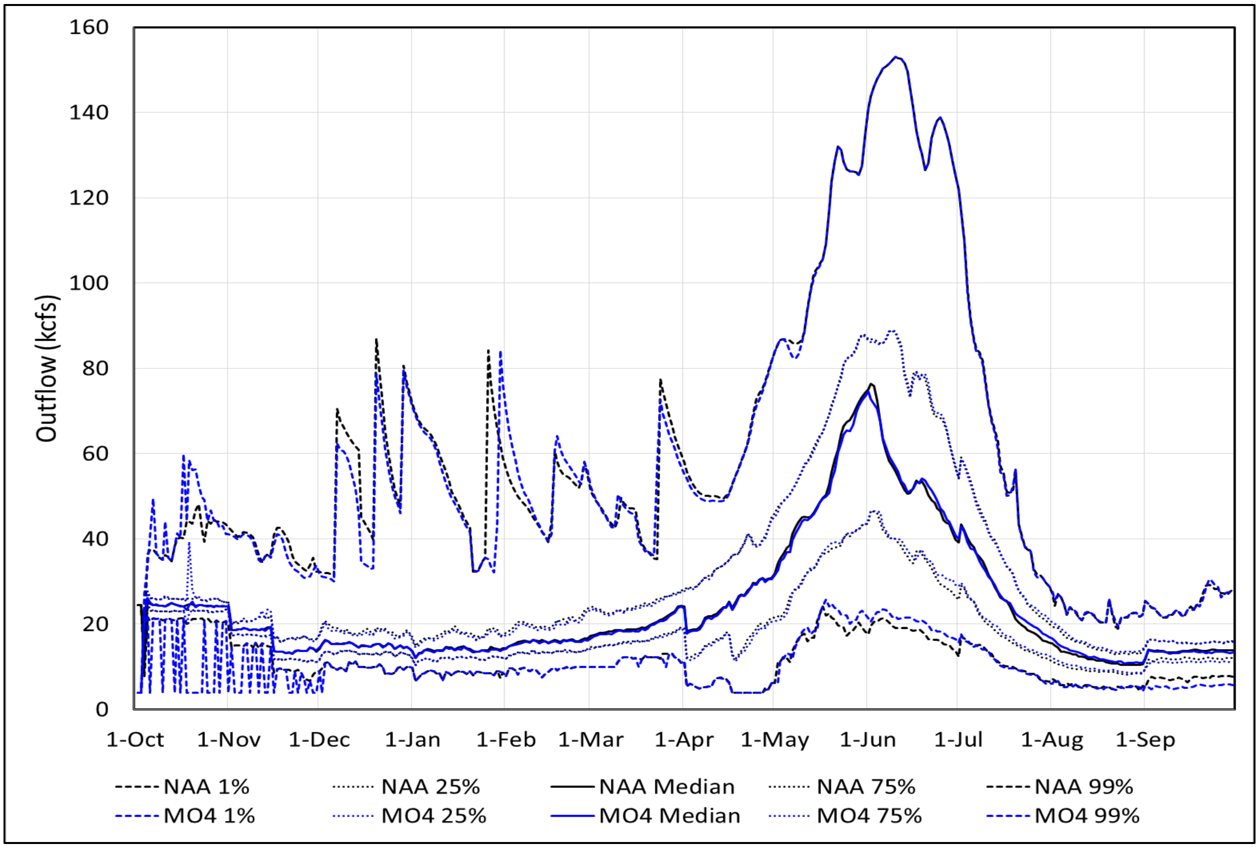

**Figure 3-90. Albeni Falls Dam Outflow Summary Hydrograph for Multiple Objective Alternative 4**

Note: The 99 percent exceedance values depicted for October/November are a modeling artifact related to ResSim model setup.

The *McNary Flow Target* measure is the main driver for the June through September outflows that would differ from the No Action Alternative. From September through May, the median value of the monthly average outflow from Albeni Falls Dam under MO4 would be the same or slightly lower than that for the No Action Alternative due to operational changes at Hungry Horse Dam; in June, July, and August it would be greater. This is shown in Table 3-45, which also includes the changes that would occur at upstream locations.

Under MO4, monthly average outflows from Albeni Falls Dam would differ from the No Action Alternative:

- In June, July, and August, the median value of the monthly average outflow would be greater than the No Action Alternative by 0.4, 0.6, and 0.7 kcfs, respectively. The *McNary Flow Target* measure is the primary cause of these changes.
- In September, the median value of the monthly average outflow would be lower than the No Action Alternative by 0.5 kcfs. The *McNary Flow Target* measure is the primary cause of this change.

The results in Table 3-45 are based on median values of monthly average flows, so by definition, they do not separate out years when the *McNary Flow Target* measure is triggered from those when it is not triggered. Rather, they represent the overall trend considering all years lumped together.

The median outflow hydrographs shown in Figure 3-91 are useful for understanding how the Albeni Falls outflow under MO4 would differ from the No Action Alternative in different types of years. Most notably, the outflow from Albeni Falls Dam under MO4 would be greater than that for the No Action Alternative in dry years, due to the *McNary Flow Target* measure. In the dry years, the late spring flows would be higher than for the No Action Alternative. Continuing through the summer, outflows would also be higher in July and August, as seen in the median hydrograph for average years.

**Table 3-45. Pend Oreille Basin Monthly Average Flows for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

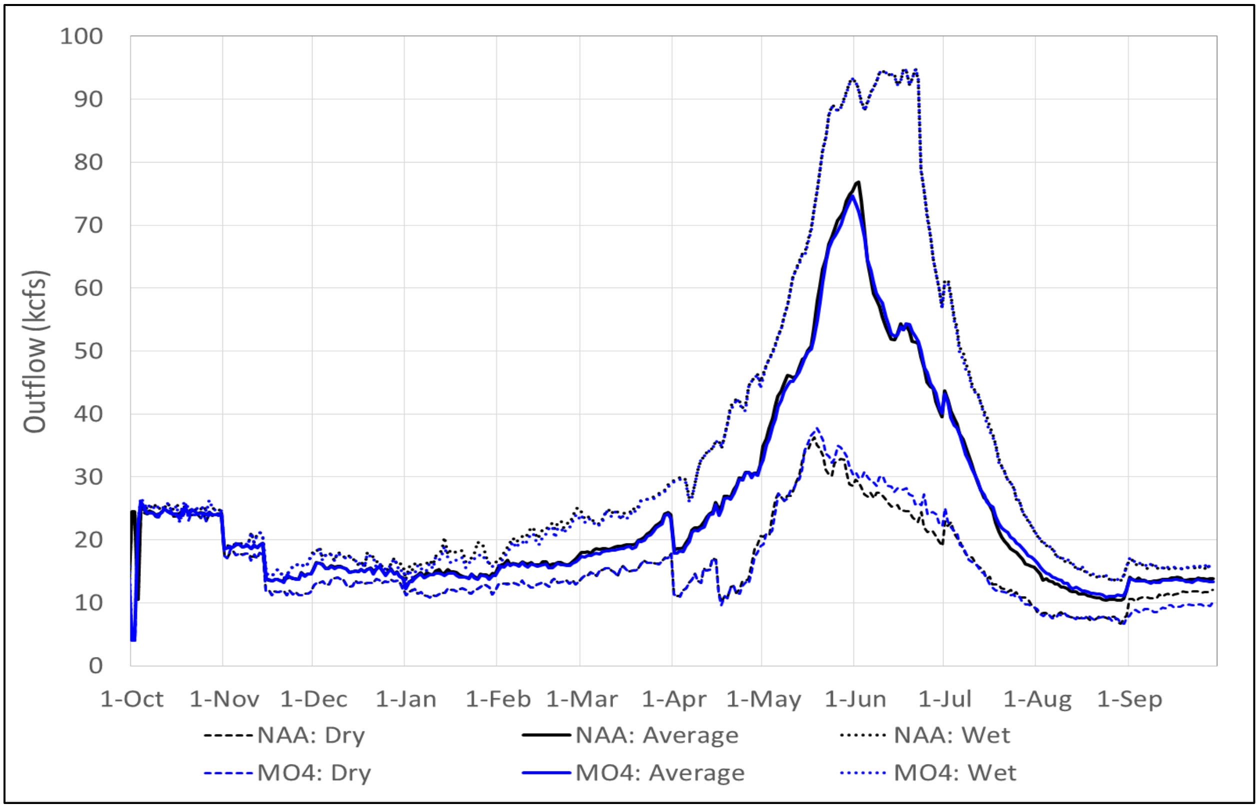

**Figure 3-91. Albeni Falls Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 4**

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Columbia River flow upstream of Grand Coulee Dam

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, and *Winter Stage for Riparian* measures would affect Columbia River flow upstream of Grand Coulee Dam. Figure 3-92 shows flows near RM 748 (just downstream of the U.S.-Canada border, about 151 river miles upstream of Grand Coulee Dam).

Figure 3-92 characterizes the timing and magnitude of flow changes between the No Action Alternative and MO4 due to the combined effect of measures at Libby, Hungry Horse, and Albeni Falls Dams. Changes in flow between MO4 and the No Action Alternative would be most noticeable in December and in July. In December, the median flow for MO4 would be about 4 kcfs lower than for the No Action Alternative due to the *December Libby Target Elevation* measure. In July, the flow for MO4 at the 75 percent exceedance level would be about 8 kcfs higher than for the No Action Alternative, primarily due to operations for the *McNary Flow Target* measure at Libby, Hungry Horse, and Albeni Falls Dams.

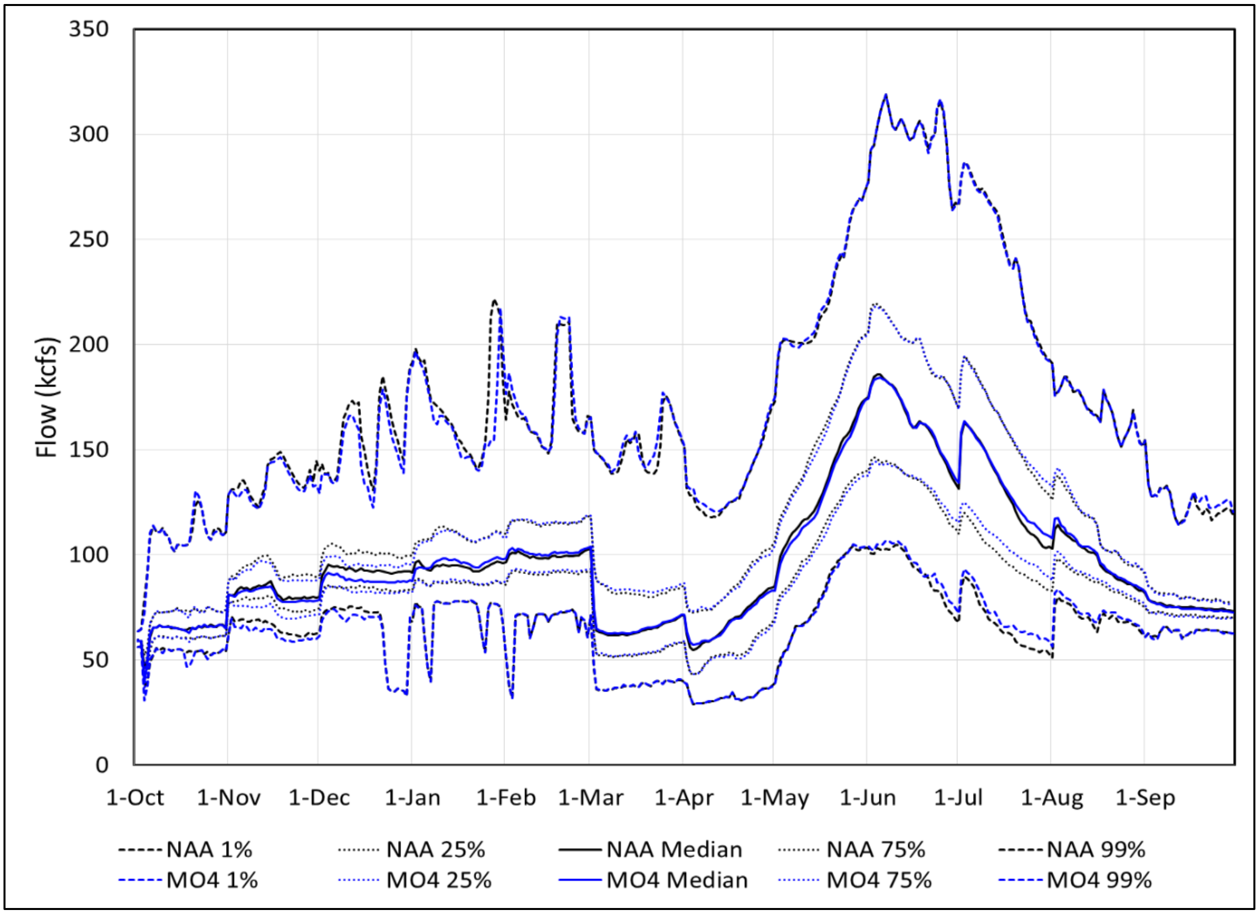

**Figure 3-92. Lake Roosevelt Inflow Summary Hydrograph for Multiple Objective Alternative 4**

**Lake Roosevelt (Grand Coulee Dam Reservoir) Elevation**

Under MO4, the *McNary Flow Target*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures relate directly to Grand Coulee Dam and would influence reservoir elevations at Lake Roosevelt.

Under MO4, the *McNary Flow Target*, *Winter System FRM Space*, and *Planned Draft Rate at Grand Coulee* measures would be the source of most changes in Lake Roosevelt's elevation. The *Update System FRM Calculation* measure would have an effect on elevation in some years. The *Grand Coulee Maintenance Operations* and *Lake Roosevelt Additional Water Supply* measures would not have an effect on the lake level, but would affect outflow and spill at Grand Coulee Dam.

In addition to the measures listed above, under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, *Winter Stage for Riparian*, and *Hungry Horse Additional Water Supply* measures would affect the inflow to Grand Coulee Dam. The hydroregulation modeling performed for MO4 incorporates all of these measures, but because each measure was not evaluated in isolation from the others, drawing a direct linkage between a single measure and an effect is not always possible. The effects that would occur from a measure or combination of measures are identified and discussed to the extent possible.

Reservoir water levels in Lake Roosevelt under MO4 would differ from the No Action Alternative, as shown in the summary hydrograph, Figure 3-93.

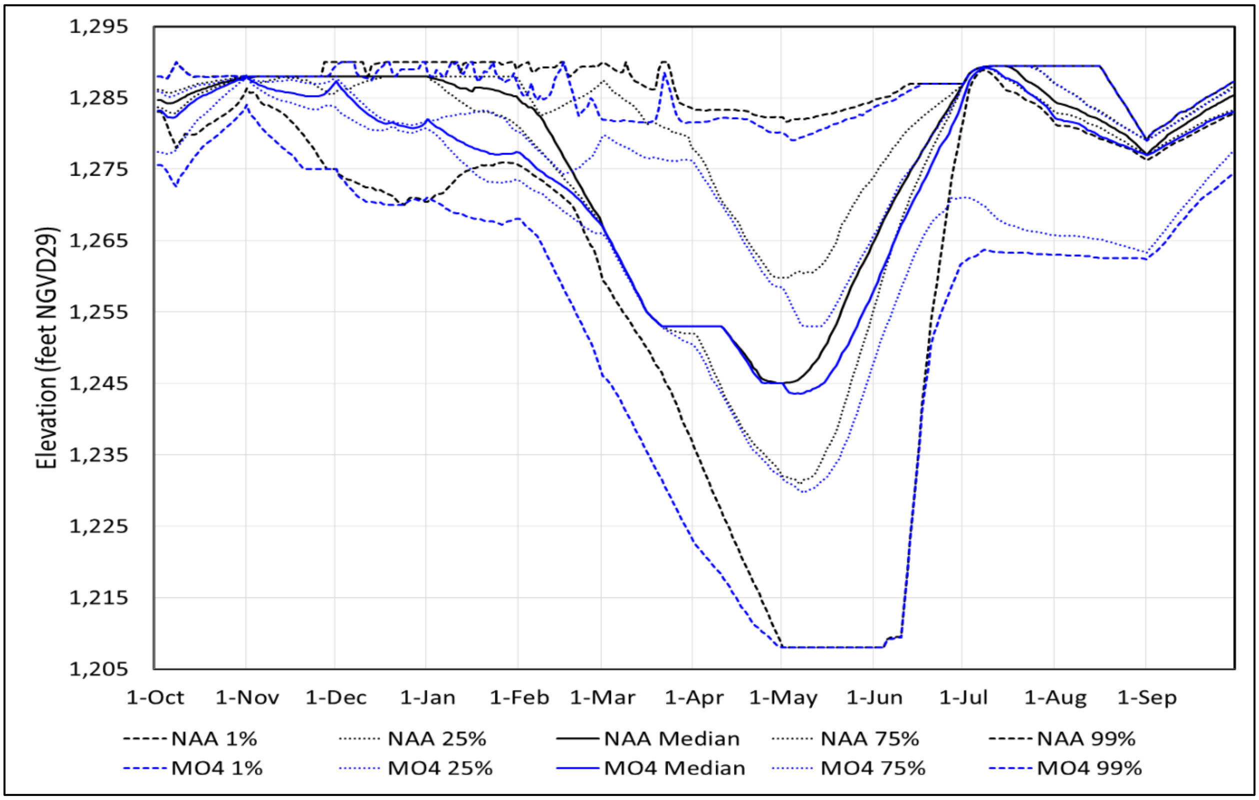

**Figure 3-93. Lake Roosevelt Summary Hydrograph for Multiple Objective Alternative 4**

Under MO4, the end of September elevation would be below 1,283 feet NGVD29 50 percent of the time, primarily due to the *McNary Flow Target* measure. In contrast, the No Action Alternative has a 1,283 feet NGVD29 refill elevation objective by the end of September in all years for resident fish considerations. In all but the driest of years, Lake Roosevelt would fill to the same elevation by the end of October as the No Action Alternative. The November elevations would generally be the same or lower than the No Action Alternative. Then, from December through February in virtually all years, the reservoir would be lower than the No Action Alternative. This is primarily due to the *Winter System FRM Space* measure, which would increase the space available at Grand Coulee Dam for FRM in the winter months when rain-induced floods may occur, and also by the *Planned Draft Rate at Grand Coulee* measure, which decreases the daily draft rate in planning drawdown to the deepest draft point, as determined by the *Update System FRM Calculation* measure. In the wettest years the *Planned Draft Rate at Grand Coulee* measure requires earlier draft, but this earlier draft is largely started already due to the *Winter System FRM Space* measure.

At the end of December, the median reservoir elevation for MO4 would be about 7 feet lower than that for the No Action Alternative due to the *Winter System FRM Space* measure. The median reservoir elevation at the end of January would be about 8 feet lower than the No Action Alternative, primarily due to the *Winter System FRM Space* measure and also the combination of the *Planned Draft Rate at Grand Coulee* and *Updated System FRM Calculation* measures, which determines the deepest draft point. By the end of February and through the end of April, the median reservoir elevation under MO4 would be nearly identical to that for the No Action Alternative. However, the wetter years (depicted by the 25 percent and 1 percent exceedance lines) and the drier years (depicted by the 75 percent and 99 percent exceedance lines) would continue with reservoir levels lower than the No Action Alternative from February through March, generally due to *Planned Draft Rate at Grand Coulee* measure. This trend would continue through April, due to a combination of several measures at Grand Coulee Dam, as well as measures at upstream projects.

Under MO4, the probability of drafting to very low reservoir elevations (elevation 1,222 feet NGVD29 or below) at Lake Roosevelt on April 30 would increase when compared to the No Action Alternative. This is due to an element in the *Update System FRM Calculation* measure which calls for the FRM space requirement at Grand Coulee Dam to increase as the water supply forecast increases. This is in contrast to the FRM space requirement at Grand Coulee Dam for the No Action Alternative, which has a “flat spot” at elevation 1,222.7 feet NGVD29 where the FRM space requirement does not increase right away with the runoff forecast over a certain range of runoff conditions.

The effects of MO4 on the April 30 level of Lake Roosevelt are summarized below:

- The chance of drawing the reservoir down to “empty” (elevation 1,208 feet NGVD29) on April 30 would be about 5 percent for MO4, the same as for the No Action Alternative.
- The chance of drawing the reservoir down to elevation 1,222 feet NGVD29 or below on April 30 would be about 15 percent for MO4, as compared to about 8 percent for the No Action Alternative.

In May, the level of Lake Roosevelt under MO4 would generally be lower than that for the No Action Alternative, mostly due to the effects of the *McNary Flow Target* measure, as shown in the summary hydrograph. When triggered, the *McNary Flow Target* measure would strive to maintain flow objectives at McNary Dam using water stored at Grand Coulee Dam as well as Libby, Hungry Horse, and Albeni Falls Dams. Up to 2.0 Maf of augmentation water from those four dams (combined), would be released, attempting to keep McNary flows above 220 kcfs from May 1 to June 15 and above 200 kcfs from June 16 to July 31 with a maximum daily augmentation of 40 kcfs per day. This would ultimately result in Lake Roosevelt not reaching its full elevation of 1,290 feet NGVD29 in about half of all years, as seen in the peak elevation frequency curve in Figure 3-94.

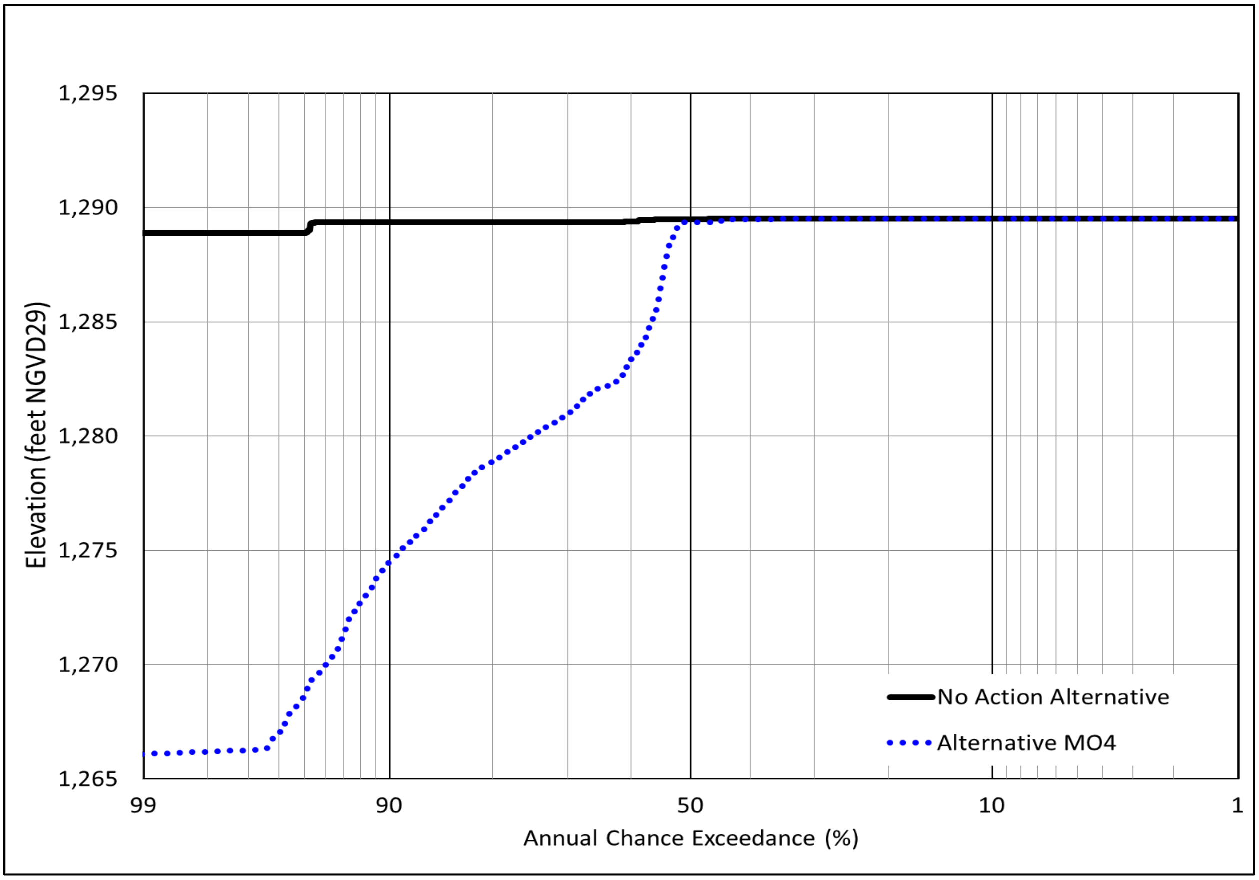

**Figure 3-94. Lake Roosevelt Peak Elevation Frequency for Multiple Objective Alternative 4**

Note: The full reservoir elevation for Lake Roosevelt is 1,290 feet NVGD29. It is represented as 1,289.5 feet NGVD29 in the HEC-ResSim model, so appears as 1,289.5 feet NGVD29.

Figure 3-95 provides another way to picture the effects described above, this time categorized by water year type. From May through September, the median hydrographs show that the level of Lake Roosevelt under MO4 would be much lower than for the No Action Alternative in dry years. This is primarily due to the *McNary Flow Target* measure. It is important to note that lower summer reservoir levels would occur in about half of all years, as shown in Figure 3-95, and as will be shown in the elevation duration curves for summer months (Figure 3-94). The median hydrograph figure for dry/average/wet years (Figure 3-95) cannot show the effect of the *McNary Flow Target* measure occurring about half of the time due to way the dry/average/wet categories are defined.

Finally, elevation duration curves are useful for understanding how lake levels under MO4 would differ from the No Action Alternative. The four panels in Figure 3-96 show monthly elevation duration curves for June, July, August, and September, respectively. The *McNary Flow Target* measure would be triggered in years that are dryer than average, and the effect of this measure is seen in all four panels. For instance, in July and August the lake level would be lower than the No Action Alternative about half of the time, with differences ranging from several feet to about 20 feet.

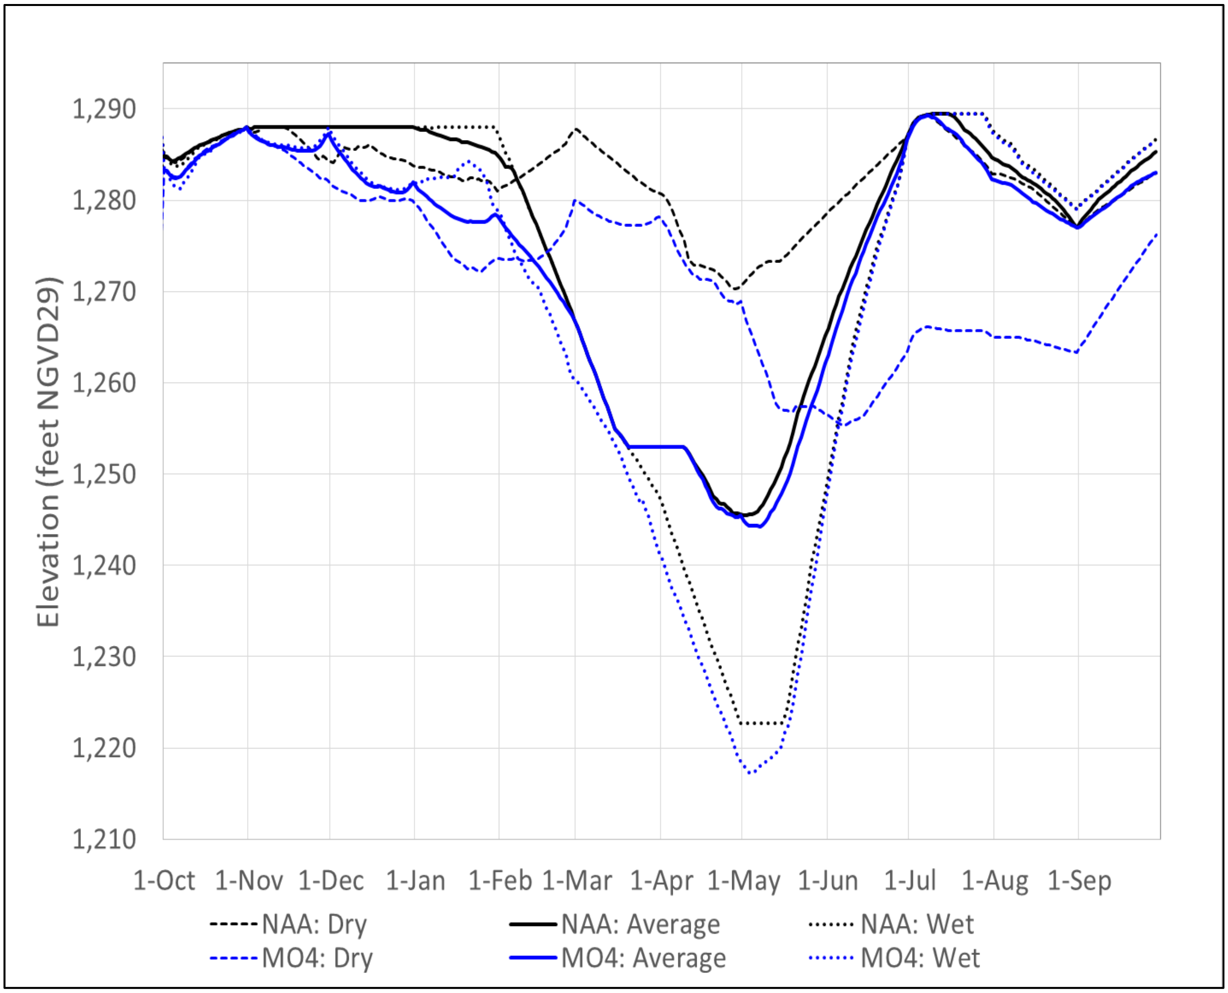

**Figure 3-95. Lake Roosevelt Water Year Type Hydrographs for Multiple Objective Alternative 4**

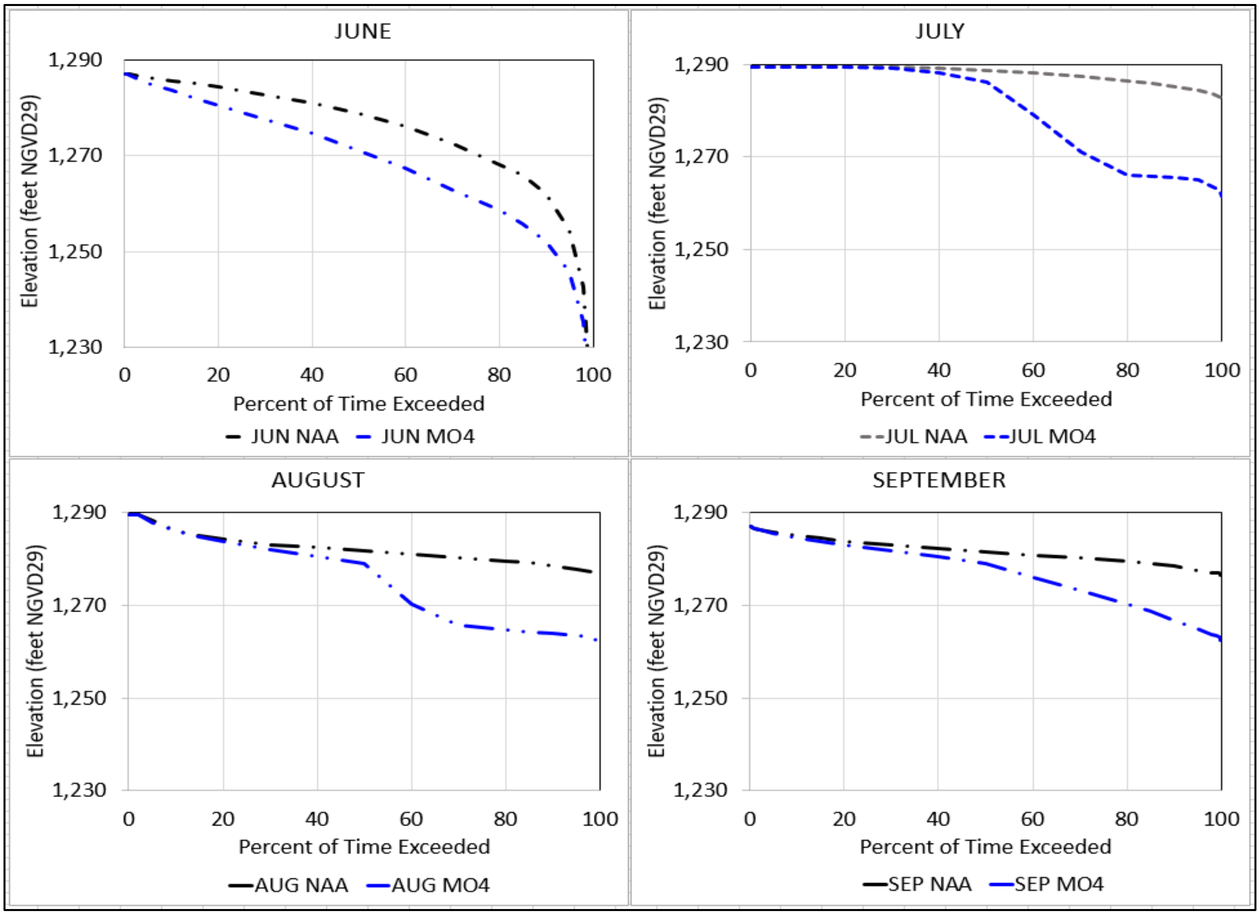

**Figure 3-96. Lake Roosevelt Summer Elevations for Multiple Objective Alternative 4**

**Grand Coulee Dam Drum Gate Maintenance**

Drum gate maintenance at Grand Coulee Dam is planned to occur annually during March, April, and May, but is not conducted in all years. The reservoir must be at or below elevation 1,255 feet NGVD29 for 8 weeks to complete drum gate maintenance. Under MO4 the *McNary Flow Target*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Space* measures would influence reservoir elevations during spring months.

The changes in elevations for MO4 that influence the decision to conduct drum gate maintenance would not change significantly relative to the No Action Alternative (April 30 FRM elevation targets and drum gate initiation methodology is discussed in more detail in Part 1 of Appendix B). The decision to conduct drum gate maintenance is based on the February water supply forecast and the resulting April 30 FRM elevation projection (April 30 FRM elevation target at or below 1,255 or 1,265 feet NGVD29 depending on how recently the maintenance has been conducted). That is not to say the spring elevations are the same for the two alternatives but rather there are a similar number of years that elevations would allow for drum gate maintenance. In both MO4 and the No Action Alternative, drum gate maintenance would be achievable in 65 percent of the years.

### Grand Coulee Dam Outflow

Under MO4, the *McNary Flow Target*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Winter System FRM Space*, and *Lake Roosevelt Additional Water Supply* measures would affect Grand Coulee Dam outflow. In addition, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, *Winter Stage for Riparian*, and *Hungry Horse Additional Water Supply* measures would affect inflows and outflows at Grand Coulee Dam. The outflows from Grand Coulee Dam would differ from the No Action Alternative depending on the time of year, as seen in Figure 3-97.

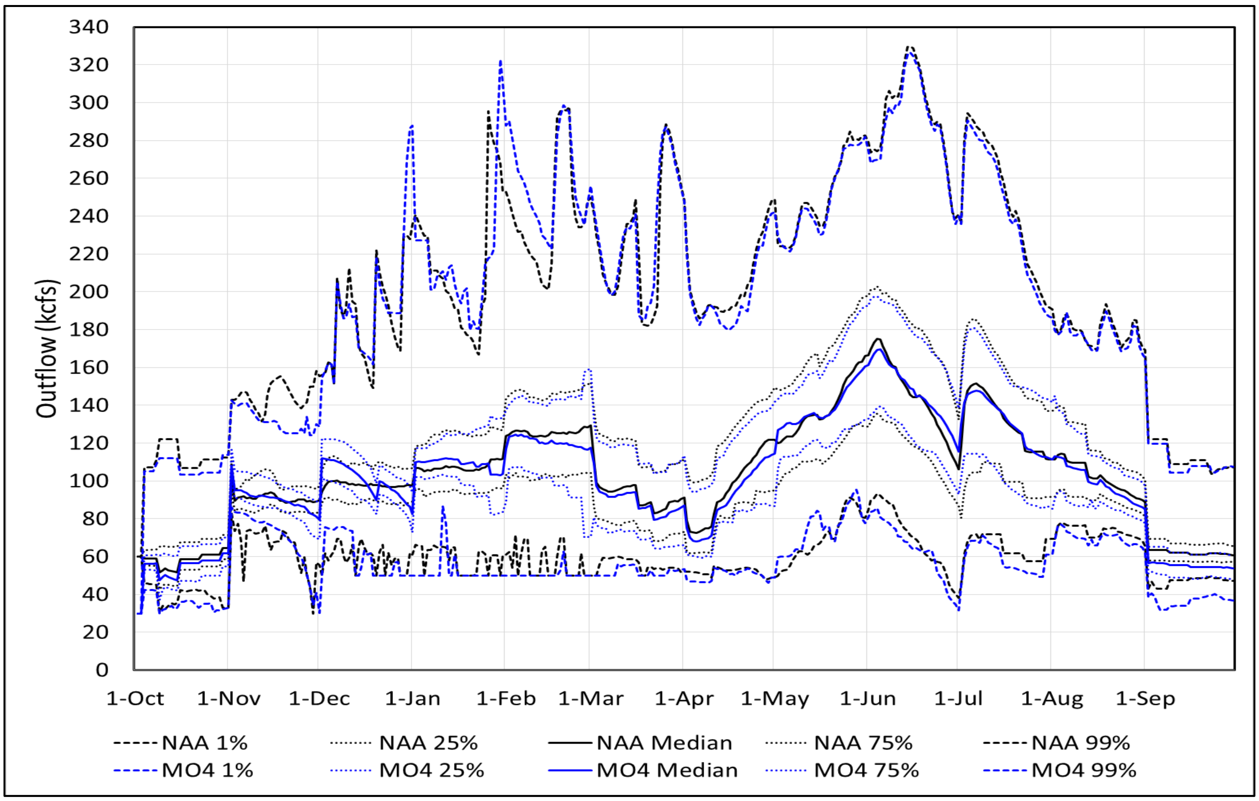

**Figure 3-97. Grand Coulee Dam Outflow Summary Hydrograph for Multiple Objective Alternative 4**

The change in average monthly outflow throughout the water year is presented in Table 3-46.

Under MO4, the *McNary Flow Target*, *Winter System FRM Space*, the *Planned Draft Rate at Grand Coulee*, and *Lake Roosevelt Additional Water Supply* measures would result in the largest changes in Grand Coulee Dam outflow. However, because there are so many measures in MO4 that would affect Grand Coulee Dam's outflow, the effects are described below and the measure (or combination of measures) causing the effect is identified where possible.

**Table 3-46. Grand Coulee Dam Monthly Average Outflow for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

| | | 99% | -15% | -2% | 2% | 12% | 0% | -9% | -3% | 12% | 1% | -6% | -5% | -17% |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows lower than the No Action Alternative flows; green shading denotes MO4 flows higher than the No Action Alternative flows.

- Under MO4, outflows in October would generally be lower than the No Action Alternative due to the carryover effects from the *McNary Flow Target* measure. The median value of the monthly average discharge would be 5.1 kcfs less than the No Action Alternative.
- In December, the median value of the monthly average outflow would increase by 2.7 kcfs. This is primarily due to the *Winter System FRM Space* measure which creates winter FRM space in Grand Coulee's reservoir. The *December Libby Target Elevation* measure at Libby Dam counteracts the effect of the *Winter System FRM Space* measure at Grand Coulee Dam by generally reducing inflows by 4 kcfs (reduction at median level), as mentioned in the previous section on Columbia River upstream of Grand Coulee Dam. In January, the median value of the monthly average outflow would increase by 1.4 kcfs. This may be caused by the *Winter System FRM Space* measure, which continues to draft Grand Coulee's reservoir in January if the winter FRM space is not achieved by the end of December. The *Update System FRM Calculation* and *Planned Draft Rate at Grand Coulee* measures can also influence flows in January.
- In February and March, the median value of the monthly average outflow would decrease by 4.3 and 2.5 kcfs, respectively. In March, the *Lake Roosevelt Additional Water Supply* measure would reduce flows approximately 0.6 kcfs.
- In April the volume of water to be pumped from Lake Roosevelt into Banks Lake as a result of the *Lake Roosevelt Additional Water Supply* measure would increase. The April through September period would have the greatest total pumping volumes, as well as the greatest additional pumping volumes as called for in the *Lake Roosevelt Additional Water Supply* measure.

- In April, the median value of the monthly average outflow would decrease by 5.2 kcfs. The *Lake Roosevelt Additional Water Supply* measure's increased pumping from Lake Roosevelt into Banks Lake accounts for the majority (3.2 kcfs) of this decrease. The *Update System FRM Calculation* and *Planned Draft Rate at Grand Coulee* measures, as well as changes to inflow from measures changing operations at upstream storage projects, would also affect Grand Coulee Dam outflows in April.
- The median value of the monthly average outflow would decrease by 2.7, 0.5, and 0.6 kcfs for May, June, and July, respectively. However, the 75 percent exceedance monthly average outflows would increase by 6.0, 6.1, and 1.9 kcfs, respectively, for those 3 months. A combination of multiple measures would cause these changes, with the *Lake Roosevelt Additional Water Supply* and *McNary Flow Target* measures being major drivers. The *Lake Roosevelt Additional Water Supply* measure's increased pumping from Lake Roosevelt into Banks Lake would reduce outflows, while the *McNary Flow Target* measure's releases for McNary flow targets would increase outflows in the drier-than-normal years when it is triggered. The *Lake Roosevelt Additional Water Supply* measure would cause flow decreases of 4.2, 2.6, and 2.5 kcfs in July, August, and September respectively. In the very driest of years, the augmentation water for McNary flow targets would be used up before July, and thus not be available in July. The overall combined effect of these and other measures is that some years would have higher outflows while other years would have lower outflows.
- In August and September, the median value of the monthly average outflow would be reduced by 2.6 and 6.3 kcfs, respectively. The 75 percent exceedance monthly average outflows would have even greater reductions. The *Lake Roosevelt Additional Water Supply* measure would contribute to these reductions, as would the *McNary Flow Target* measure, when triggered.
- The *Grand Coulee Maintenance Operations* measure would not impact reservoir elevations or total outflows, but would reduce the hydraulic capacity through the power plants, resulting in additional spill and an increase in TDG in some situations.

Finally, median hydrographs for Grand Coulee Dam outflow in dry, average, and wet years are shown in Figure 3-98. The figure provides another way to picture the effects described above, this time categorized by water year type. Comparing the median hydrographs for dry years, it can be seen that during May and the first half of June, outflows from Grand Coulee Dam would be higher under MO4 than for the No Action Alternative. This is caused by the *McNary Flow Target* measure.

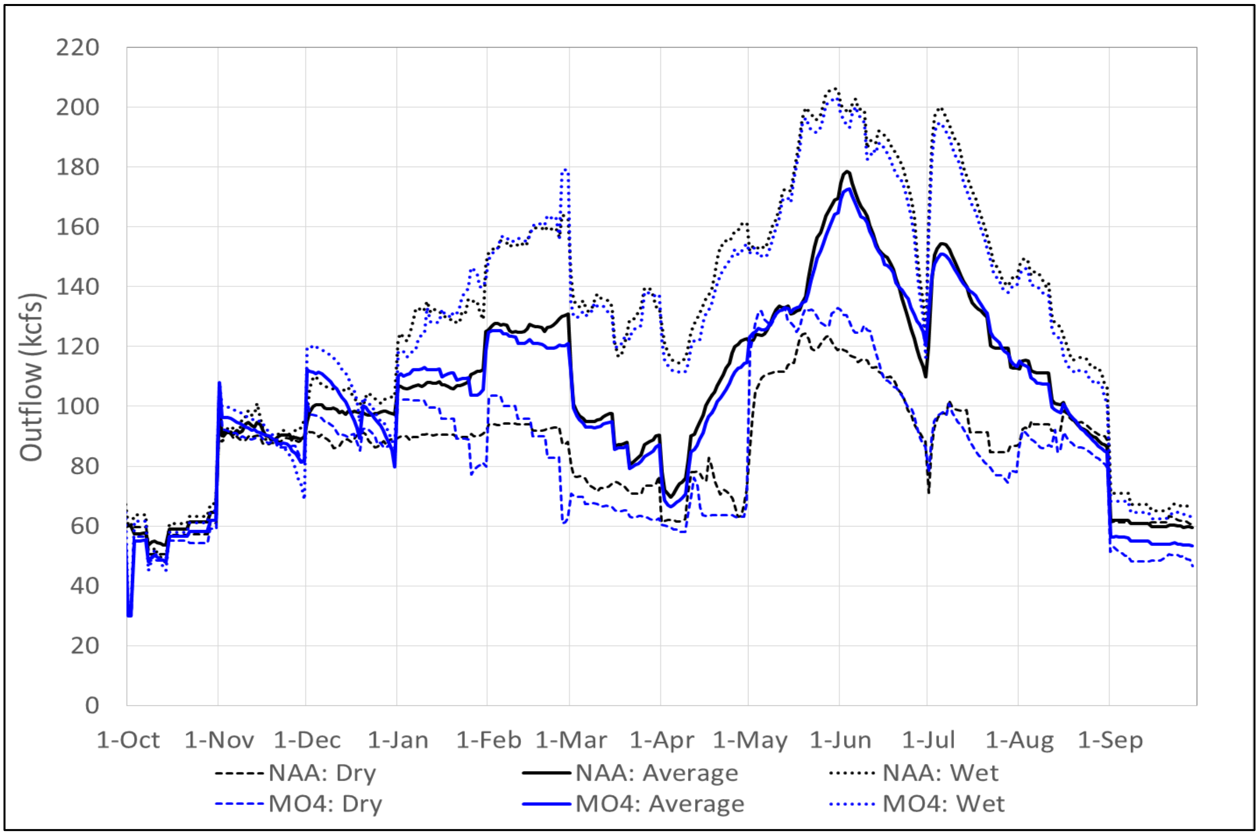

**Figure 3-98. Grand Coulee Dam Outflow Water Year Type Hydrographs for Multiple Objective Alternative 4**

### Middle Columbia River below Grand Coulee Dam

Under MO4, the pattern of flow changes in the middle Columbia River would be similar to those described for Grand Coulee Dam outflow, with the changes occurring for the same reasons as described for Grand Coulee Dam outflow. An additional measure, *Chief Joseph Dam Project Additional Water Supply*, calls for an increase in water diversion (at a maximum rate of 0.05 kcfs) from the Columbia River for Chief Joseph Dam. The total flow impact from the *Chief Joseph Dam Project Additional Water Supply* measure is 9.6 kaf annually, which is significantly smaller than the impacts from the *Lake Roosevelt Additional Water Supply* measure that reduces flows an additional 1.1 Maf annually. For perspective, the flow change for the *Chief Joseph Dam Project Additional Water Supply* measure is two orders of magnitude smaller than that for the *Lake Roosevelt Additional Water Supply* measure. As compared to the *McNary Flow Target* measure when triggered, the flow for the *Chief Joseph Dam Project Additional Water Supply* measure may be three orders of magnitude smaller than that for the *McNary Flow Target* measure. The reservoir elevation at Chief Joseph Dam would not change from the No Action Alternative.

Table 3-47 shows changes in the median values of monthly average flows at locations in middle Columbia River.

**Table 3-47. Middle Columbia River Monthly Average Flows for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | Location | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| NAA (kcfs) | Lake Roosevelt Inflow | 64 | 82 | 92 | 95 | 100 | 65 | 69 | 131 | 166 | 133 | 98 | 75 |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows lower than the No Action Alternative flows; green shading denotes MO4 flows higher than the No Action Alternative flows.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Dworshak Dam

MO4 does not have any operational measures that would directly affect Dworshak Reservoir elevations or Dworshak Dam outflows. Given this, the effects would be the same as those for the No Action Alternative.

### Lower Snake River Reservoir Elevations

Under MO4, the reservoir elevations at the four lower Snake River dams would have an adjusted MOP operation from March 15 through August 15 due to the *Drawdown to MOP* measure. At all four projects, the seasonal MOP range is increased from a 1.0-foot range to a 1.5-foot range, each with a 0.5-foot increase in the upper end of the range. The proposed elevation ranges for March 15 through August 15 at each of the four projects are described below:

- Lower Granite Dam: 733.0 to 734.5 feet NGVD29, compared to 733.0 to 734.0 feet NGVD29 for the No Action Alternative
- Little Goose Dam: 633.0 to 634.5 feet NGVD29, compared to 633.0 to 634.0 feet NGVD29 for the No Action Alternative
- Lower Monumental Dam: 537.0 to 538.5 feet NGVD29, compared to 537.0 to 538.5 feet NGVD29 for the No Action Alternative
- Ice Harbor Dam: 437.0 to 438.5 feet NGVD29, compared to 437.0 to 438.5 feet NGVD29 for the No Action Alternative

#### Clearwater River below Dworshak Dam and the Lower Snake River

Under MO4, there are no changes at Dworshak Dam, so inflow to the lower Snake River would be unchanged from the No Action Alternative. The changes in MOP ranges at the lower Snake River reservoirs would have negligible effects on flow.

### REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

#### Lower Columbia River Reservoir Elevations

Under MO4, there would be changes to the reservoir elevations at McNary Dam, John Day Dam, The Dalles Dam, and Bonneville Dam. All would have an adjusted operating range because of *Drawdown to MOP* measure, which results in decreased operating range from March 25 through August 15. The proposed MOP elevation ranges for each of the four projects and the changes from the No Action Alternative are described below:

- McNary Dam would have a 1.0-foot MOP range from March 25 to August 15 (337.0 to 338.0 feet NGVD29). This is a 2.0-foot decrease in operating range from the No Action Alternative, where McNary Dam does not have a MOP operation and the normal operating range is between 337.0 to 340.0 feet NGVD29.
- John Day Dam would have a 1.5-foot range from March 25 to August 15 (261.0 to 262.5 feet NGVD29). This differs from the No Action Alternative, where John Day Dam operates between 262.5 to 265.0 feet NGVD29 from March 15 to April 9, and between 262.5 to 264.0 feet NGVD29 from April 10 to September 30. In both periods, the new operating range minimum is shifted down 1.5 feet, and the range is decreased by 1.5 to 2.5 feet.
- The Dalles Dam would have a 1.5-foot MOP range from March 25 to August 15 (155.0 to 156.5 feet NGVD29). This is a 3.5-foot decrease in operating range from the No Action Alternative, where The Dalles Dam does not have a MOP operation and is operated between 155.0 to 160.0 feet NGVD29 year round.
- Bonneville Dam would have a 1.5-foot MOP range from March 25 to August 15 (71.5 to 73.0 feet NGVD29). This is a 3.5-foot decrease in operating range from the No Action Alternative, where Bonneville Dam does not have a MOP operation and is operated between 71.5 to 76.5 feet NGVD29 year round.

The operating range for John Day Dam for MO4 is shown in Figure 3-99. The No Action Alternative operating range is shown for comparison purposes.

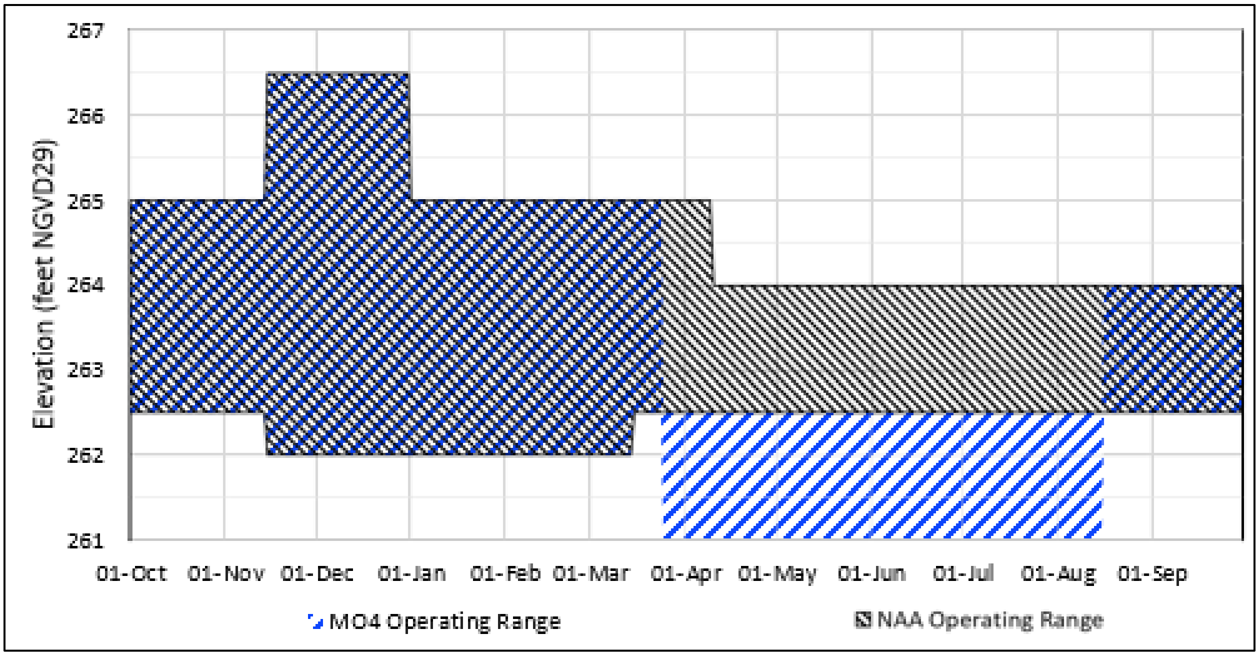

**Figure 3-99. John Day Dam Operating Range for Multiple Objective Alternative 4**

Note: John Day may be operated between 257 feet and 268 feet NGVD29 for FRM purposes. These limits are not shown on this figure in order to show greater detail in the vertical scale.

**Lower Columbia River Flows**

Under MO4, the *McNary Flow Target*, *Sliding Scale at Libby and Hungry Horse*, *Modified Draft at Libby*, *December Libby Target Elevation*, *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Winter System FRM Space*, *Lake Roosevelt Additional Water Supply*, *Hungry Horse Additional Water Supply*, *Chief Joseph Dam Project Additional Water Supply*, *Drawdown to MOP,* and *Winter Stage for Riparian* measures would cause changes in flow patterns in the lower Columbia River.

At McNary Dam, the outflows under MO4 would differ from the No Action Alternative to various extents through the water year. The magnitude and timing of differences in flow are displayed in the summary hydrograph, Figure 3-100. The flow spike that appears in mid-March, as well as the flow dip that appears in mid-August, are both related to the way that changes in pool levels were modeled for the *Drawdown to MOP* measure. This spike/dip would not be expected to occur in actual implementation, as the elevation changes for starting and ending MOP would be spread out over more than 1 day, thus smoothing out changes in releases.

In addition to the daily flow values depicted in Figure 3-100, the monthly average outflows from McNary Dam that would occur under MO4 were compared to those for the No Action Alternative, as shown in Table 3-48.

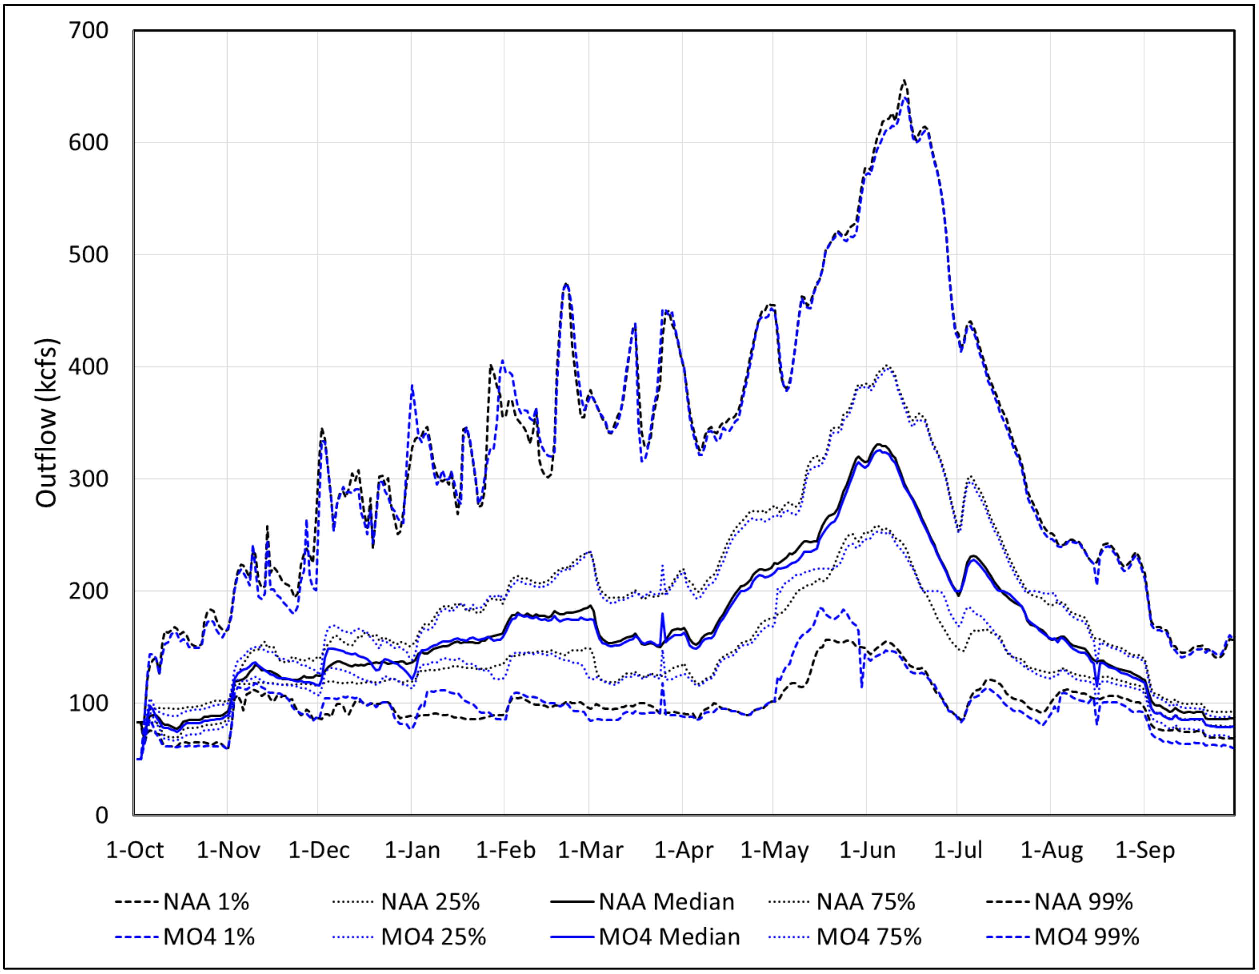

**Figure 3-100. McNary Dam Outflow Summary Hydrograph for Multiple Objective Alternative 4**

Several conclusions can be drawn from this comparison:

- In December and January, the median value of monthly average outflow would increase by 3.0 and 1.7 kcfs, respectively. There would be increases for other exceedance values as well. For instance, the 75 percent exceedance values in December and January would increase by 5.0 and 2.6 kcfs, respectively. The *Winter System FRM Space* measure calling for winter FRM space at Grand Coulee Dam is the main reason for these flow increases.
- In March and April, monthly average outflow would be less than the No Action Alternative at all flow levels.
- In May, June, and July, the 75 percent exceedance values of monthly average outflow would increase by 2.3, 8.9, and 6.1 kcfs, respectively. And in the very driest years (reflected in the 99 percent exceedance value), the monthly average outflow in May would be 21.5 kcfs higher than for the No Action Alternative. The *McNary Flow Target* measure is the main reason for these flow increases.
- In August, September, October, and November, monthly average outflow would be less than the No Action Alternative at all flow levels.

**Table 3-48. McNary Dam Monthly Average Outflow for Multiple Objective Alternative 4 (as change from No Action Alternative)**

| | | Exceedance Probability | OCT | NOV | DEC | JAN | FEB | MAR | APR | MAY | JUN | JUL | AUG | SEP |

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows lower than the No Action Alternative flows; green shading denotes MO4 flows higher than the No Action Alternative flows.

Finally, median hydrographs for McNary Dam outflow in dry, average, and wet years are shown in Figure 3-101. MO4 and the No Action Alternative results are shown. With the results categorized by water year type, it is readily seen that the *McNary Flow Target* measure's flow objective of 220 kcfs in the spring would generally be achieved. The summertime objective of 200 kcfs (from June 16 to July 31), which is also part of the *McNary Flow Target* measure, would generally not be achieved in average and dry years. In September, the flows at McNary Dam under MO4 would be lower than for the No Action Alternative in average and dry years, with the difference being most pronounced in dry water years.

Along the lower Columbia River, the median value of the average monthly flow for MO4 would be higher than the No Action Alternative in some months (for example, December, January, and July), and lower in others (for example, April, May, June, August, and September). The flow change patterns seen at the confluence of the Columbia and Snake Rivers continue downstream to other locations. This is seen in Table 3-49.

With the exception of effects of the *Drawdown to MOP* measure at John Day, the effects on McNary Dam outflow from MO4 would occur similarly, and for the same reasons, at John Day Dam, The Dalles Dam, and Bonneville Dam. The measure would result in an increase in March flows and a decrease in August, reversing the flow trend shown in the McNary Dam outflow for March, and adding to the decrease shown in August.

Note: Values for the No Action Alternative are shaded gray. Orange shading denotes MO4 flows greater than the No Action Alternative flows; green shading denotes MO4 flows less than the No Action Alternative flows.

**SUMMARY OF EFFECTS**

Under MO4, the largest changes in water levels occur at Libby, Grand Coulee, and the lower Columbia River dams. Lake Koocanusa water levels are less variable in the winter and spring, with deeper drafts in low forecast years and less-deep drafts in large forecast years. August through November reservoir levels are lower in most years but can be higher in higher forecast years. Lake Roosevelt water levels are notably lower in the winter due to additional winter FRM space, slightly higher later in the year, and notably lower in the summer into the fall in low forecast years. At Hungry Horse Reservoir, additional water demand in the summer months results in slightly lower reservoir levels for most of the year, particularly in a low forecast year at The Dalles. The forebay operating range is slightly higher in the summer months at the lower Snake River projects and notably lower at the lower Columbia River projects. There are no changes at Dworshak Dam.

Changes in Libby outflows vary greatly across the year; November and December releases are decreased, winter releases after December are notably higher, April and May releases are lower, and summer releases are higher, particularly in June and July in low forecast years at The Dalles. Due to additional water demands from Hungry Horse Dam, Flathead River flows are lower in winter and spring months. In low forecast years at The Dalles, Hungry Horse and Albeni Falls Dams release extra water in June and July, and these are followed by larger decreases in flow in the fall and winter months. Water supply delivery increases from Grand Coulee and Chief Joseph Dams contribute to lower spring and summer flows in the Columbia River downstream. In low forecast years at The Dalles, flows are increased May through July, and then further decreased in September and October. With the exception of September, which can be more than 10 percent lower in lower water years, changes in average monthly flow through the lower Columbia River are typically within 5 percent of the No Action Alternative for all months for typical years.

## 3.3 RIVER MECHANICS

This river mechanics section consists of four parts: (1) a description of the study area, (2) a summary of the baseline sediment transport and geomorphologic conditions for the study area, (3) a discussion of the methodology and quantitative metrics, and (4) an estimate of the potential impacts to river mechanics metrics under the No Action Alternative and four MOs. Relative impacts are then compared between the MOs and No Action Alternative. See Chapter 7 for a description of impacts to river mechanics as a result of implementing the draft preferred alternative.

### 3.3.1 Area of Analysis

For the geomorphology and sediment transport discussions, the area of analysis is the CRS reservoirs and the river reaches downstream that are within the borders of the United States. River mechanics effects for reaches in Canada downstream of CRS reservoirs would be expected to be similar to the effects described in neighboring river reaches in the United States. Discussion of reaches in this chapter is organized by the four physiographic NEPA regions listed in Table 3-50 and depicted in Figure 3-102. Within each of the four lettered CRSO regions, the river mechanics analyses were subsequently grouped by the following: major reach, minor reach, and subreach, each representing a finer resolution level. In general, major reaches coincide physiographically with river segments or groups. Minor reaches were defined as reservoir or river segments between FCRPS projects, and subreaches were delineated by contiguous similarity in physical properties such as the following: valley type, morphology, energy grade slope, and flow depth. More information regarding the reach delineations is presented in Appendix C.

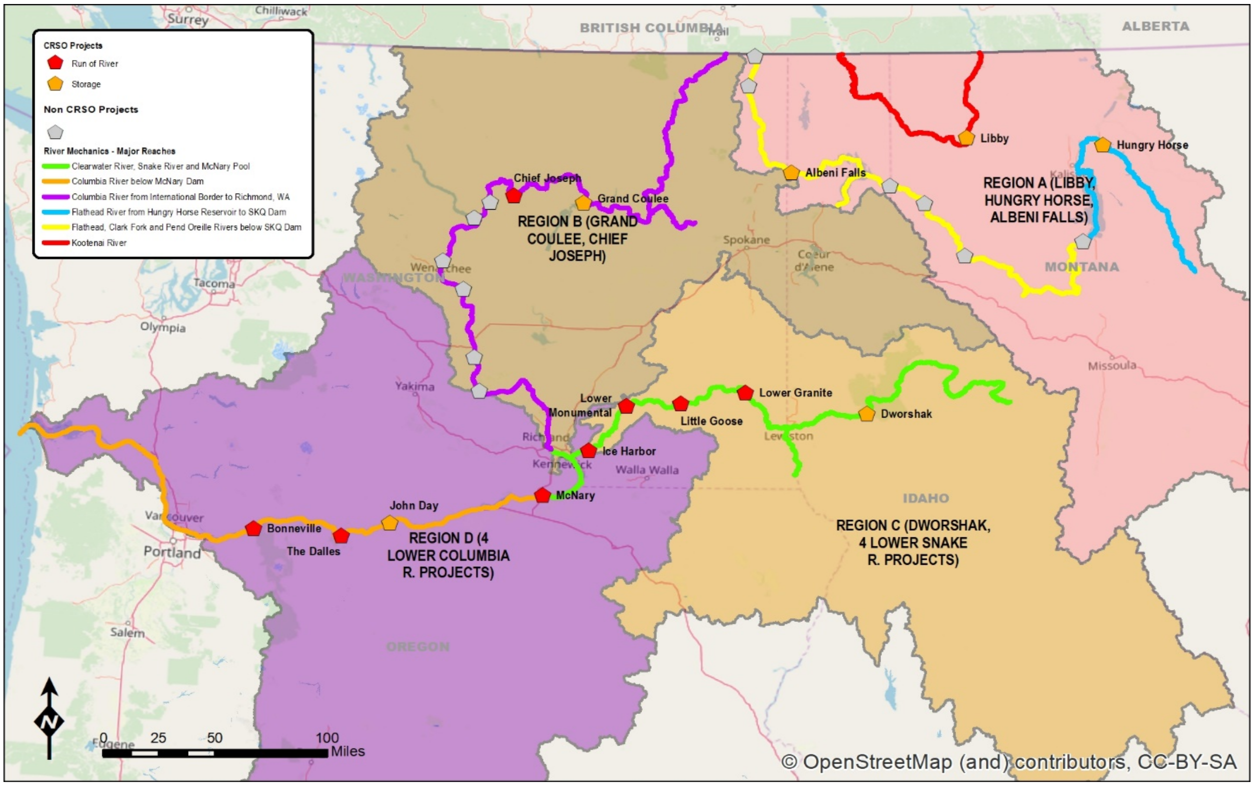

**Figure 3-102. Overview Map of Study Area Regions Used for River Mechanics Assessment**

**Table 3-50. River Mechanics Study Area National Environmental Policy Act Regions**

| CRSO Region | River Basins |
|---|---|
| A | Kootenai, Flathead, and Pend Oreille Rivers |
| B | Middle Columbia River |
| C | Clearwater and lower Snake Rivers |
| D | Lower Columbia River |

### *3.3.1.1 Region A – Kootenai, Flathead, and Pend Oreille Basins*

Region A includes the Kootenai, Flathead, and Pend Oreille Basins. There are nine hydroregulation projects located within Region A. Only three of the projects are CRS projects operated for storage (Libby Dam, Hungry Horse, and Albeni Falls). The remaining six projects (SKQ, Thompson Falls, Noxon Rapids, Cabinet Gorge, Box Canyon, and Boundary) are not part of the CRS but were included in the hydroregulation planning model to quantify potential departure in metrics that could result due to operational changes between the upper basin storage projects and the Columbia River.

#### REGION A – KOOTENAI RIVER

The Kootenai(y) River major reach lies within the NEPA Region A. The Libby Dam reservoir (Lake Koocanusa) extends upstream across the U.S.-Canada border, which forms the upstream end of the study area. The upper 70 miles of the Kootenai River is free flowing between Libby Dam and

Bonners Ferry, Idaho. Downstream of Bonners Ferry is a backwatered reach which flows back across the U.S.-Canada border to Kootenay Lake, B.C., marking the downstream analysis extent.

**REGION A – FLATHEAD RIVER FROM HUNGRY HORSE RESERVOIR TO SKQ DAM**

The Flathead River from Hungry Horse Reservoir to SKQ Dam major reach lies within NEPA Region A and spans approximately 85 river miles. The Hungry Horse storage project lies within this major reach, and the upstream extent of Hungry Horse Reservoir coincides with the upstream extent of the study area. The Flathead River analysis area is free-flowing for approximately 28 river miles from the Hungry Horse Dam tailrace upstream to the confluence with the Stillwater River downstream. From there, the lower 20 river miles of the Flathead River are seasonally backwatered by Flathead Lake, which inundates the lower 35 miles of the reach.

**REGION A – FLATHEAD, CLARK FORK, AND PEND OREILLE RIVERS BELOW SKQ DAM**

The Flathead, Clark Fork, and Pend Oreille Rivers below SKQ Dam major reach lies within NEPA Region A. SKQ Dam on the Flathead River marks the upstream extent of this major reach. The Pend Oreille River, flowing across the U.S.-Canada border, marks the downstream reach extent. The Lower Clark Fork River subreach extends approximately 109 river miles from the confluence with the Flathead River upstream to Lake Pend Oreille downstream.

There are three non CRS run-of-river projects within the subreach: Thompson Falls, Noxon Rapids, and Cabinet Gorge, which can locally influence Clark Fork River hydraulics. The Pend Oreille River subreach spans approximately 118 river miles between the Clark Fork River Delta on Lake Pend Oreille upstream to Boundary Dam downstream at the U.S.-Canada border in northeast Washington. There is one CRS storage project (Albeni Falls) and two non-CRS run-of-river projects (Box Canyon and Boundary) that influence hydraulics within the reach. Downstream of Boundary Dam, the Pend Oreille River flows north into Canada where it joins the Columbia River approximately 17 miles downstream near Waneta Dam, B.C.

### *3.3.1.2 Region B – Middle Columbia River*

Region B includes the middle Columbia River Basin as it enters the United States from Canada. The middle Columbia River Basin analysis reach spans approximately 413 river miles from the U.S.-Canada border upstream in northeastern Washington to Richland, Washington, downstream near the Yakima River confluence. The downstream extent of this major reach ends at the transition from the free-flowing Hanford Reach to the backwatered McNary Reservoir.

There are seven hydroregulation projects located within Region B (Grand Coulee, Chief Joseph, Wells, Rocky Reach, Rock Island, Wanapum, and Priest Rapids). Only one of the Region B projects (Grand Coulee) is operated for storage; two of the projects (Grand Coulee and Chief Joseph) have modified operational measures under the CRSO EIS. The remaining five private non-Federal projects downstream of Chief Joseph are all run-of-river and are not part of the CRS; however, they were included in the hydroregulation planning model to quantify potential departure in metrics that could result due to operational changes between Lake Roosevelt upstream and the lower Columbia River downstream.

#### *3.3.1.3 Region C – Clearwater and Lower Snake Rivers*

Analysis Region C includes the Clearwater and lower Snake River Basins in western Idaho and eastern Washington. There are five hydroregulation projects located within Region C that have modified operational measures under the CRSO EIS. Only one of the projects (Dworshak) on the Clearwater River is operated for storage, while the remaining four on the lower Snake River below Lewiston, Idaho (Lower Granite, Little Goose, Lower Monumental, and Ice Harbor), are run-of-river projects. The Clearwater River study minor reach spans approximately 42 river miles from Dworshak Dam to the confluence with the Snake River near Lewiston, Idaho. The lower Snake River minor reach spans approximately 168 river miles from above the Grande Ronde River confluence upstream to the Columbia River confluence near Pasco, Washington, downstream. There is an authorized navigation channel between the Snake River confluence with the Columbia River and the city of Lewiston, Idaho, in the Lower Granite Reservoir that is part of this major reach.

#### *3.3.1.4 Region D – Lower Columbia River*

Region D includes the Columbia River below Richland, Washington. There are four hydroregulation projects located within Region D that have modified operational measures under the CRSO EIS (McNary, John Day, The Dalles, and Bonneville Dam). These projects generally operate as run-of-river projects, even though there is a small amount of storage at John Day Dam. The upstream extent of Region D begins at the downstream extent of Region B near the confluence of the Columbia and Yakima Rivers as well as the downstream extent of Region C (at the confluence of the Columbia and Snake Rivers). The lower Columbia River reach extends approximately 316 river miles from the confluence with the Yakima River upstream to the mouth of the Columbia River downstream near Astoria, Oregon. There is an authorized navigation channel between RM 3 near the Pacific Ocean and McNary Reservoir that is also part of this major reach.

### 3.3.2 Affected Environment

For this EIS analysis, river mechanics response in the analysis area is a combined function of the following: hydrology, sediment supply, and hydraulic response which is driven by slope, channel geometry, and roughness. Hydraulic response within the system is characterized by three major types: storage reservoirs, run-of-river reservoirs, and free-flowing reaches. The baseline characteristics for the affected environment analysis area are summarized in the following section.

#### *3.3.2.1 Hydrology*

The typical mean daily flows throughout the year at a few key locations in the Columbia River Basin are shown in Figure 3-103. The largest alteration to flow occurs at storage dams, which are operated to balance various flow release and water storage needs according to the operational goals for each project. Because of flow regulation, high discharges during the flood season (spring freshet period) are less frequent than during pre-regulation (pre-1930s) times; conversely, there are typically higher discharges during the summer and fall than during pre-regulation times.

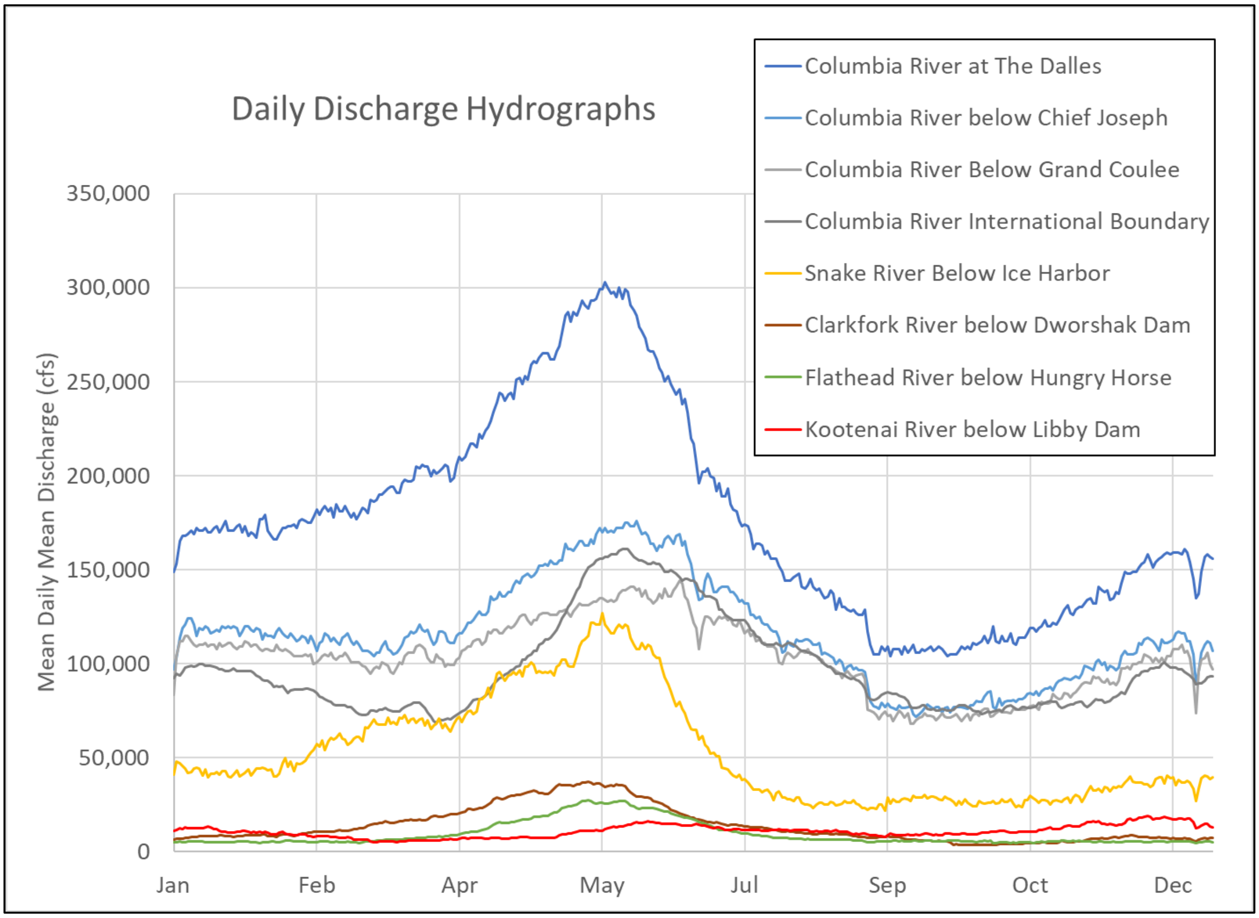

**Figure 3-103. Mean Daily Mean Discharges at U.S. Geological Survey Gages**

Note: Data is for water years 1977 to 2017 downstream of storage dams, at Chief Joseph Dam, at Ice Harbor Dam just upstream of the confluence of the Snake River with the Columbia River, and at the U.S.-Canada border.

#### *3.3.2.2 Sediment Supply*

Very little sediment crosses the U.S.-Canada border because upstream dams trap it. Primary mechanisms of sediment delivery to the Columbia River Basin between Grand Coulee and Bonneville Reservoir are landslides and bank erosion that contribute fine-grained sediment that is mostly transported in suspension (e.g., Alden 1953; Kiver and Stradling 1995; Washington Division of Geology and Earth Resources 2016a, 2016b; Washington Geological Survey 2017a, 2017b). From Bonneville Reservoir downstream, sediment is largely sourced from volcanic rocks and is typically coarse grained, contributing to bedload (Whetten, Kelley, and Hanson 1969). Overall, tributaries that produce the greatest volumes of sediment include the Snake, Okanogan, Yakima, and Palouse Rivers (Whetten, Kelley, and Hanson 1969). Sediment deposits in river reaches now occupied by reservoirs are also subject to shoreline erosion. This is especially true during filling of reservoirs, periods with fluctuating water levels, and reservoir drawdowns (e.g., Schuster 1979; Cox et al. 2005). Wave energy can cause shoreline erosion following reservoir filling; however, if reservoir levels are maintained, the shoreline may eventually approach an equilibrium profile (e.g., Lorang, Komar, and Stanford 1993), decreasing the sediment yield from shoreline erosion over time.

Sediment supply and transport is affected by dams and flow regulation. Mainstem and tributary dams trap sediment by changing hydraulic conditions in their impoundments and reducing sediment supply in downstream river reaches. Flow regulation and the reduction of peak flows through dam operations further reduce sediment transport capacity. Because sediment transport capacity is much greater at high flows than low flows, reducing the magnitude of high flows can reduce the overall capacity of a reach to move sediment. The primary sediment sources in the Columbia River Basin are incoming sediment load from reaches and tributaries upstream of a given location, point sources such as landslides and debris flows contributed from hillslopes along the river and reservoir reaches, and locally eroded sediment from the channel bed, river banks, reservoir shorelines, and floodplains. However, most of the reaches evaluated have more than 90 percent of the upstream drainage area affected by upstream dams, which alters the incoming flow and greatly reduces the incoming sediment supply. A few exceptions include Hungry Horse Dam (Flathead River), Libby Dam (Kootenai River), and Dworshak Dam (North Fork Clearwater River) with largely unaltered incoming river flow and sediment supply due to the relatively pristine conditions of the upper watersheds. Existing sediment inputs to the reaches are described below to provide context for potential changes in sediment transport under the No Action Alternative and MOs.

The current average annual sediment load in the Columbia River at Vancouver, Washington, has been reduced by an estimated 58 percent from pre-1930s conditions (Sherwood et al. 1990). This reduction in total sediment load is biased toward coarse sediment, with an 80 percent reduction in sands and a 42 percent reduction in silts and clays from pre-1930s conditions. The total reduction in sediment load can be attributed to multiple factors including reduction in peak flows due to system regulation and land use practices, as well as trapping of sediments in the reservoirs. With an estimated pre-1934 total load at Vancouver at 18.5 million tons per year, the 241,000-square-mile basin upstream of Vancouver has historically been a low-sediment-yield basin relative to other major rivers with an average of 77 tons per square mile. This yield per square mile is 28 percent of the Mississippi River and 7 percent of the Colorado River suspended load yield, for comparison (Holman 1968).

#### *3.3.2.3 Storage Reservoirs*

In the CRS, there are six dams that are designed and operated for flood, irrigation, or other storage purposes: Libby, Hungry Horse, Albeni Falls, Grand Coulee, John Day and Dworshak. In this analysis, John Day Dam is included in both the storage project and run-of-river categories. While John Day is authorized for FRM, it has limited storage capacity and is operated more like a run-of-river project where the project does not store incoming flow. Operators change the pool elevation at these storage projects over large ranges throughout the year to capture and release water in specifically designed ways.

**HEAD OF RESERVOIR SEDIMENT MOBILIZATION**

All reservoirs formed by dams on natural watercourses trap some sediment over time. Sand, gravel, and cobbles entering a reservoir as bedload typically deposit as a delta in the upstream end of reservoirs and along the upstream river channels as the flow of the river encounters backwater from the reservoir, slowing velocities and spreading out flow through multiple channels (Figure 3-104). Sediment deposited in the delta (commonly referred to head of reservoir deposits) can be remobilized farther downstream when the reservoir operating pool lowers (during reservoir drawdown), or during floods when sediment transport capacity is increased. In dams that operate over a wide range of elevations throughout the year, the upstream extent of reservoir backwater may shift considerable distances. Very fine, suspended silts and clays tend to transport past the delta and slowly settle out of the water column along the reservoir bottom as a lakebed deposit. Reservoirs with large storage volumes relative to the annual volume of water passing through the reservoir tend to trap more suspended sediment than reservoirs with smaller relative storage volumes.

If reservoir drawdown leaves the delta exposed to riverine conditions during high flow periods, the upper layers of the delta are often eroded and transported further into the reservoir, potentially increasing turbidity and downstream sediment deposit thickness. Changes in storage project elevations or changes to the flow of water and sediment into the reservoir can result in changes to the delta erosion and deposition patterns. This metric compares the paired relationships of flow and stage over time to indicate potential for change in sediment mobilization at the head of reservoir for each alternative. Changes in delta sediment mobilization could alter the sediment load farther downstream within the reservoir and potentially the amount of sediment passing a dam, particularly during high flow periods.

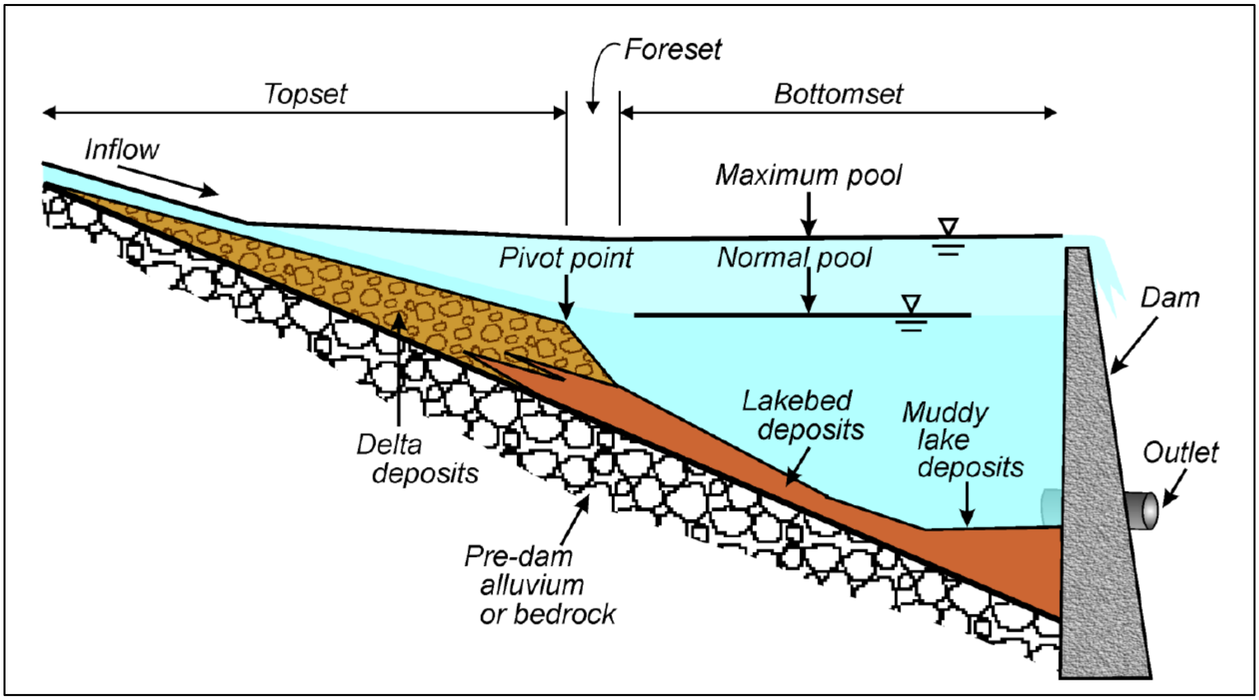

**Figure 3-104. Reservoir Sediment Profile with Delta and Lakebed Sediment Deposits**

Note: Reproduced with permission from Randle and Bountry (2017) after Morris and Fan (1997).

### Region A – Libby Dam: Head of Reservoir Sediment Mobilization

The focal point for deposition within the Libby reservoir (Lake Koocanusa) depends on the minimum drawdown elevation in the spring before the spring freshet (when 90 percent of the annual sediment load is mobilized). Since the early 2000s, the minimum pool elevation has ranged from a low of about 2,370 to a high of 2,420 feet NGVD29 (2,374 to 2,424 feet NAVD88) in elevation, which correlates to minimum lake backwater extent of RM 280 (near Kragmont, British Columbia) to RM 300 (4 miles downstream from Wardner, British Columbia). The maximum pool elevation (2,459 feet NGVD29 [2,463 feet NAVD88]) can extend upstream of Wardner to the Bull River confluence. Thus, Kootenai(y) River sedimentation (sand and gravel) in Lake Koocanusa is likely concentrated between Wardner and the Kootenai(y) and Tobacco River confluence, given that these locations correspond with the maximum and minimum reservoir elevations. Fine sediment is likely depositing throughout the reservoir but is focused primarily in the deeper portions of the reservoir near the dam.

### Region A – Hungry Horse: Head of Reservoir Sediment Mobilization

Little information is available regarding sedimentation in Hungry Horse Reservoir because of a lack of sediment load data and limited bathymetric survey. A recent bathymetric survey is available from 2018 that provides a longitudinal profile of Hungry Horse Reservoir with more detailed survey for the forebay extending about 0.5 mile upstream of the dam (Collins 2020). There are no large tributaries entering this reach as the reach is closely paralleled by the Swan Range to the west and the Flathead Range to the east. The majority of flow into the reservoir is from the upper South Fork Flathead River. One of the larger tributaries entering the reservoir, Sullivan Creek, has mean annual flows on the order of a few hundred cubic feet per second (U.S. Geological Survey [USGS] Gage 12361000). The drainage basin is almost all within U.S. Forest Service land management areas that were historically logged. Based on historical survey contours of unknown date (provided by Reclamation Pacific Northwest Regional Office, Boise, Idaho), the minimum pool elevation of 3,426 feet NGVD29 (3,430 feet NAVD88) has a backwater extent near RM 32 and the maximum pool elevation of 3,560 feet NGVD29 (3,564 feet NAVD88) extends another 9 miles to RM 41. A sediment delta is visible on a September 23, 2003, aerial photograph of the area between RM 38 and at least RM 41. The delta likely extends farther upstream. The reservoir delta is currently expected to be eroded and mobilized farther downstream in the reservoir during drawdown and would be expected to continue in No Action Alternative conditions.

**Region A – Albeni Falls: Head of Reservoir Sediment Mobilization**

The downstream control point of Lake Pend Oreille is Albeni Falls Dam, although there is a natural restriction near Dover, Idaho at RM 113—roughly 24 miles upstream of the dam—that can control flow based on lake elevation (velocities in the dam forebay channel can be “river-like” during high flow conditions). The water surface elevation of the lake may be 6 to 10 feet higher than that of the forebay due to the natural channel restriction at the lake outlet. The head of the reservoir is effectively the 4-mile-long Clark Fork River Delta, including the mouth of Lightning Creek. Lake level influences the velocity, depth, and general hydraulic conditions up to about a mile above Lightning Creek.

Rain-on-snow events and spring runoff have the potential to move tremendous amounts of bed load in tributaries of the Clark Fork River, but especially in the Lightning Creek drainage. A large alluvial gravel deposit has developed in the mainstem of the Clark Fork River in the floodplain of Lightning Creek, just upstream of the Clark Fork River Delta. The gravel bar includes a layer of gravels and sands deposited in the area by Lake Missoula, but now also hosts the thick gravel fragments and coarse cobbles of the Lightning Creek alluvial deposit.

The Lake Pend Oreille delta is composed of fine-grain sediments deposited in slackwater by the low-gradient Clark Fork River. The delta has likely been depositing since its formation, but the process likely accelerated following completion of the dam. The reduction in available sediment bedload within the Clark Fork River following completion of the upstream dams (Cabinet Gorge and Noxon Rapids) has also likely contributed. The bedload coming out of Lightning Creek is relatively high and dominantly comprised of large gravels and cobbles which ultimately settle at the Clark Fork River confluence due to the abrupt decrease in gradient between the creek and river.

**Region B – Grand Coulee: Head of Reservoir Sediment Mobilization**

Much of the sediment that would enter this reach from upstream is trapped by reservoirs in Canada, including behind four large hydroelectric dams. The reach of the Columbia River between the U.S.-Canada border and Grand Coulee Dam is naturally a bedrock-controlled river, lacking a thick alluvial cover (Whetten, Kelley, and Hanson 1969).

The mainstem Columbia River profile measured in 2010 and 2011 includes numerous pools between the U.S.-Canada border and Grand Coulee Dam that range in depth from 20 to more than 100 feet. The first 40 miles upstream of the dam contain several scour pools 30 to 40 feet deeper than the typical reservoir bottom, which indicates sediment supply has not been large enough to fill in the pools. The maximum reservoir pool extends upstream approximately 150 miles from the dam at RM 596 to about RM 746 based on 2010 topography. The minimum pool extends 121 miles upstream from the dam to about RM 717. Any sediment delta present between RM 717 and RM 746 could be eroded during reservoir drawdown operations. However, in this reach there was no sediment delta present, and several pools persist that are tens of feet deep, indicating sediment deposits are likely limited to partially filling pools and on floodplains when inundated at higher reservoir elevations. Two of the largest pools are more than 140 feet deep located near the confluences of the Columbia River with Onion Creek (RM 733.6) and the Kettle River (RM 709). The persistence of the deep pools means that either there are fast velocities along the reservoir bottom at these locations or the reservoir sedimentation rates are slow.

Sediment deltas can also form where tributaries enter the backwater from Lake Roosevelt. The first major tributary upstream of the dam is the Sanpoil River (RM 615) where Lake Roosevelt inundates about 9 miles of the tributary at full pool. The difference between maximum and minimum pool is 2 miles long where there is potential to mobilize any sediment deposited from the Sanpoil River Basin. Within Lake Roosevelt, the largest tributary is the Spokane River (total drainage area of 6,750 square miles), which begins at the outlet of Lake Coeur d'Alene, Idaho, and enters the Columbia River at RM 640 about 44 miles upstream of Grand Coulee Dam. The Spokane River contributes the largest amounts of suspended sediment to Lake Roosevelt (Whetten, Kelley, and Hanson 1969), but coarse sediment contributions that would tend to form a sediment delta are limited. Seven hydroelectric dams have been constructed on the mainstem Spokane River between 1890 and 1922 (Northwest Power and Conservation Council [NW Council] 2019c). Based on topographic intersection of reservoir pool elevations measured in 1974 (5-foot contours), the backwater from Lake Roosevelt extends about 18.5 miles upstream at minimum pool and 32 miles upstream at full pool (Ferrari 2012). Aerial photography from 1936 (after construction of the seven Spokane River dams) and recent aerial photography (1992 to 2017) do not show any exposed sediment delta downstream of Little Falls Dam. Further, the 2010–2011 survey measured several scour pools around 20 feet in depth (Ferrari 2012). The lack of visible sediment delta may be due to limited sediment supply due to trapping in upstream Lake Coeur d'Alene and behind the seven dams. There are several landslides along the Lake Roosevelt Arm of the Spokane River. A major landslide deposited more than 60 feet of eroded material above the original river channel area at RM 3.7. However, the landslide deposit is 40 feet below the minimum pool so it would not be expected to have any mobilization due to reservoir drawdown.

Lake Roosevelt creates about a 1.5-mile backwater up the Colville River, which enters the Columbia River near RM 702.4. The difference in maximum and minimum pool exposes about 1 mile of river that could create a sediment delta subject to erosion during reservoir drawdown. A larger tributary is the Kettle River, which enters near RM 709 on the mainstem Columbia River.

The 2010–2011 survey went about 3.5 river miles upstream on Kettle River near Kettle Falls. The maximum pool extends about 8 miles upstream on the Kettle River, and the minimum pool drops all the way to the Kettle River confluence with the Columbia River. Reservoir drawdown does have the potential to mobilize any deposited sediment from Kettle River incoming sediment loads. Upstream of Kettle Falls the reservoir does not create a substantial backwater pool in any tributaries.

Since the late 1800s, large amounts of slag have been released into the upper Columbia River from an upstream smelter operation. Because Lake Roosevelt has a high sediment trapping efficiency, much of the incoming slag has been retained within Lake Roosevelt, particularly in the upstream reaches (Teck 2017). As a result, bed and bank sediments in Lake Roosevelt contain elevated metals.

**Region C – Dworshak: Head of Reservoir Sediment Mobilization**

Dworshak Reservoir lies within narrow, steep canyons of the North Fork Clearwater River. Dworshak Dam traps sediment from 26 percent of the Clearwater River drainage basin (which is 2 percent of the Snake River drainage area). The reservoir extends approximately 51 miles upstream of the dam at full pool elevation. The drainage area upstream of the dam is topographically rugged, densely timbered, sparsely populated, and largely undeveloped with a total area of approximately 2,440 square miles (Corps 1986). The reservoir is drawn down during the winter to provide storage space for FRM.

Note that Dworshak Reservoir is the only reservoir in Region C operated for storage; the remaining reservoirs in Region C are run-of-river reservoirs. Sediment mobilization at the head of run-of-river reservoirs was computed separately via the "Potential for Bed Material Change Metric." Discussion of the head of reservoir sedimentation for Lower Granite Reservoir is presented in Section 3.3.2.4, below.

**Region D – John Day: Head of Reservoir Sediment Mobilization**

Unlike the other CRS storage reservoirs, John Day was constructed with navigation as a primary purpose. The project provides for minimum depth of 15 feet of water between John Day and McNary Dams. Due to this design requirement, and sediment trapping in upstream dams, there is no traditional head of reservoir delta or deposition occurring in the mainstem Columbia River in the John Day Reservoir.

**SEDIMENT TRAP EFFICIENCY**

All the reservoirs in the study area can trap a portion of the material that enters their pools, reducing the incoming sediment to downstream reservoirs. Trap efficiency is the proportion of inflowing sediment deposited in the reservoir relative to the total incoming sediment load. The trap efficiency is computed based on the ratio of reservoir storage volume to annual inflow. Reservoirs with high trap efficiency generally trap the coarse sediment in reservoir deltas, while a portion of the fine sediment can be transported through the reservoir and released downstream. The actual amount of sediment trapped is dependent not only on trap efficiency but also the incoming sediment load.

A trap efficiency less than 10 percent indicates very little sediment has accumulated in a reservoir, whereas a trap efficiency greater than 90 percent indicates potential for a large accumulation of reservoir sediment. John Day traps the least amount of sediment (44.9 percent) amongst the storage projects, which can be attributed to its small reservoir volume relative to the annual hydrograph. Albeni Falls (70.6 percent) and Grand Coulee (77.8 percent) trap approximately three-quarters of incoming sediment. Libby (90.7 percent), Hungry Horse (95.0 percent), and Dworshak (93.0 percent) have the highest sediment trap efficiencies.

**Region A – Libby Dam: Sediment Trap Efficiency**

Based on the sediment flux (total tons transported per year) measured in the 1960s near Libby Dam, it was estimated that 100,000 acre-feet of sediment would be trapped in Lake Koocanusa over a period of 100 years (Corps 1971). The volume of sediment that this represents over a 100-year period equates to about 2 percent of the 5-Maf total reservoir active flood control space (Corps 1971). By comparing the pre- and post-dam average annual sediment loads at the Libby and Copeland stations, the annual average sediment deposition can be estimated. Data confirms the 1971 estimate of 1,000 acre-feet per year and estimates that Libby Dam could accumulate about 31,000 acre-feet of sediment (suspended load, plus 10 percent for bedload) in a 30-year period.

**Region A – Hungry Horse Dam: Sediment Trap Efficiency**

While not much is known about reservoir sedimentation in Hungry Horse, it has a high trapping efficiency for sediment delivery from the 1,168-square-mile South Fork Flathead River catchment that prevents the majority of incoming sediment from going downstream past the dam to the main stem Flathead River.

**Region A – Albeni Falls Dam: Sediment Trap Efficiency**

Lake Pend Oreille, at more than 1,000 feet deep in some locations, acts as a natural sediment sink upstream of Albeni Falls Dam. The sediment trap efficiency is relatively high (70-plus percent), and it is responsible for reduced sediment supply conditions downstream along the lower Pend Oreille River.

**Region B – Grand Coulee Dam: Sediment Trap Efficiency**

The historical Columbia River channel within Lake Roosevelt is governed by the underlying bedrock because the riverbed does not have a deep layer of alluvium. Within the reservoir (Lake Roosevelt), substantial alluvial deposits are widely spaced and generally small in volume in both the riverine and lacustrine reaches of the reservoir (Ferrari 2012). The sediments that do accumulate in Lake Roosevelt consist of armored gravels between the U.S-Canada border and Onion Creek, which can become riverine during minimal pool conditions. Farther downstream, the river bed is primarily silt and clay in the middle and lower Lake Roosevelt (lacustrine) reaches (Whetten, Kelley, and Hanson 1969; Windward Environmental LLC 2017).

**Region C – Dworshak Dam: Sediment Trap Efficiency**

Sediment range lines have been surveyed in Dworshak Reservoir to measure sediment deposition, but the survey measurements are not reported here because the accuracy could not be verified; Dworshak Reservoir can exceed 600 feet in depth and is thermally stratified, making precise acoustic measurements highly sensitive to depth-varying calibration of the speed of sound. The Dworshak water control manual (Corps 1986) estimated an average annual sediment load on the order of 300 acre-feet per year, based on measurements of other streams in the region. Since the time of that estimate, limited sediment load measurements have been taken on the North Fork Clearwater River upstream of Dworshak and on two tributaries of the South Fork Clearwater River, which seem to support the argument made in the water control manual that the north fork is like other streams in the region. However, these measurements were taken during the spring season, and therefore would not have included mass wasting during large winter floods, which have the potential to exceed spring sediment loads. The estimate provided in the water control manual is higher than current sediment load estimates for the entire Clearwater River and is the only available estimate at this time. If the 300 acre-feet estimate is reasonable, it could take more than 2,500 years to accumulate a volume of sediment equal to the dead storage space in Dworshak Reservoir. However, this is an order of magnitude estimate and could therefore be conservatively reported as 250 to 2,500 years. In either case, the sediment load appears to be relatively small compared to the storage volume.

**Region D – John Day Dam: Sediment Trap Efficiency**

The most recent assessment of sediment deposition and bed material composition in the John Day Reservoir was completed by USGS (Cross and Twichell 2004). Geophysical survey data collected in 2000 and ground-validation data collected in 2000 and 2002 revealed that reservoir had lost approximately 0.2 percent of its volume since construction. Data analysis indicated that the reservoir bottom consists of 23 percent exposed basalt, 5 percent boulders, 9 percent fine-grained sediment with an estimated thickness of 20 inches, and 53 percent shallow discontinuous veneer of fine-grained sediment. This thin veneer covers historical bars, gravel beds, alluvial fans, and other unconsolidated deposits. The upstream-most 12.5 to 15.5 miles of reservoir, representing 10 percent of the total reservoir floor, showed gravel beds completely free of fine sediment.

**SHORELINE EXPOSURE**

Wave erosion, reservoir currents, freeze-thaw, reservoir drawdown, and other processes can result in shoreline erosion of bank sediments along the reservoir margins.

**Region A – Libby Dam: Shoreline Exposure**

During the design of Libby Dam, the Corps assumed that far less sediment would enter the reservoir from mass wasting and shoreline erosion than from the river itself (Corps 1971). Corps review of available aerial imagery showed that extensive shallow landslides along the 224-mile-long shoreline has occurred around the reservoir and that few large slides were evident. No subsequent estimates of reservoir sedimentation were available to assess if the amount of shoreline erosion that has occurred since the construction of Libby Dam is in line with predictions made during earlier design efforts. It is thought that in the first decades after reservoir filling, reservoir erosion rates were likely higher than under current conditions because more than four decades have elapsed since construction allowing for the reservoir side-slopes to erode back to stable conditions.

**Region A – Hungry Horse Dam: Shoreline Exposure**

Hungry Horse Reservoir has approximately 175 miles of shoreline with little available documentation on shoreline erosion. Most of the surrounding landscape contains forested hillslopes, but areas subject to reservoir drawdown may experience erosion. A prior Columbia River System Operation Review EIS (DOE, Corps, Reclamation 1995) noted that "Hungry Horse Reservoir exhibits significant shoreline erosion in its upstream reaches, as well as several large, active landslides." The magnitude of erosion is not known.

**Region A – Albeni Falls Dam: Shoreline Exposure**

Lake Pend Oreille has a seasonal variable operating range of about 11 feet as regulated by Albeni Falls Dam, which has caused lateral shoreline erosion of the delta at a rate of about 5 to 8 feet per year for the last 50-plus years (Clark Fork Delta Restoration 2018). The Clark Fork River delta at the east end of the lake is not the only area around Lake Pend Oreille with eroding shorelines. Receding protective and stabilizing shorelines and islands at the mouths of streams and rivers have seen accelerated erosion caused by wave action, landslides, and river flows. Additional sites in the subbasin where ongoing erosion is of concern include the Pack River Delta, Strong's Island, and the mouths of Priest River, Hoodoo Creek, Hornby Creek, and Carr Creek (Idaho Department of Environmental Quality [IDEQ] 2007). Overall, the riverbank conditions of the Pend Oreille River above Albeni Falls are highly susceptible to erosion where the banks do not consist of bedrock or large boulders (Tri-State Water Quality Council 2005).

**Region B – Grand Coulee Dam: Shoreline Exposure**

Landslides are an important source of sediment along the Lake Roosevelt shoreline. Some landslides along the Columbia River within Lake Roosevelt existed before the construction of Grand Coulee Dam and are a few hundred to a few thousand years old (Pardee 1918; Kiver and Stradling 1995); other landslides appear to have been associated with destabilization of the landscape during glaciation (Flint and Irwin 1939; Jones et al. 1961). More than 500 landslides also formed along the shoreline of Lake Roosevelt in response to the filling of the reservoir and fluctuating water level (Cox et al. 2005).

**Region C – Dworshak Dam: Shoreline Exposure**

Dworshak Reservoir's shoreline is approximately 175 miles at full pool (Corps 1986). The widest sections of the reservoir are in the lower one-third of its length, where the widths range generally from about 0.5 to 1 mile, with the widest point being nearly 2 miles. The upper two-thirds of the reservoir is much narrower, ranging mostly between 1,000 and 2,000 feet. The lake water surface elevation can fluctuate up to 155 feet due to Dworshak Dam flood risk operations, but during lower risk years, the water surface is only drawn down 80 feet below full pool. Bank erosion or sloughing resulting from fluctuations in pool elevation is not known to be a serious issue.

**Region D – John Day Dam: Shoreline Exposure**

There are deep-seated landslides in the vicinity of John Day Dam and reservoir. Most mass wasting has occurred on the Washington shore. A landslide on the Washington shore was reactivated during dam construction but appears stable now. Most of the shoreline is not being significantly eroded, and riprap protection seems to be adequate for lower pool operation (Gustafson 1992).

#### *3.3.2.4 Run-of-River Reservoirs and Free-Flowing Reaches*

Run-of-river reservoirs and free-flowing reaches include all the river reaches downstream of CRS storage projects. Run-of-river reservoirs are formed by dams that are operated to discharge water downstream at rates that generally match the upstream inflows. The effect on river discharge from dam operations is generally smaller for run-of-river reservoirs than storage reservoirs. Bonneville Dam is an example of a run-of-river project that operates in a small range of pool elevations for daily or weekly hydropower purposes but does not attempt to store water for release in later seasons. There are nine CRS run-of-river reservoirs. Region B includes Chief Joseph at RM 545.7. Region C includes Lower Granite (RM 430.9), Little Goose (RM 393.8), Lower Monumental (RM 365.0), and Ice Harbor (RM 333.4) on the Lower Snake River. Region D on the Lower Columbia River includes McNary (RM 291.0), John Day (RM 216.6), The Dalles (RM 192.0), and Bonneville Dam (RM 145.7). Note that John Day Dam generally operates as a run-of-river project even though there is a small amount of storage, and thus is included in both categories. Five non-CRS run-of-river reservoirs exist in Region A and another five exist in Region B.

Free-flowing reaches are portions of the river that are not influenced by the backwater of a downstream reservoir. Free-flowing reaches experience altered hydrology where upstream dam operations have an influence on changing river discharge. The altered hydrology can affect floodplain connectivity, river morphology, and sediment transport capacity. Free-flowing reaches in Region A include the Kootenai River between Libby Dam and Bonners Ferry, Idaho, the Flathead River downstream of Hungry Horse Dam and upstream of Flathead Lake, and the Clark Fork River between SKQ Dam and Thompson Falls Reservoir. Other notable free-flowing reaches in the study area include the Northport Reach of the Columbia River upstream of Kettle Falls and the Hanford Reach of the Columbia River downstream of Priest Rapids Dam (Region

B), the Clearwater River between Dworshak Dam and Lower Granite Reservoir (Region C), and the tidal Columbia River downstream of Bonneville Dam (downstream Region D).

**SEDIMENT TRANSPORT AND SUPPLY.**

Unlike the large storage projects, nearly all the run-of-river reservoirs have a small volume of water in their pools relative to the volume of annual water flow. This results in lower trapping efficiencies than the large storage projects. In addition to the decreased ability of the run-of river reservoirs to trap sediment, the upstream sediment load is reduced because of upstream reservoirs.

Free-flowing reaches are operating in a reduced sediment environment from their historical unregulated (pre-1930s) condition because of cumulative trapping of sediment in upstream reservoirs. These reaches commonly pass the reduced incoming sediment load and have developed coarsened bed conditions, some of which are naturally armored against erosion.

Bed-material load consisting of sands and gravels entering run-of-river reservoirs and free-flowing reaches from tributaries and other processes such as localized erosion can deposit on the beds and be permanently stored in the system. Given the variability in size and nature of tributaries flowing into the study area, the amount of sediment delivered and stored at each tributary may be negligibly small or quite sizable. The Salmon River (via the Snake River) and Clearwater River sediment delivery to Lower Granite Reservoir on the Snake River is an example of a large tributary sediment supply that deposits a large volume of sediment annually.

**Region A – Kootenai River Sediment**

Glaciation on the Kootenai River during the ice ages is responsible for carving deep valleys now occupied by lakes and rivers over long and short time periods, storing large quantities of unconsolidated sediment in the basin valleys. When the ice sheet and associated glacial lake receded, the steep, rejuvenated rivers and streams widened their valleys, transporting large volumes of sediment downstream. In some places, the Kootenai River has cut through the glacial sediments into the underlying bedrock. Bedrock is exposed in the riverbed near the Fisher River, in the Kootenai Falls area, and near Troy, Montana. It is also exposed in riverbanks and bottomlands near Bonners Ferry, Idaho.

The bedrock sill at the outlet of the West Arm of Kootenay Lake arrested down-cutting. It is likely that post-glacial Kootenay Lake originally extended south along the Purcell Trench nearly to Bonners Ferry, but it was gradually filled with hundreds of feet of fine sediment eroded from up valley so that the lake was gradually converted into a floodplain (Alden 1953).

The Kootenai River downstream of Libby Dam is free flowing for approximately 61 miles, after which it becomes progressively less able to transport sediment due to backwater influences from Kootenay Lake located north of the U.S.-Canada border. In a 6-mile reach known as the “Braided Reach” immediately above Bonners Ferry, the river can pass sediment sizes up to gravels. Downstream of Bonners Ferry, sand silt and clay become the dominant material in transport with little gravel passing into the downstream reach known as the "Meander Reach." Due to the Kootenay Lake backwater, the 45-mile long Meander Reach is the least-efficient reach at passing sediment in U.S. waters below Kootenai Falls, passing fine sand and smaller grain sizes downstream.

Below Libby Dam, tributaries supply large quantities of gravel- and cobble-sized materials at rates greater than the rates the mainstem river can erode them, resulting in the formation of alluvial fan deposits. Because these locations constrict the river, they tend to transport all but the largest-sized sediment that enter from upstream. The largest-sized sediment from steeper tributaries is often found in tributary fans that persist despite high flows from the river (e.g., at the Fisher River, Yaak River, and Boulder Creek confluences). Cobble, gravel, and sand sized sediments that make it into the reaches upstream of Bonners Ferry can be transported by the river downstream to the Braided Reach; however, much of this material is too large to be transported very far downstream. Thus, the Braided Reach is a sink for gravel and coarser-sized sediment supplied by the river upstream.

Downstream of Libby Dam to Bonners Ferry, the percentage of sand within the exposed bars increases with distance from the dam because of unregulated tributary inputs. The percentage of the bed composed of sand increases dramatically in the critical Kootenai River white sturgeon spawning reach, where the Braided Reach transitions into the Meander Reach (Barton, McDonald, and Nelson 2009; Fosness and Williams 2009; McDonald et al. 2010). Previous research (Barton, McDonald, and Nelson 2009; McDonald et al. 2010) has determined that the Kootenai River white sturgeon spawning reach substrate is sand dominated now, but that this is an artifact of the reduction in peak discharges as the pre-dam high flows were routinely capable of scouring sand and exposing coarser lag deposits of gravel and cobble suitable for spawning. The researchers found that the post-dam hydrologic regime, under the highest post-dam flows, can still scour sand from these spawning areas (Fosness and Williams 2009; McDonald et al. 2010), but this occurs much less frequently than under pre-dam conditions.

**Region A – Flathead, Clark Fork, and Pend Oreille Rivers Sediment**

Even before the completion of SKQ Dam, the naturally occurring Flathead Lake and delta functioned as a sediment trap for the downstream Flathead River. Joyce (1980) concluded that Flathead Lake had been accumulating roughly 0.55 inches per year of sediment since the 1964 flood of record. The largest sources of sediment within the study reach exist in the thick Quaternary (a recent period of geologic time spanning from 2.58 million years ago until today that was marked by the advance and retreat of glaciations, greatly sculpting the landscape morphology) deposits within Flathead Valley, upstream of Flathead Lake. Shorelines of Flathead Lake provide an additional source of sediment; however, this source is not as substantial, as Flathead Lake receives more than 90 percent of its sediment from the Flathead River (Moore, Jiwan, and Murray 1982). Sediment from upstream and eroded from Flathead Lake is likely trapped within the lake, rather than traveling downstream.

Downstream of the Hungry Horse Reservoir in the South Fork Flathead, Alden (1953) notes that till (glacially transported sediment that is typically poorly sorted) and gravel have been largely eroded from many locations, allowing the river to cut bedrock gorges, leaving terraces of Quaternary gravels bordering the river in some locations.

The Flathead River below the confluence with the South Fork Flathead River is an active, anastomosing river (a river planform type where multiple channels are separated by stable mid-channel islands commonly associated with flood regimes) within a massive valley. The undammed North and Middle Forks of the Flathead River are a sediment source, and large amounts of sediment and wood are associated with a large peak flow. Deposition of debris that fills a channel, or flood flows that occupy alternative channel routes with steeper paths, are both potential risks for channel avulsions (the process of a river channel changing its planform by abandoning its previous path in favor of another channel path; this can result in the creation of a new channel or the shifting of flow to a side channel or previously abandoned channel path). In part because Flathead Lake controls the river's base level, there has also been substantial re-working, rather than removal, of these deposits within the basin (Smith 2004).

The natural sink of the deep Flathead Lake and the regulated operations of SKQ Dam make for a sediment-starved lower Flathead River. Downstream of SKQ Dam, Lake Pend Oreille is an efficient natural sediment sink in the Flathead, Clark Fork, and Pend Oreille Rivers. Between SKQ Dam and Albeni Falls, Noxon Rapids Dam traps the highest percentage of inflowing sediment. Downstream of Albeni Falls, the Slate Creek to Boundary Dam reach traps the highest percentage of inflowing sediment.

The Clark Fork River subbasin is prone to rapid runoff events; however, system wide flow regulation has curtailed this phenomenon. Glacial fluvial deposits are present in the valley, river banks, and on mountainside slopes. The highly erosive sediments have worked their way through the Clark Fork River System in infrequent flood pulses, such as 1948 and 1997, while conversely getting trapped behind hydroelectric dam projects during low- to moderate-hydrologic years.

Following the construction of Albeni Falls Dam, the lake has been held at a higher-than-natural condition and operated over a range of 11 feet. While the Clark Fork River contributes approximately 92 percent of the annual inflow to Lake Pend Oreille (IDEQ 2007), most of the annual suspended sediment load is contributed from Lightning Creek. Lightning Creek gradient and channel incision make for fairly unstable banks that are prone to naturally occurring mass failures (U.S. Department of Agriculture [USDA] 2015). A recent sediment model estimated a delivery to the Clark Fork River via Lightning Creek of more than 4,100 tons of sediment per year (IDEQ 2007). The majority of large gravels, cobbles, and boulders it transports to the river settle at the confluence because of the extreme decrease in grade from Lighting Creek to the river. The Clark Fork River Delta is an important sediment depositional zone.

The Pend Oreille River channel substrate above Albeni Falls Dam is dominated by granitic type sands and silt with areas of embedded heavy woody organic debris that is derived from catchments below Cabinet Gorge Dam. Although some recent substrate sampling work was somewhat limited in scope, very little gravel was found on the river bottom, and the gravel that was encountered was buried within sand and silt.

Box Canyon Dam likely traps coarse sediments brought in by tributaries or bank erosion. Downstream of Box Canyon Dam, the reservoir behind Boundary Dam becomes a substantial sink of bed material and some suspended sediment. Clay deposits appear in the Boundary Dam forebay, though most all of it passes through the project, according to a sediment model built for 2009 sedimentation study (Fullerton et al. 2009). Approximately one-quarter of the silt is trapped in the reservoir, and nearly 100 percent of the bed material load is trapped. The clay fractions represent on average approximately 20 percent of the forebay samples, with silt comprising most of the remaining material.

**Region B – Middle Columbia River Sediment**

Below Grand Coulee Dam, tributaries are an important source of sediment and alluvial fans exist near the junctions with many tributaries. Landslides also exists along shorelines below Grand Coulee Dam, providing sediment to these reaches. Suspended sediment concentrations in the upper Columbia River are typically low; the greatest amounts of suspended sediment are sourced from the Okanogan River. During high flow events, suspended sediment can pass through structures to downstream reaches; otherwise, suspended sediment is trapped by reservoirs.

From Grand Coulee Dam to Priest Rapids Dam, bed material is dominated by thin deposits of gravel and sand over bedrock. Generally, the grain size of reservoir deposits increases with distance upstream of the dams in each reservoir (Kelley and Whetten 1961; Whetten, Kelley, and Hanson 1969).

Below Priest Rapids Dam, the free-flowing Hanford Reach composition is largely sand, gravel, and cobbles up to 8 inches in diameter, with small fractions of silt and clay in lower-velocity deposition areas (Jamison 1982).

**Region C – Lower Snake River Sediment**

Sediment yield to the lower Snake River is derived from three major basins: upper Snake River, Clearwater River, and Salmon River. Sediment contributions to the Snake River from upstream of Hells Canyon Dam are effectively trapped by the Hells Canyon Complex (Hells Canyon Dam, along with upstream Oxbow and Brownlee Dams), and are essentially small enough to be considered negligible. The North Fork of the Clearwater River is regulated by Dworshak Dam, which retains all sediment upstream. The remaining Clearwater Tributaries (Lochsa, Selway, South Fork Clearwater, Potlatch River, and Lapwai Creek) comprise about 10 percent of the lower Snake River sediment load on average. Downstream of Hells Canyon Dam, the Salmon River sediment yield averages about two-thirds of the lower Snake River sediment load. Downstream of these confluences, the Snake River at Anatone, Washington, comprises about 90 percent of the sediment load to the lower Snake River (PSMP, Corps 2014c).

The deep run-of-river reservoirs of the four lower Snake River dams have the least ability to transport sediment of all reaches between the Columbia River and Dworshak Dam. While the four reservoirs have similar characteristics, the upstream reservoir, Lower Granite, receives a substantially larger sediment load originating in the free-flowing Salmon River, upper Clearwater River, and other smaller tributaries. Lower Granite only passes clay and silt-sized material up to coarse silt, which is largely capable of passing through the lower three Snake River Dams to McNary Reservoir.

Lower Granite Reservoir continues to be a depositional zone for Clearwater and Snake River sands and silts. Coarse sediment (median particle diameter by mass, $d_{50}$, of medium sand) settles out first near the upstream end of the reservoir, followed by finer sediment moving downstream ($d_{50}$ approaching very fine silt at Lower Granite Dam). Suspended sediments passing Lower Granite Dam largely pass through the remainder of the downstream Snake River dams. Bed material in the lower three reservoirs range from a $d_{50}$ of medium sand to fine silt with Ice Harbor Reservoir sediment being coarsest and Lower Monumental Reservoir sediment being finest. Sediment deposition in the Snake River is managed per the Lower Snake River Programmatic Sediment Management Plan (PSMP) (Corps 2014c). The PSMP is the sediment management strategy for the lower Snake River system extending from the Snake River confluence with the Columbia River to the upstream limits of Lower Granite Reservoir, including the lower portion of the Clearwater River. The management measures fall within four general categories: dredging and dredged material management, structural management, system management, and upland sediment reduction. The PSMP does not attempt to address all sediment deposition in the lower Snake River. It addresses only sediment that interferes with existing authorized project purposes of the lower Snake River Projects.

***Region C – Lower Snake River Navigation Sedimentation***

Sediment accumulates in areas where it impacts navigation or other authorized purposes in the lower Snake River System. Sediment management is conducted in these areas in conformance with the PSMP. The PSMP is the Corps' adaptive management plan for maintenance actions managing sediment accumulation in the lower Snake River Projects (Corps 2014c). According to the PSMP, "Approximately 80 percent of the volume of material historically dredged from the LSRP [lower Snake River Projects] system has come from Lower Granite Reservoir." The primary area of concern for recurring immediate actions is near the confluence of the Snake and Clearwater Rivers, which is at the upstream end of the Lower Granite Reservoir. The navigation channel can be dredged on an as-needed basis to the federally authorized depth of 14 feet at MOP. The dredged material may be placed in-water (sometimes to create beneficial shallow-water habitat for juvenile salmonids and other species) or upland.

**Region D – Lower Columbia River Sediment**

Bed material in the Columbia River at the Snake River confluence has an observed $d_{50}$ of fine sand. The bed material becomes finer going downstream with a $d_{50}$ of medium silt in the 25 miles of reservoir immediately upstream of McNary Dam. The McNary Reservoir receives sediment from multiple tributaries including the mainstem Columbia, Yakima, Snake, and Walla Walla Rivers. Sand-sized and larger sediments, as well as some silts, deposit in the reservoir below the Snake River confluence with the Columbia River, and only clays and silts are capable of passing McNary Dam.

Downstream of McNary, the lower John Day Reservoir has the lowest ability of any subreach to transport coarse sediment. While John Day Dam is a CRS storage project, the reservoir more resembles the mainstem Columbia River run-of-river reservoirs in how upstream sediment loads are supplied and transported through. Despite John Day's low ability to transport sediment relative to the downstream reaches, the upstream sediment supply is primarily silt, which largely passes through John Day Reservoir. The lower Columbia Dams do effectively trap the coarse Cascade Range tributary sediments with only medium to fine silt and clay passing Bonneville Dam. Sediments capable of passing Bonneville Dam transport all the way to the Columbia River estuary and Continental Shelf.

Bed material sediments (sand and gravel) in the Columbia River reservoirs below McNary tend to persist in these areas. The Bonneville Reservoir retains a large volume of relict fine sand that was likely deposited behind the massive Bridge of the Gods landslide 550 years ago. Episodic high sediment loading from Cascade Range tributaries will continue to provide coarse material that deposits as bed material at tributary confluences with the Columbia. The reservoirs below McNary hydraulically trap some suspended sediment passing McNary Dam and from tributary inflow directly to the reservoirs, resulting in shallow silt deposits on coarser bed material. Below Bonneville Dam, deep historical bed material deposits along with Cascade Range tributary inflow supply a bed composed primarily of medium to fine sand. Large sand waves can form in all sections of the tidal reach below Bonneville Dam, indicating active reworking and transport of bed material within the reach.

***Region D – Lower Columbia River Navigation Channel Dredging Volumes***

The current 43-foot-deep Lower Columbia River Federal Navigation Channel (LCR FNC) was authorized by Section 101(b)(13) of the Water Resources Development Act of 1999 (Public Law 106-53), and Division H, Section 123 of the Consolidated Appropriations Act of 2004 (Public Law 108-199), and constructed from 2005 to 2010. The previously authorized LCR FNC was authorized to a shallower 40-foot-deep channel. The current channel is:

- 43 feet deep and 600 feet wide from RM 3.0 to 101.4
- 43 feet deep and 500 feet wide from RM 101.4 to 105.5
- 43 feet deep and 400 feet wide in the downstream 1.5 miles of Oregon Slough
- 35 feet deep from RM 105.5 to 106.5

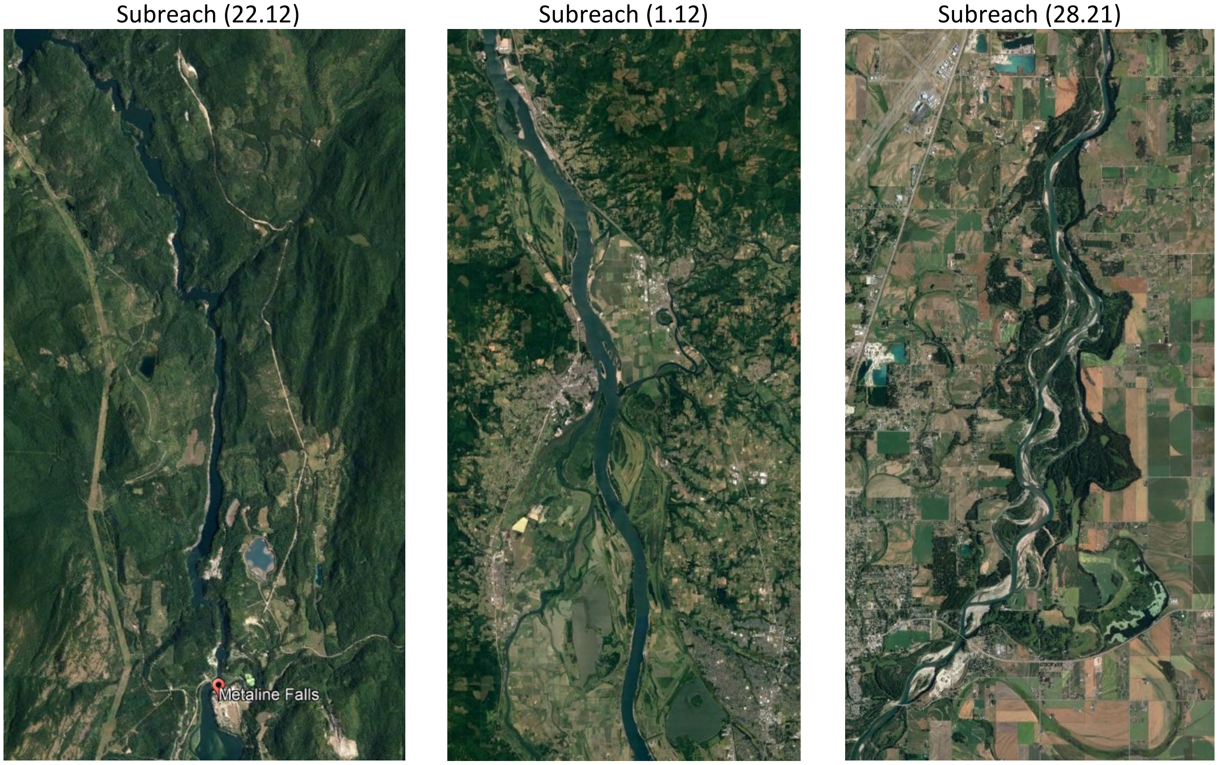
The rapidly changing and uncontrollable shoaling (shallow) conditions within the LCR FNC require continual maintenance dredging. Segments of the LCR FNC are dredged on an annual or semi-annual basis due to reoccurring shoals. Shoals require dredging depending on intensity and timing of flows and seasons. The Corps also relies on channel training features, including pile dikes, to scour sediments from the LCR FNC and thereby reduce the need for maintenance dredging over time. Present sedimentation processes require that the Corps annually remove 6 to 10 million cubic yards (MCY) of sand from the LCR FNC below Bonneville Dam. Dredged material is primarily placed in-water or adjacent to the LCR FNC, along the shoreline, and at upland sites, but the material can also be placed at designated ocean disposal and near-shore sites.

## RIVER MORPHOLOGY

The width to depth (W/D) ratio is a measure of bankfull (i.e., active channel) width to mean bankfull depth perpendicular to stream flow (Figure 3-105). High W/D ratios tend to reflect river reaches that have wide, connected floodplains or are geomorphologically complex, such as river confluences. In the Columbia River Basin, high W/D ratio reaches are typically free-flowing alluvial reaches like the Hanford Reach of the Columbia River or unique geomorphic features. An example of a unique feature is the Snake and Walla Walla River confluences with the Columbia River immediately upstream of the Wallula Gap where the Columbia River was carved wide by the Missoula Floods and is impounded by McNary Dam.

Low W/D ratios tend to indicate geologically or anthropogenically confined reaches with little floodplain connection and deeper channels that have high sediment transport potential. Within the area of analysis, low W/D ratio is typically due to natural valley confinement such as on the South Fork Flathead River immediately downstream of Hungry Horse Dam where the river flows in a deep mountain canyon. The majority of reaches in the study area exhibit a W/D ratio between 10 and 100 for annual peak flows.

| **Low** | **Moderate** | **High** |
|---|---|---|
| Pend Oreille River between Metalne Falls, Washington, and Slate Creek Subreach (22.12) | Columbia River between Willamette and Cowlitz Rivers Subreach (1.12) | Flathead River, Columbia Falls, Montana Subreach (28.21) |



| | | |
|---|---|---|
| Median W/D radio: 9, Interquartile range: 6–14 | Median W/D radio: 78 Interquartile range: 64–100 | Median W/D radio: 160 Interquartile range: 118–293 |

**Figure 3-105. River Planform Examples of Relatively Different Width to Depth Ratio Ranges Observed in the Columbia River System study area.**

**Region A – Kootenai River Morphology**

In the 26 river miles between Libby Dam and Kootenai Falls, median W/D ratios are moderate (68 to 78) with an interquartile range between 45 and 118. Downstream of Kootenai Falls, the river enters the 33-mile-long Canyon Reach with a median W/D ratio of 50 and an interquartile range between 29 and 74.

Relatively moderate to high W/D ratios occur in the active alluvial Braided Reach of the Kootenai River with an interquartile range between 70 and 200 and median around 90. This is a transitional reach from the steeper, confined upstream Canyon Reach (median W/D ratio around 50) to the flat-gradient expansive Meander Reach that enters Kootenay Lake. Despite the wide valley and high relative W/D ratio, the Braided Reach has experienced levee construction that confined the active valley by approximately 50 percent.

Low W/D ratios are observed downstream in the Meander Reach of the Kootenai River. Despite the expansive valley width due to its geologic history as a former embayment of the Glacial Kootenai Lake, the reach exhibits low W/D ratio with an interquartile range between 18 and 33 and a median around 23. Continuous levees on both banks have reduced the floodplain by 90 percent and confined the active valley by 66 percent. The moderately active channel has greater depths than the upstream Braided Reach, adding to the low W/D ratio.

**Region A – Flathead, Clark Fork, and Pend Oreille Rivers Morphology**

Within the Flathead, Clark Fork, and Pend Oreille Rivers below SKQ Dam, there is great variability in W/D ratios.

Between Hungry Horse and SKQ Dams, the upstream and downstream ends of the major reach have low W/D ratios while the middle reaches and Flathead Lake have high W/D ratios. Immediately downstream of Hungry Horse Dam the South Fork Flathead River has a single-thread stream channel in a narrow bedrock canyon resulting in low W/D ratio with a median less than 30. The Polson to SQK Dam reach is similarly a single-thread channel flowing in a narrow gorge cut through bedrock.

From the confluence of the South Fork Flathead River with the mainstem Flathead River downstream to Polson, the reaches exhibit high W/D ratios (median between 135 and 160). The reaches upstream of Flathead Lake are characterized by an anastomosing stream channel within a wide valley filled with thick unconsolidated deposits. Flathead Lake itself is simply immensely wide and not necessarily well represented by the W/D ratio metric as it is fundamentally a naturally formed lake.

The highest W/D ratios in Region A are seen at the Clark Fork River Delta (median around 85), which is the largest area of contiguous wetland complex in the Pend Oreille River System. The delta extends roughly 4 miles downriver from the town of Clark Fork, Idaho, and is roughly 3 miles wide where the delta meets Lake Pend Oreille. The Indian Creek to River Bend subreach below Albeni Falls Dam is another high W/D ratio reach with an interquartile range between

106 and 160 and a median near 132. The valley between the Selkirk Mountains to the east and the Kalispell Mountains to the west becomes wide at this point.

Reaches of low W/D ratios are seen throughout the Clark Fork River between Thompson Falls Dam and Cabinet Gorge Dam with median ratios between 17 and 38. This reach follows the Hope fault, which lies on the riverbed as a structural separation of the Cabinet and Bitterroot Mountains (USGS 1946). Near Cabinet Gorge, there are now vertical rock cliffs hundreds of feet high. Low W/D ratios are also present downstream of Box Canyon Dam between Metaline Falls and Boundary Dam with median ratios less than 10.

**Region B – Middle Columbia River Morphology**

Between Grand Coulee Dam and the U.S.-Canada border, there are four defined subreaches of the middle Columbia River spanning approximately 143 river miles. The three upstream-most subreaches constitute approximately 99 river miles upstream of the Spokane River confluence with median W/D ratios between 37 and 45 and an interquartile range between 26 and 77. The lower 44 river miles downstream of the Spokane River confluence comprise the lower Lake Roosevelt subreach with a median W/D ratio of 25 and an interquartile range between 19 and 34.

Downstream of Grand Coulee Dam to the Yakima River confluence there are two reaches that exhibit high W/D ratios. Within the Upper Wells Reservoir subreach, there is high variability of W/D ratios (interquartile range between 30 and 300) including a wide and shallow area near the Okanogan River confluence at Brewster, Washington. The second highest W/D ratio subreach extends from Lower Wanapum Reservoir downstream to Richland, Washington, with median W/D ratios between 90 and 100. Despite appearing as a continuously wide W/D zone, the river upstream of Priest Rapids Dam is impounded while the Hanford and Richland Reaches are free-flowing. The inundated width at the Wanapum and Priest Rapids projects is particularly wide relative to the depth of the reservoirs, resulting in the high W/D ratio. The free-flowing alluvial reaches downstream have bar and island complexes throughout. There are two Middle Columbia reaches that exhibit low W/D ratios. Chief Joseph Reservoir is narrowly confined in Columbia Plateau bedrock, particularly in the downstream portion of the reservoir with a median W/D ratio around 12. Low W/D ratios are also observed downstream in the Lower Rock Island Reservoir reach near the community of Wenatchee, Washington, with a median W/D ratio around 40 and the 25th percentile ratio near 20.

The Middle Columbia River from Grand Coulee Dam to the Yakima River confluence is extensively shaped by Ice Age outburst flooding. Below Grand Coulee, the Columbia River has an irregular channel with meanders that are narrowly confined by Columbia Plateau bedrock bluffs to Bridgeport, Washington. Downstream of Bridgeport, the Columbia River flows along the border between the Columbia Plateau and North Cascade province. The reach between Bridgeport and Priest Rapids Dam is a semi-confined channel separated by alluvial valleys. Below Priest Rapids Dam, the free-flowing alluvial Hanford Reach flows along the edge of Channeled Scabland.

**Region C – Clearwater and Lower Snake River Morphology**

The Clearwater and Lower Snake River reaches are cut deeply into the Columbia River Basalt Plain. In the lower subreach between Ice Harbor and McNary Reservoir confluence, the Snake River enters the downstream portions of the Channeled Scablands carved by Ice Age floods with a median W/D ratio around 130. The Ice Harbor Reservoir subreach is distinct in that there are localized areas of both relatively high and low W/D ratio zones intermittently occurring within the subreach with a median W/D ratio of around 50. This variability demonstrates the scale and complexity of the alternating slots, pools, and bars carved into the basalt plain by Ice Age events. Between Ice Harbor Dam and the Clearwater confluence near Lewiston, Idaho, the Snake River is more confined with median subreach W/D ratios between 30 and 70. While portions of the free-flowing Clearwater and Snake Rivers upstream of Lower Granite Reservoir are highly confined in a steep and deep valley, median W/D ratios range between 40 and 110.

**Region D – Lower Columbia River Morphology**

Similar to the Lower Snake River below Ice Harbor, the McNary Reservoir reach is cut deeply into the Columbia River Basalt Plain and occupies the downstream portions of the Channeled Scablands carved by Ice Age floods. In the McNary Reservoir area, the subreach between the Snake River confluence and Wallula is characterized by a relatively high W/D ratio with a median of nearly 500. This wide and shallow reach upstream of the bedrock basalt Wallula Gap was carved by the Missoula Floods and is impounded by McNary Dam. The alluvial Snake and Walla Walla River confluences with the Columbia River are both located in this subreach.

The Columbia River below McNary cuts a narrow sea-ward path through the Cascade Range before meeting the north end of the Willamette Valley. The Columbia River then passes through the Coast Range before flowing into the Pacific Ocean. Columbia River waters are affected by the tide upstream to Bonneville Dam. Prior to construction of the dam, the head of tide extended 3 miles further upstream to Cascade Falls near the town of Cascade Locks, Oregon, and the site of the historical Bridge of the Gods Landslide.

On the Columbia River below McNary Dam, there are three areas that exhibit high W/D ratios. The upstream most reach is the upper John Day Reservoir near the Blalock Islands where the valley is wide and the river flows through Quaternary deposits. Further downstream, below Bonneville Dam, in the area between Skamania and Vancouver, Washington, are free-flowing sand bed reaches at the downstream end of the Columbia River Gorge where the river meets the wide Willamette Valley. The most downstream zone is the Columbia River below the Cowlitz River, a zone that includes the wide and shallow tidal estuary.

Two Lower Columbia subreaches exhibit moderately low W/D ratios. Upstream is The Dalles Dam to Memaloose Island subreach where the Columbia River passes through a tightly confined bedrock slot downstream of the now inundated Celilo Falls with a median W/D ratio around 50. Downstream is the Cascade Falls to Bonneville Dam subreach which is confined from the north by remnants of the Bridge of the Gods Landslide with a median W/D ratio under 20.

### 3.3.3 Environmental Consequences

Environmental consequences related to river mechanics processes were evaluated in a comparative nature between a select MO and the baseline No Action Alternative. The general approach for evaluating system response for river mechanics was to use the stochastic daily output from the quantitative hydroregulation planning models as analysis inputs to compute a suite of seven quantitative metrics as described in Section 3.3.3.1, below. Note that in order to accurately represent spatiotemporal effects, the hydroregulation model analyses were applied using daily average values over the entire FCRPS basin and metrics presented herein are limited to the previously identified CRS projects. Due to a number of limitations associated with the H&H modeling process (see Appendix B), the baseline conditions established by the No Action Alternative results may not necessarily completely characterize the actualized conditions. More specifically, the daily average resolution of H&H results are limited in that sub-daily variability is not represented. The most sensitive parameter to sub-daily variability is expected to be reservoir operational stage which is used to compute energy grade slope and subsequently boundary shear stress, one of the primary inputs for sediment transport metrics. Nonetheless, considering the size of the study area and the stochastic methodology used, the No Action Alternative and MO results were deemed sufficiently representative to adequately describe the hydrology and hydraulics as required to establish a general baseline of the study area for trend and departure analysis.

Environmental consequence impacts are identified for each of seven river mechanics metrics based on thresholds of relative change (MO versus No Action Alternative) normalized to five levels (No Effect, Negligible, Minor, Moderate, and Major). To facilitate interpretation, the results for the estimated environmental consequences are presented in the following sections organized by each alternative and grouped by CRS project type (storage or run-of-river).

#### *3.3.3.1 Analysis Metrics*

Both quantitative and qualitative assessment methods were used to assess relative potential changes to river mechanics (sediment transport and geomorphology) for each MO. Seven quantitative metrics were developed to represent various physical characteristics and processes that could affect storage reservoirs, run-of-river reservoirs, and free-flowing reaches as enumerated below.

- Storage Project Metrics
  - Head of Reservoir Sediment Mobilization
  - Sediment Trap Efficiency
  - Shoreline Exposure
- Run-of-River Reservoirs and Free-Flowing Reach Metrics
  - Potential for Sediment Passing Reservoirs and Reaches
  - Potential for Bed Material Change

- Potential Change to Width to Depth Ratio
- Potential Changes to Navigation Channel Dredging Volumes

These seven scalar metrics are derived as deterministic calculations based on the H&H numerical modeling work (see Section 3.2.2.1) which established stochastic datasets that represent the system state of hydrology, hydroregulation, and riverine hydraulics. While dimensionally consistent, the geomorphic and sediment transport metrics are intended to provide a measure of relative change between a single MO and the baseline No Action Alternative insofar as it relates to trends in hydraulic departure for a select MO. It is also important to note that the stochastic hydrology for the No Action Alternative (see Section 3.2) was derived assuming climactic stationarity (i.e., without climate change). A discussion of sediment and geomorphology for the No Action Alternative under a future with climate change is presented separately in Chapter 4.

Due to the large size of the study area, the spatiotemporal variability of supporting calibration data (e.g., bed material gradation and sediment supply), and limitations of the base input planning models, the scalar magnitude of a select metric at a discrete location and time may not necessarily represent actualized conditions. The quantitative metrics were interpreted within a subreach context to estimate qualitative trends for anticipated impacts at various locations within the study area. In addition, for the Environmental Consequences assessment of the *Breach Snake Embankments* measure under MO3, a numerical mobile bed riverine hydraulic model was developed as described in Section 3.4 of Appendix C. Additional detail regarding the geomorphology and sediment transport metrics can be found in Appendix C.

**STORAGE PROJECT METRICS**

There are six CRS dams that are designed and operated for flood, irrigation, or other storage purposes: Libby, Hungry Horse, Albeni Falls, Grand Coulee, John Day and Dworshak. Note that while John Day can be operated as a run-of-river project, it also includes a small amount of storage and thus was also evaluated for the storage project metrics. Operators change the pool elevation at these storage projects over large ranges throughout the year to capture and release water in specifically managed ways.

**Head of Storage Reservoir Sediment Mobilization**

The head-of-reservoir sediment mobilization metric is designed to indicate the potential for changes in sediment scour and deposition patterns in the most upstream portion of storage reservoirs. In dams that use large amounts of storage volume and operate over a wide range of elevations throughout the year, the transition from riverine to reservoir conditions can shift upstream and downstream considerable distances. If reservoir drawdown leaves the delta exposed during high-flow periods, the upper layers of delta will be eroded and transported farther into the reservoir, potentially increasing turbidity and downstream sediment deposit thickness. Changes in storage project elevations or changes to the flow of water and sediment into the reservoir can result in changes to the head-of-reservoir erosion and deposition patterns. This metric compares the paired relationships of flow and stage over time to indicate the potential for change in sediment mobilization at the head-of-reservoir for each alternative. Changes in delta sediment mobilization could alter the sediment load farther downstream within the reservoir and potentially the amount of sediment passing a dam, particularly during high-flow periods.

**Storage Reservoir – Sediment Trap Efficiency**

The sediment trap efficiency metric estimates the potential for changes in the amount of sediment that can deposit within or pass through the storage reservoirs. Trap efficiency is the proportion of inflowing sediment deposited in the reservoir relative to the total incoming sediment load. The trap efficiency is computed based on the ratio of reservoir storage volume to annual inflow. Because the volume of water stored at any given time in the storage projects can vary between MOs, there is potential for the amount of material being deposited in the reservoir to change between MOs. This metric compares the paired relationship of flow and reservoir storage to indicate the potential for changes in the amount of sediment being trapped by the storage projects for each alternative. The actual amount of sediment trapped is dependent not only on trap efficiency but also the incoming sediment load. Qualitative inferences are discussed on potential trap efficiency changes using sediment source documentation where available in the affected environment section (3.3.2).

**Storage Reservoir – Shoreline Exposure**

Shoreline erosion of bank sediments along reservoir margins is a complex process that is influenced by the cumulative effects of wave erosion, reservoir currents, precipitation runoff, freeze-thaw, soil properties, exposure, and vegetation density and type. One commonly observed process is that during times of extended reservoir drawdown, exposed un-vegetated shoreline soils that were previously saturated are prone to erosion and slumping. The shoreline exposure metric was developed as a surrogate for shoreline erosion processes. It compares the number of days that the reservoir water surface spends at any elevation to identify change in shoreline exposure and indicate the potential for change in shoreline erosion in the CRS storage projects. Elevation-duration curves used in this metric are developed from daily average data extracted from the 5,000-year stochastic hydroregulation operations model. The curves are integrated to calculate an average and are compared with the average of the No Action Alternative baseline. While the shoreline exposure metric does not directly consider reservoir draft rate, it does represent the duration effects that could result from draft rate operational measures.

Absolute shoreline exposure differences less than ±5 feet are likely not discernable within a storage reservoir due to sub-daily operational fluctuations and other processes such as waves, which occur within a similar range. A difference of at least ±5 feet is estimated to be the threshold when shoreline effects would be observable on the landscape and would be considered minor. Differences greater than ±10 feet would be observable and would be expected to result in moderate changes in shoreline exposure. A modification in the operational range of a storage project would be required to generate major changes in shoreline exposure with existing shoreline becoming permanently exposed or submerged. However, none of the analyzed MO operational measures changed the operational range at the CRS storage projects.

An additional metric for shoreline erosion was developed to evaluate potential impacts to cultural resources. This metric considered draft frequency and amplitude and is detailed in Section 3.16.3.

**RUN-OF-RIVER RESERVOIR AND FREE-FLOWING REACH METRICS**

The remaining CRS reservoirs within the study area (Chief Joseph, Lower Granite, Little Goose, Lower Monumental, Ice Harbor, McNary, The Dalles, and Bonneville) are run-of-river dams that do not store water for later discharge. Note that while John Day includes a small amount of storage, it can also be operated as a run-of-river project. Run-of-river reservoirs and free-flowing reaches include all the river reaches downstream of CRS storage projects. Run-of-river reservoirs are formed by dams that are operated to discharge water downstream at rates that generally match the upstream inflows. Bonneville Dam is an example of a run-of-river project that operates in a small range of pool elevations for daily or weekly hydropower purposes but does not attempt to store water for release in later seasons. Free-flowing reaches are portions of the river that are not influenced by the backwater of a downstream reservoir. The Flathead River downstream of Hungry Horse Dam and upstream of Flathead Lake is an example of a free-flowing reach.

**Potential for Sediment Passing Reservoirs and Reaches**

This metric estimates the size of material that can be held in suspension in the water column through each run-of-river reservoir and free-flowing reach due to operations of CRS projects. Water flowing in nature is predominately turbulent with chaotic changes in flow intensity and direction occurring at many scales internal to the overall downstream movement of the water. These turbulent forces can be strong enough to hold small sediment particles in suspension in the water column. The more energetic the turbulent forces, the larger the particle that can be suspended. Changes in the hydraulic conditions within the run-of-river reservoirs and reaches can change the ability of the river to transport sediment high in the water column. This metric calculates the grain size that can be held with 100 percent of its transporting mass in suspension for a given hydraulic condition using the Rouse profile (Rouse 1937). Comparison of the suspended sediment size between MOs as well as upstream and downstream in a single MO can inform managers whether there is potential for changes in material passing through or settling in a run-of-river reservoir or free-flowing reach.

**Potential for Bed Material Change**

This metric is designed to indicate the hydraulic potential for the bed of the river to become coarser (sand to gravel) or finer (gravel to sand) due to operations of CRS projects. Changes in operations can alter hydraulic conditions in run-of-river reservoirs and free-flowing reaches such that the river can move more or less riverbed sediment of various size classes. A change in the hydraulic ability for a reach to move sediment does not necessarily indicate that bed material will change. Sediment of specific size classes must be available in the reach at a sufficient supply for a change to occur. A bedrock or heavily armored (i.e., coarse) bed may withstand increases in the hydraulic capacity to transport sediment without changing. Conversely, a decrease in hydraulic ability to move sediment may not result in finer material depositing if no finer material is being locally supplied or transported into the reach. This metric calculates the distribution of critical grain size at the subreach level for each alternative supplemented with qualitative interpretation of existing bed material and sediment load to estimate if there is potential for bed material to trend coarser or finer in run-of-river reservoirs and reaches.

**Potential Changes in Width-Depth Ratio**

This metric evaluates if proposed changes in reservoir operations will alter the range and frequency of W/D ratios relative to affected environment conditions. Storage reservoirs and run-of-river reservoirs alter the physical landscape of rivers. Reservoirs change the width and depth of river channels and connectivity to floodplain surfaces and wetlands. Changes in the river framework alter ecological functions, including habitat, water quality, and riparian corridors, to name a few. The affected environment has larger wetted widths and hydraulic depths relative to pre-dam conditions due to reservoir conditions. Changes in the W/D ratio can indicate a potential for departure in channel hydraulics, or wetland and floodplain availability. MOs that do not change the minimum or maximum operating levels within a reservoir affected reach would not be expected to have a change in W/D ranges. However, operation changes could alter the frequency of W/D ratios, affecting the frequency of connectivity to floodplain surfaces or wetlands depending on local topography. A dam breaching would be expected to result in the largest change to W/D ratios.

**Potential Changes to Navigation Channel Dredging Volumes**

This metric evaluates if there is an expected change in the volume of sediment needing to be dredged from the federally authorized navigation system to provide safe and efficient deep- and shallow-draft navigation. As a part of its Congressional authorization, the Corps operates and maintains the navigation system from Lewiston, Idaho, to the Pacific Ocean along the Snake and Columbia Rivers. Changes in flow have the potential to change the volume of material depositing in the navigation channel. This metric estimates the average annual volume of sediment depositing in the deep- and shallow-draft sections based on relationships between flow in the river and sediment shoaling and historical dredging rates.

**ALTERNATIVE COMPARISON THRESHOLDS**

The River Mechanics Technical Appendix (Appendix C) discusses the quantitative basis for the impact metrics and the thresholds for impact assessment. While the impact thresholds are specific to each metric, the five standardized levels can generally be described as listed in Table 3-51.

**Table 3-51. Summary of impact assessment thresholds used for River Mechanics assessment.**

| | |
|---|---|
| **No Effect:** | No change |
| **Negligible:** | Change so small as to be unmeasurable and unable to be observed in the field. |
| **Minor:** | Change passes the likely threshold for being measurable but is likely not observable in the field. |
| **Moderate:** | Change is measurable and also passes the likely threshold for being observable in the field. |
| **Major:** | Change would be readily apparent to an observer in the field. |

An example of a minor impact in the "Potential for Bed Material Change" metric would be hydraulic conditions modified from No Action Alternative such that the median grain size in the bed (by mass) could change by up to 10 percent of a grain size class. This means that a fine sand bed reach would still have fine sand bed. A moderate impact would mean the bed material could change by up to 50 percent of a grain size class. A major impact would mean the bed material could change by one whole grain class or more. An example of a major impact would be a reach where the bed material could change from a fine sand to a medium sand or coarser (larger grain sizes) or from a fine sand to a very fine sand or finer (smaller grain sizes).

### *3.3.3.2 NO ACTION ALTERNATIVE*

Environmental consequences under the No Action Alternative are defined as the geomorphology and sediment transport conditions that would be expected within the CRS study area, without any changes in system configuration, maintenance, or operation. In other words, the No Action Alternative shows what would happen if proposed new action was not taken (Bass, Henderson, and Bogdan 2001) and project operations, maintenance, and configuration remained the same as they were in September 2016 (the EIS Notice of Intent date). For this No Action Alternative assessment, future geomorphology and sediment transport conditions are evaluated for the next 50 years. River mechanics metrics related to the No Action Alternative are generally described below from a process-based perspective, and then further summarized by region for any unique location-specific impacts (Table 3-52).

Under the No Action Alternative, water storage patterns are expected to be generally within the same range as historically experienced. There is a wide range in the water elevation in the storage reservoirs depending on the season and precipitation, and this variation will continue to control the location of the transition between riverine and reservoir conditions. The flow rates and project operating stages within the system are expected to remain within the historical range of variations. The incoming flow rate and downstream stage within a river segment or reservoir directly affect the hydraulic grade, which is the primary driver of sediment transport and suspension.

Shoreline erosion occurs to varying degrees in the storage reservoirs, depending on water level, wind (wave erosion), ice, currents, and other processes. Under the No Action Alternative, the duration and timing of reservoir water levels are not expected to change compared to the historical range. Similarly, it is anticipated that winds, freeze-thaw patterns, and flow rates within the reservoir would be within the historically experienced range.

Under the No Action Alternative, climatic conditions, land use patterns, and the amount of sediment entering the reservoirs from upstream is expected to remain the same as historically experienced. Climatic conditions, land use, and precipitation are major drivers for sediment erosion and yield into the river system. Climatic conditions were assumed to be consistent within historical ranges. The range of precipitation is expected to be within the historical range experienced, including some very wet and some very dry years. Land use is anticipated to follow similar patterns as currently experienced, with discrete population centers in some areas, but with a large portion of the watershed held as public lands. Sources of sediment such as agricultural fields are expected to continue cultivation in a manner similar to the current conditions. Under the No Action Alternative, the sediment loading throughout the basin is not expected to change from the historical range experienced.

**Table 3-52. Summary of No Action Alternative River Mechanics Impact Estimates**

| Metric | No Action Impact |
|---|---|
| **Storage Projects** | |
| Head of Reservoir Sediment Mobilization | Sediment will continue to deposit at the head of reservoirs (deltas) due to the slow-velocity backwater zone caused by the dams. Erosion and transport of head of reservoir sediment are expected to continue as a result of fluctuating reservoir pools. The transport of sediment from the head of the reservoir (delta) further downstream are expected to remain within the historically experienced range. |
| Trap Efficiency | Reservoirs will continue to trap incoming sediment due to the slow-velocity backwater pool created by the dams. The amount of sediment trapped in storage reservoirs is expected to be within historical levels, since the reservoir operations and sediment loading are not expected to change. |
| Shoreline Exposure | The amount of time that the storage project water surface elevations spend at any given elevation will not change from historical conditions. Reservoir shoreline erosion is expected to continue at locations and rates similar to those historically experienced at each project. |
| **Run-of-River Reservoirs and Free-Flowing Reaches** | |
| Potential for Sediment Passing Reservoirs and Reaches | A portion of the incoming sediment load will continue to pass run-of-river reservoirs and free-flowing reaches at magnitudes and rates similar to those historically experienced. |
| Potential for Bed Material Change | Bed material erosion and deposition patterns will continue to be altered by the CRS, since flow rates, operational stages, and sediment loading to the system are expected to be similar to historical ranges. Deposition and finer bed-material gradation is expected to continue in areas backwatered by dams. |
| Potential Change in Width to Depth Ratio | Due to continued operation of the CRS, the overall geomorphic character of the rivers will have the majority of reaches impacted by reservoirs, creating larger W/D ratios than pre-dam conditions. Under NAA, the W/D ratio is not expected to change, since the operating water levels and flow rates within the system are expected to be within the historical range experienced. |

| Metric | No Action Impact |
|---|---|
| Potential Changes to Navigation Channel Dredging Volumes | Sediment loading into the FNC will continue and the navigation system will continue to be maintained through existing dredging authorities and operational plans. Under NAA, sediment loading into and sediment transport capacity within the FNC is not expected to change from the historical range of conditions. |

### REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS

#### Storage Projects

Under the No Action Alternative in Region A, sediment transport, deposition, and erosion processes will continue to be impacted by CRSO. Head of Reservoir Sediment Mobilization, Trap Efficiency, and Shoreline Exposure processes will continue at a similar magnitude and rates to those described in the Affected Environment (Section 3.3.2.3).

#### Run-of-River Reservoir and Free-Flowing Reaches

Under the No Action Alternative in Region A, the Run-of-River Reservoir and Free-Flowing Reaches will continue to be impacted by CRSO. The sediment loads passing through each reservoir, altered bed material gradation, and altered W/D ratios will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.4).

### REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

#### Storage Projects

Under the No Action Alternative in Region B, negligible change is expected in Storage Project metrics for Head of Reservoir Sediment Mobilization, Trap Efficiency, and Shoreline Exposure indicating that these processes will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.3). The negligible change in these metrics results from negligible change in water storage patterns, seasonal reservoir elevations, sediment loading, and sediment properties.

#### Run-of-River Reservoir and Free-Flowing Reaches

Under the No Action Alternative in Region B, negligible change is expected in the Run-of-River Reservoir and Free-Flowing Reach metrics for potential changes in Sediment Passing Reservoirs and Reaches, Bed Material Change, and Width-to-Depth Ratio, indicating that these processes will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.4). The negligible change in these metrics results from negligible change in flow rates, operating levels, hydraulic energy regime, sediment sources and loading, and sediment properties.

### REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

#### Storage Projects

Under the No Action Alternative in Region C, negligible change is expected in Storage Project metrics for Head of Reservoir Sediment Mobilization, Trap Efficiency, and Shoreline Exposure indicating that these processes will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.3). The negligible change in these metrics results from negligible change in water storage patterns, seasonal reservoir elevations, sediment loading, and sediment properties.

#### Run-of-River Reservoir and Free-Flowing Reaches

Under the No Action Alternative in Region C, negligible change is expected in the Run-of-River Reservoir and Free-Flowing Reach metrics for Potential changes in Sediment Passing Reservoirs and Reaches, Bed Material Change, and Width-to-Depth Ratio, indicating that these processes will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.4). The negligible change in these metrics results from negligible change in flow rates, operating levels, hydraulic energy regime, sediment sources and loading, and sediment properties.

Under the No Action Alternative in Region C, negligible change is expected in the accumulation of sediment and FNC maintenance requirements. The negligible change results from negligible change in various factors that affect sediment accumulation including climatic conditions, watershed yield and loading to the reservoir, the hydraulic capacity to transport sediment material through the reservoir, and changes in the bed materials as detailed above. Currently dredging within the system occurs on the lower Columbia River and on the lower Snake River, in discrete locations. Areas which historically have required dredging (lock chamber approaches, the confluence of the Snake and Clearwater Rivers, harbor and port berthing areas and entrances) would still experience shoaling (buildup of sediment into shallow areas). Dredging within the LCR FNC and private dock-face/berthing areas to maintain navigation would still occur. Sediment management activities in the Snake River (as described in the PSMP, Corps 2014c) would continue as currently planned.

### REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

#### Storage Projects

Under the No Action Alternative in Region D, negligible change is expected in Storage Project metrics for Head of Reservoir Sediment Mobilization, Trap Efficiency, and Shoreline Exposure, indicating that these processes will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.3). The negligible change in these metrics results from negligible change in water storage patterns, seasonal reservoir elevations, sediment loading, and sediment properties.

**Run-of-River Reservoir and Free-Flowing Reaches**

Under the No Action Alternative in Region D, negligible change is expected in the Run-of-River Reservoir and Free-Flowing Reach metrics for Potential Changes in Sediment Passing Reservoirs and Reaches, Bed Material Change, and Width-to-Depth Ratio, indicating that these processes will continue at magnitudes and rates similar to those described in the Affected Environment (Section 3.3.2.4). The negligible change in these metrics results from negligible change in flow rates, operating levels, hydraulic energy regime, sediment sources and loading, and sediment properties.

Under the No Action Alternative in Region D, negligible change is expected in the accumulation of sediment and FNC maintenance requirements. The negligible change results from negligible change in various factors that affect sediment accumulation including climatic conditions, watershed yield and loading to the reservoir, the hydraulic capacity to transport sediment material through the reservoir, and changes in the bed materials as detailed above.

### *3.3.3.3 MULTIPLE OBJECTIVE ALTERNATIVE 1*

See Section 2.3.3 for a complete description of MO1. Impacts related to MO1 relative to the No Action Alternative are summarized by region and enumerated in Table 3-53.

**Table 3-53. Summary of Multiple Objective Alternative 1 River Mechanics Impact Estimates**

| Metric | MO1 Impact |
|---|---|
| **Storage Projects** | |
| Head of Reservoir Sediment Mobilization | Negligible change in erosion or deposition processes and patterns at the head of storage project reservoirs with the exception of:<br>**Columbia River entering Lake Roosevelt**. There is potential for a minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream, although available deposit volume is limited. Head-of-reservoir deposits may include contaminants (slag) that are also mobilized slightly farther downstream in the reservoir but are not expected to be transported past the dam. The ultimate long-term fate of head-of-reservoir sediments within the reservoir is expected to remain unchanged given there are no proposed changes in the Grand Coulee operational range. Draft duration related to the *Winter System FRM Space* measure at Grand Coulee Dam contributes to the impact. |
| Trap Efficiency | Negligible change in potential for storage projects to trap sediment indicating that reservoir sediment pass-through at CRS storage projects will continue at magnitudes and rates similar to the NAA. |
| Shoreline Exposure | Negligible change in the amount of time that the storage projects' water surface elevations spend at any given elevation, indicating that reservoir shoreline erosion processes are expected to continue at locations and rates similar to those under the NAA. |
| **Run-of-River Reservoirs and Free-Flowing Reaches** | |
| Potential for Sediment Passing Reservoirs and Reaches | Negligible change in the potential for sediment to pass run-of-river reservoirs and free-flowing reaches with the exception of: |

| Metric | MO1 Impact |
| --- | --- |
| | **Lower Clearwater River above the Snake Confluence (Subreach 10.11)**. There is potential for a minor decrease in the amount of sediment passing the Clearwater River at the Snake and Clearwater River confluence. The *Modified Dworshak Summer Draft* measure causes the impact. |
| Potential for Bed Material Change | Negligible change in the processes that supply, transport, and deposit sediment in the system with the exception of:<br>**Lake Roosevelt Upper Reach on the Columbia River** (Subreach 21.13). There is potential for a minor amount of coarsening of bed sediment at the head of Lake Roosevelt. Draft duration related to the *Winter System FRM Space* measure at Grand Coulee Dam contributes to the impact. |
| Potential Change in Width to Depth Ratio | Negligible change in the overall geomorphic character of the rivers. |
| Potential Changes to Navigation Channel Dredging Volumes | **Snake River:**<br>Estimated average annual volume of sediment depositing in the Snake River navigation channel due to MO1 operations is less than 1% change from No Action.<br>**Lower Columbia River:**<br>Estimated average annual volume of sediment depositing in the LCR FNC due to MO1 operations is less than 1% decrease from the NAA. |

## REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS

### Storage Projects

Negligible change in Region A Storage Project metrics under MO1.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region A Run-of-River Reservoirs and Free-Flowing Reach metrics under MO1.

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Storage Projects

Negligible change in Region B Storage Project metrics under MO1 with the exception of Head of Reservoir Sediment Mobilization at the **Columbia River entering Lake Roosevelt**. There is potential for a minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream, although available deposit volume is limited. Head-of-reservoir deposits may include contaminants (slag) that are also mobilized slightly farther downstream in the reservoir but are not expected to be transported past the dam. The ultimate long-term fate of head-of-reservoir sediments within the reservoir is expected to remain unchanged given there are no proposed changes in the Grand Coulee operational range. Draft duration related to the *Winter System FRM Space* measure at Grand Coulee Dam contributes to the impact.

**Run-of-River Reservoir and Free-Flowing Reaches**

Negligible change in Region B Run-of-River Reservoirs and Free-Flowing Reach metrics under MO1 with the exception of the Potential for Bed Material Change at the **Lake Roosevelt Upper Reach on the Columbia River** (Subreach 21.13). There is potential for a minor amount of coarsening of bed sediment at the head of Lake Roosevelt. Draft duration related to the *Winter System FRM Space* measure at Grand Coulee Dam contributes to the impact.

**REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS**

**Storage Projects**

Negligible change in Region C Storage Project metrics under MO1.

**Run-of-River Reservoir and Free-Flowing Reaches**

Negligible change in Region C Run-of-River Reservoirs and Free-Flowing Reach metrics under MO1 with the exception of the potential for sediment to pass run-of-river reservoirs and free-flowing reaches on the **Lower Clearwater River above the Snake Confluence (Subreach 10.11)**. There is potential for a minor decrease in the amount of sediment passing the Clearwater River at the Snake and Clearwater River confluence. The *Modified Dworshak Summer Draft* measure causes the impact. Negligible change in Region C to Navigation Channel Dredging volumes was estimated under MO1.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Storage Projects**

Negligible change in Region D Storage Project metrics under MO1.

**Run-of-River Reservoir and Free-Flowing Reaches**

Negligible change in Region D Run-of-River Reservoirs and Free-Flowing Reach metrics under MO1. Negligible change in Region D Navigation Channel Dredging volumes was estimated under MO1.

### *3.3.3.4 MULTIPLE OBJECTIVE ALTERNATIVE 2*

Refer to the complete alternative description in Section 2.3.4. Impacts related to MO2 relative to the No Action Alternative are summarized by region and enumerated in Table 3-54.

**Table 3-54. Summary of Multiple Objective Alternative 2 River Mechanics Impact Estimates**

| Metric | MO2 Impact |
|---|---|
| **Storage Projects** | |
| Head of Reservoir Sediment Mobilization | Negligible change in erosion or deposition processes and patterns at the head of storage project reservoirs with the exception of:<br>**Dworshak Reservoir.** There is potential for a minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream. Ultimate long-term fate of head-of-reservoir sediments within the reservoir is unchanged given no changes in Dworshak operational range. The *Slightly Deeper Draft for Hydropower* measure causes the impact. |
| Trap Efficiency | Negligible change in potential for storage projects to trap sediment indicating that reservoir sediment pass-through at CRS storage projects will continue at magnitudes and rates similar to the NAA. |
| Shoreline Exposure | Negligible change in the amount of time that the storage project water surface elevations spend at any given elevation with the exception of:<br>**Dworshak Reservoir.** There is potential for a minor change in shoreline exposure at Dworshak with the reservoir being held at lower elevations for long enough to potentially cause a minor increase in the shoreline erosion pattern. The *Slightly Deeper Draft for Hydropower* measure causes the impact.<br><br>At Lake Roosevelt, the increased shoreline exposure was estimated to be 1.8 feet, which is within the negligible interval. In addition, the proposed measure for slower drawdown from the *Planned Draft Rate at Grand Coulee* could have the potential to provide minor reductions in local landslides related to reservoir levels. |
| **Run-of-River Reservoirs and Free-Flowing Reaches** | |
| Potential for Sediment Passing Reservoirs and Reaches | Negligible change in the potential for sediment to pass run-of-river reservoirs and free-flowing reaches. |
| Potential for Bed Material Change | Current processes that supply, transport and deposit sediment in the system will continue at historical rates (same as NAA) with the exception of:<br>**Lower Flathead River between Stillwater and Flathead Lake (*Subreach 28.13*).** There is potential for a minor, unobservable amount of fining of bed sediment in the reach immediately upstream of Flathead Lake. The impact results from slight reductions in Hungry Horse outflow, which dampens the energy grade as the Flathead River enters Flathead Lake backwater; the flow reduction is tied to the reduced outflows during the FRM period, which results from the *Slightly Deeper Draft for Hydropower* measure during winter months.<br>**Lake Roosevelt Upper Reach on the Columbia River (*Subreach 21.13*).** There is potential for a minor amount of coarsening of bed sediment at the head of Lake Roosevelt. Draft duration from the *Winter System FRM Space* and *Slightly Deeper Drafts for Hydropower* measures at Grand Coulee contribute to the impact. |
| Potential Change in Width to Depth Ratio | Negligible change in the overall geomorphic character of the rivers. |

| Metric | MO2 Impact |
|---|---|
| Potential Changes to Navigation Channel Dredging Volumes | **Snake River:**<br>Estimated average annual volume of sediment depositing in the Snake River navigation channel due to MO2 operations is less than 1% change from the NAA.<br>**Lower Columbia River:**<br>Estimated average annual volume of sediment depositing in the LCR FNC due to MO2 operations is less than 1% increase from the NAA. |

## REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS

### Storage Projects

Negligible change in Region A Storage Project metrics under MO2.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region A Run-of-River Reservoirs and Free-Flowing Reach metrics under MO2 with the exception of Potential for Bed Material Change within the **Lower Flathead River between Stillwater and Flathead Lake (*Subreach 28.13*).** There is potential for a minor amount of fining of bed sediment in the reach immediately upstream of Flathead Lake. The impact results from slight reductions in Hungry Horse outflow, which dampen the energy grade as the Flathead River enters Flathead Lake backwater; the flow reduction is tied to the reduced outflows during the FRM period, which result from the *Slightly Deeper Draft for Hydropower* measure during winter months.

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Storage Projects

Negligible change in Region B Storage Project metrics under MO2.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region B Run-of-River Reservoirs and Free-Flowing Reach metrics under MO2 with the exception of the Potential for Bed Material Change within the **Lake Roosevelt Upper Reach on the Columbia River (*Subreach 21.13*).** There is potential for a minor amount of coarsening of bed sediment at the head of Lake Roosevelt. Draft duration from the *Winter System FRM Space* and *Slightly Deeper Drafts for Hydropower* measures at Grand Coulee contributes to the impact.

**REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS**

**Storage Projects**

Negligible change in Region C Storage Project metrics under MO2 with the exception of Head of Reservoir Sediment Mobilization and Shoreline Exposure at Dworshak Reservoir. There is potential for a minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream at Dworshak Reservoir. The ultimate long-term fate of head-of-reservoir sediments within the reservoir is unchanged given no changes in Dworshak operational range. The *Slightly Deeper Draft for Hydropower* measure causes the impact. There is also potential for a minor change in shoreline exposure at Dworshak with the reservoir being held at lower elevations for long enough to potentially cause a minor increase in the shoreline erosion pattern. The *Slightly Deeper Draft for Hydropower* measure causes the impact.

**Run-of-River Reservoir and Free-Flowing Reaches**

Negligible change in Region C Run-of-River Reservoirs and Free-Flowing Reach metrics under MO2. Negligible change in Region C Navigation Channel Dredging volumes under MO2.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Storage Projects**

Negligible change in Region D Storage Project metrics under MO2.

**Run-of-River Reservoir and Free-Flowing Reaches**

Negligible change in Region D Run-of-River Reservoirs and Free-Flowing Reach metrics under MO2. Negligible change in Region D Navigation Channel Dredging volumes under MO2.

### *3.3.3.5 MULTIPLE OBJECTIVE ALTERNATIVE 3*

See Chapter 2 for a complete description of the dam embankment breach alternative. Structural measures for this alternative include:

- Breach Snake Embankments: Remove earthen embankments, as required, at each dam to facilitate reservoir drawdown at the lower Snake River dams.
- Lower Snake Infrastructure Drawdown: Modify existing equipment and dam infrastructure at the lower Snake River dams to adjust to drawdown conditions (Existing equipment would not be used for hydropower generation but would be used as low-level outlets for drawdown below spillway elevations).
- Additional Powerhouse Surface Passage: Construct additional powerhouse and surface passage routes at the McNary Project.

Under MO3, four reservoirs will be drawn down and converted to a riverine environment. The current reservoirs contain fine sediment deposits that will partially erode, leaving margin sediment on high terraces behind. The new river bottom after breaching will initially become finer and gradually coarsen over the long term. The change in the overall geomorphic character will occur on the Snake and Clearwater Rivers within the backwater extents of Lower Granite Reservoir downstream to the confluence with the Columbia River. River Mechanic metric impacts related to MO3 relative to the No Action Alternative are summarized by region and enumerated in Table 3-55. See Appendix C, *River Mechanics Technical Appendix*, for additional information on estimated dam breaching impacts.

**Table 3-55. Summary of Multiple Objective Alternative 3 River Mechanics Impact Estimates**

| Metric | MO3 Impact |
|---|---|
| **Storage Projects** | |
| Head of Reservoir Sediment Mobilization | Negligible change in erosion or deposition processes and patterns at the head of storage project reservoirs. |
| Trap Efficiency | Negligible change in potential for storage projects to trap sediment, indicating that reservoir sediment pass-through at CRS storage projects will continue at magnitudes and rates similar to the NAA. |
| Shoreline Exposure | Negligible change in the amount of time that the storage project water surface elevations spend at any given elevation, indicating that reservoir shoreline erosion processes are expected to continue at locations and rates similar to the NAA. |
| **Run-of-River Reservoirs and Free-Flowing Reaches** | |
| Potential for Sediment Passing Reservoirs and Reaches | Negligible change in the potential for sediment to pass run-of-river reservoirs and free-flowing reaches with the exception of:<br>**The Snake River from the upstream extents to Lower Granite Reservoir downstream to the Columbia River (*Reaches 6–9 and 11.1*)** and the **Clearwater River backwatered by Lower Granite Reservoir (*Subreach 10.1*)**. There is potential for a major increase in the size and amount of sediment passing these reaches. The *Breach Snake Embankments* measure causes the impact by converting four run-of-river reservoirs to a riverine environment.<br>**Columbia River from the Snake River confluence downstream to the Pacific Ocean (*Reaches 1–5*).** Due to the increase in amount of sediment passing from the Snake River into the Columbia River, there is potential for a major increase in the amount of sediment passing downstream of the Snake River confluence. The *Breach Snake Embankments* measure causes the impact. |

| Metric | MO3 Impact |
|---|---|
| Potential for Bed Material Change | Current processes that supply, transport and deposit sediment in the system will continue at historical rates (same as NAA) with the exception of:<br>**The lower Snake River from the upstream extents of the CRS study area to Lower Granite Reservoir downstream to the Columbia River (*Reaches 6–9 and Subreach 11.1*)** and the **Clearwater River backwatered by Lower Granite Reservoir (*Subreach 10.1*)**. There is potential for a major amount of coarsening of bed sediment throughout these reaches. The *Breach Snake Embankments* measure causes the impact.<br>**The Columbia River from the Snake River confluence to McNary Dam (*Subreach 5.1*).** Due to the increase in amount of sediment passing from the Snake River into the Columbia River, there is potential for a major increase in the amount of material depositing in McNary Reservoir. The bed material size may become finer in the short term and coarsen in the long term. The *Breach Snake Embankments* causes the impact. |
| Potential Change in Width to Depth Ratio | Negligible change in the overall geomorphic character of the rivers with the exception of:<br>**The lower Snake River from the upstream extents of the CRS study area to Lower Granite Reservoir downstream to the Columbia River (*Reaches 6–9 and Subreach 11.1*)** and the **Clearwater River backwatered by Lower Granite Reservoir (*Subreach 10.1*).** There is a major change in geomorphic character in these reaches with the river becoming much shallower relative to its wetted width. The *Breach Snake Embankments* measure causes the impact. The four lower Snake River reservoirs contain fine sediment deposits that, following dam embankment removal, will partially erode leaving margin sediment on high terraces behind. The new lower Snake river bottom after breaching will initially become finer and gradually coarsen over the long term. The change in the overall geomorphic character will occur on the Snake and Clearwater Rivers within the backwater extents of Lower Granite Reservoir downstream to the confluence with the Columbia River. |
| Potential Changes to Navigation Channel Dredging Volumes | **Snake River:**<br>Navigation maintenance of the Snake River FNC is assumed to cease following breaching of the four Snake River projects. Estimated change in the average annual volume of watershed sediment yield to the lower Snake River is less than 1% compared to the NAA. Following breaching of the dam embankments, this watershed sediment would pass the breached dam embankments and be routed to the Columbia River confluence as discussed below.<br>**Lower Columbia River:**<br>Estimated average annual volume of sediment depositing in the LCR FNC due to MO3 operations is less than 1% decrease from the NAA based on sediment load from the Lower Columbia River. In addition, near-term sedimentation effects following dam embankment breaching are expected to last up to 10 years as legacy sediment deposits within the reservoirs are incrementally eroded and re-deposited throughout the lower Snake River reach. Near-term sedimentation effects are expected to be particularly large in the upstream end of Lake Wallula above McNary Dam. The impacts of sediment deposition at left bank recreation and boat-launch sites below the Snake River confluence would likely be permanent. Long-term sedimentation effects would include continued deposition in quiescent areas prone to shoaling as a result of annual sediment delivery that had previously been trapped by the lower Snake River dams. |

## REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS

### Storage Projects

Negligible change in Region A Storage Project metrics under MO3.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region A Run-of-River Reservoirs and Free-Flowing Reach metrics under MO3.

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Storage Projects

Negligible change in Region B Storage Project metrics under MO3.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region B Run-of-River Reservoirs and Free-Flowing Reach metrics under MO3. At Lake Roosevelt, the increased shoreline exposure was estimated to be 1.8 feet, which is within the negligible interval. In addition, the proposed measure for slower drawdown from the *Planned Draft Rate at Grand Coulee* could have the potential to provide minor reductions in local landslides related to reservoir levels.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Storage Projects

Negligible change in Region C Storage Project metrics under MO3.

### Run-of-River Reservoir and Free-Flowing Reaches

Within Region C, significant changes were identified under MO3 for the Run-of-River Reservoirs and Free-Flowing Reach metrics caused by the *Breach Snake Embankments* measure, which converts four run-of-river reservoirs to a riverine environment. The spatial impact of change includes **the Snake River from the upstream extents to Lower Granite Reservoir downstream to the Columbia River confluence (*Reaches 6–9 and Subreach 11.1*)** and the **Clearwater River backwatered by Lower Granite Reservoir (*Subreach 10.1*).** Within these reaches, there is potential for a major increase in the size and amount of sediment passing and a major amount of coarsening of bed sediment. There is also a major change in geomorphic character in these reaches, with the river becoming much shallower relative to its wetted width. The four lower Snake River reservoirs contain fine sediment deposits that following dam embankment removal will partially erode, leaving margin sediment on high terraces behind. The new lower Snake

River bottom after breaching will initially become finer and gradually coarsen over the long term.

Under MO3, navigation maintenance of the Snake River FNC is assumed to cease following breaching of the four Snake River projects. Following breaching of the dam embankments, watershed sediment will now pass the breached dam embankments and be routed to the Columbia River confluence.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Storage Projects**

Negligible change in Region D Storage Project metrics under MO3.

**Run-of-River Reservoir and Free-Flowing Reaches**

Within Region D, changes were identified under MO3 for the Run-of-River Reservoirs and Free-Flowing Reach metrics caused by the *Breach Snake Embankments* measure which converts four run-of-river reservoirs to a riverine environment. Due to the increase in the amount of sediment passing from the Snake River into the Columbia River, there is potential for a major increase in the amount of sediment passing downstream of the Snake River confluence. Due to the increase in amount of sediment passing from the Snake River into the Columbia River, there is potential for a major increase in the amount of material depositing in McNary Reservoir. The bed material size may become finer in the short term and coarsen in the long term.

Under MO3, negligible changes were estimated in Region D Navigation Channel Dredging volumes based on sediment loads supplied from Region B. In addition, near-term sedimentation effects following dam embankment breaching are expected to last up to 10 years as legacy sediment deposits within the reservoirs are incrementally eroded and re-deposited throughout the lower Snake River reach. Near-term sedimentation effects are expected to be particularly large in the upstream end of Lake Wallula above McNary Dam. The impacts of sediment deposition at left bank recreation and boat-launch sites below the Snake River confluence would likely be permanent. Long-term sedimentation effects would include continued deposition in quiescent areas prone to shoaling as a result of annual sediment delivery that had previously been trapped by the lower Snake River dams.

### *3.3.3.6 Multiple Objective Alternative 4*

A complete description of MO4 can be found in Section 2.3.6. The MO includes structural measures as well as operational measures. The structural measures are related to powerhouse, turbine, spillway and fish passage features, and do not include the breaching of any dams. The operational measures include a long list of changes to current flow and power operations, including increasing the irrigation to authorized amounts which are detailed in Chapter 2. Impacts related to MO4 relative to the No Action Alternative are summarized by region and enumerated in Table 3-56.

**Table 3-56. Summary of Multiple Objective Alternative 4 River Mechanics Impact Estimates**

| Metric | MO4 Impact |
|---|---|
| **Storage Projects** | |
| Head of Reservoir Sediment Mobilization | Negligible change in erosion or deposition processes and patterns at the head of storage project reservoirs with the exception of:<br>**Columbia River and Spokane River entering Lake Roosevelt.** There is potential for a minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream, although available deposit volume is limited. Head-of-reservoir deposits may include contaminants (slag) that are also mobilized slightly farther downstream in the reservoir but are not expected to be transported past the dam. Ultimate long-term fate of head-of-reservoir sediments within the reservoir is expected to remain unchanged given there are no proposed changes in the Grand Coulee operational range. The *Winter System FRM Space*, *Planned Draft Rate*, and *McNary Flow Target* measures at Grand Coulee contribute to the impact.<br>**Columbia River Entering John Day Reservoir.** There is potential for a minor change in head-of-reservoir sediment mobilization with deposits becoming coarser. The *Drawdown to MOP* measure at the John Day Project causes the impact. |
| Trap Efficiency | Negligible change in potential for storage projects to trap sediment, indicating that reservoir sediment pass-through at CRS storage projects will continue at magnitudes and rates similar to the NAA. |
| Shoreline Exposure | Negligible change in the amount of time that the storage project water surface elevations spend at any given elevation with the exception of Hungry Horse Reservoir. There is potential for a minor increase in shoreline exposure duration at Hungry Horse with the reservoir being held at lower elevations for a long enough period to potentially increase the erosion pattern. A combination of the *Hungry Horse Additional Water Supply* and *McNary Flow Target* measures causes the impact.<br>At Lake Roosevelt, the increased shoreline exposure was estimated to be 4.7 feet, which is within the negligible interval. In addition, the proposed measure for slower drawdown from the *Planned Draft Rate at Grand Coulee* could have the potential to provide minor reductions in local landslides related to reservoir levels. |
| **Run-of-River Reservoirs and Free-Flowing Reaches** | |
| Potential for Sediment Passing Reservoirs and Reaches | Negligible change in the potential for sediment to pass run-of-river reservoirs and free-flowing reaches with the exception of<br>**Columbia River upstream of Kettle Falls, Washington, to the U.S.-Canada border (*Subreaches 21.13 and 21.14*).** There is potential for a minor increase in the amount of sediment passing through the upper reach of Lake Roosevelt and into the middle reach of Lake Roosevelt Downstream of Kettle Falls, Washington. The *Winter System FRM Space*, *Planned Draft Rate*, and *McNary Flow Target* measures at Grand Coulee are contributors the impact. |

| Metric | MO4 Impact |
|---|---|
| Potential for Bed Material Change | Negligible change in the processes that supply, transport and deposit sediment in the system with the exception of:<br>**The Columbia River between Grand Coulee Dam and U.S.-Canada border (*Reach 21*).** There is potential for a minor amount of bed sediment coarsening in Lake Roosevelt and reaches upstream to the U.S.-Canada border. *Winter System FRM Space*, *Planned Draft Rate* and *McNary Flow Target* measures at Grand Coulee contribute to the impact.<br>**Snake River downstream of Ice Harbor (*Subreach 6.1*).** There is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at the McNary Project is causing in the impact.<br>**Columbia River from the Snake River Confluence to Wallula, Washington (*Subreach 5.12*).** There is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at the McNary Project is causing in the impact.<br>**Columbia River at the upstream end of John Day Reservoir (*Subreach 4.12*).** There is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at the John Day Project causes the impact.<br>**Columbia River between John Day Dam and Skamania, Washington (*Reaches 2, 3, and subreach 1.23*).** There is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at The Dalles and Bonneville Projects causes this impact. |
| Potential Change in Width to Depth Ratio | Negligible change in the overall geomorphic character of the rivers. |
| Potential Changes to Navigation Channel Dredging Volumes | **Snake River:**<br>Estimated average annual volume of sediment depositing in the Snake River navigation channel due to MO4 operations is less than 1% change from No Action.<br>**Lower Columbia River:**<br>Estimated average annual volume of sediment depositing in the LCR FNC due to MO4 operations is a less than 1% decrease from No Action. |

## REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS

### Storage Projects

Negligible change in Region A Storage Project metrics under MO4 with the exception of Shoreline Exposure at Hungry Horse Reservoir. There is potential for a minor increase in shoreline exposure duration at Hungry Horse with the reservoir being held at lower elevations for a long enough period to potentially increase the erosion pattern. A combination of the *Hungry Horse Additional Water Supply* and *McNary Flow Target* measures causes the impact.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region A Run-of-River Reservoirs and Free-Flowing Reach metrics under MO4.

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Storage Projects

Negligible change in Region B Storage Project metrics under MO4 with the exception of Head of Reservoir Sediment Mobilization on the **Columbia River and Spokane River entering Lake Roosevelt.** There is potential for a minor change in depositional patterns with temporary head-of-reservoir deposits shifting downstream, although available deposit volume is limited. Head-of-reservoir deposits may include contaminants (slag) that are also mobilized slightly farther downstream in the reservoir but are not expected to be transported past the dam. The ultimate long-term fate of head-of-reservoir sediments within the reservoir is expected to remain unchanged given there are no proposed changes in the Grand Coulee operational range. The *Winter System FRM Space*, *Planned Draft Rate*, and *McNary Flow Target* measures at Grand Coulee contribute to the impact. At Lake Roosevelt, the increased shoreline exposure was estimated to be 4.7 feet, which is within the negligible interval. In addition, the proposed measure for slower drawdown from the *Planned Draft Rate at Grand Coulee* could have the potential to provide minor reductions in local landslides related to reservoir levels.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region B Run-of-River Reservoirs and Free-Flowing Reach metrics under MO4 with the exception of the Potential for Sediment Passing Reservoirs and Reaches and Potential for Bed Material Change with *Winter System FRM Space*, *Planned Draft Rate,* and *McNary Flow Target* measures at Grand Coulee contributing to the impacts. On the **Columbia River between Grand Coulee Dam and U.S.-Canada border (*Reach 21*),** there is potential for a minor amount of bed sediment coarsening in Lake Roosevelt and reaches upstream to the U.S.-Canada border. On the **Columbia River upstream of Kettle Falls, Washington, to the U.S.-Canada border (*Subreaches 21.13 and 21.14*),** there is potential for a minor increase in the amount of sediment passing through the upper reach of Lake Roosevelt and into the middle reach of Lake Roosevelt downstream of Kettle Falls, Washington.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Storage Projects

Negligible change in Region C Storage Project metrics under MO4.

### Run-of-River Reservoir and Free-Flowing Reaches

Negligible change in Region C Run-of-River Reservoirs and Free-Flowing Reach metrics under MO4 with the exception of the potential for a minor amount of bed sediment coarsening on the **Snake River downstream of Ice Harbor (*Subreach 6.1*)**. The *Drawdown to MOP* measure at the McNary Project is causing in the impact. Negligible change in Region C Navigation Channel Dredging volumes under MO4.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Storage Projects**

Negligible change in Region D Storage Project metrics under MO4 with the exception of Head of Reservoir Sediment Mobilization on the **Columbia River Entering John Day Reservoir.** There is potential for a minor change in head-of-reservoir sediment mobilization with deposits becoming coarser. The *Drawdown to MOP* measure at the John Day Project causes the impact.

**Run-of-River Reservoir and Free-Flowing Reaches**

Negligible change in Region D Run-of-River Reservoirs and Free-Flowing Reach metrics under MO4 with the exception of the Potential for Bed Material Change. On the **Columbia River from the Snake River Confluence to Wallula, Washington (*Subreach 5.12*).** There is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at the McNary Project is causing in the impact. On the **Columbia River at the upstream end of John Day Reservoir (*Subreach 4.12*).** There is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at the John Day Project causes the impact. On the **Columbia River between John Day Dam and Skamania, Washington (*Reaches 2, 3, and subreach 1.23*),** there is potential for a minor amount of bed sediment coarsening. The *Drawdown to MOP* measure at The Dalles and Bonneville Projects causes this impact. Negligible change in Region D Navigation Channel Dredging volumes under MO4.

### 3.3.4 Tribal Interests

As described above, MO1, MO2, and MO4 generally result in negligible to minor changes in metrics used to analyzed effects to river mechanics processes. Tribal interests under those alternatives would not be impacted. MO3 includes a measure to breach the downstream-most four dam embankments on the Snake River which would result in major changes to river mechanics processes and corresponding metrics. The MO3 alternative would change the lower Snake River landscape that is currently backwatered by the four dams (Lower Granite, Little Goose, Lower Monumental, and Ice Harbor) and the localized areas of the Columbia River below the Snake River confluence.

Areas that are currently inundated by the Snake River reservoirs will become free-flowing river sections, although the incoming hydrology may still be regulated by upstream dams where present. Along the reservoir margins, some higher elevation surfaces will be abandoned and no longer inundated after the breaching of the dams. These newly exposed surfaces could contain cultural resources important to tribes that will no longer be protected by inundation from the reservoirs. Sediment currently stored in the reservoirs will either become part of the new river and floodplain features, transported downstream, or be left behind on the abandoned margin surfaces. During dam embankment breaching and in the near term (up to 10 years) following, sediment loads downstream will be elevated as the Snake River erodes and processes the sediment deposits behind the dams and residual deposits left on higher terrace surfaces. These higher sediment loads may affect current tribal access and types of recreation and fisheries use in the former reservoirs and downstream areas altered from changed sediment conditions.

Over the long term, watershed sediment loads that were historically trapped behind the lower Snake River Dams will be seasonally routed to the Columbia River where it is expected to deposit primarily in the upper 10 miles of the McNary Reservoir between the confluence and Wallula, Washington. Over the long term, the free-flowing river conditions will provide alternate recreation and fisheries opportunities discussed in other EIS chapters.

## 3.4 WATER QUALITY

The water quality of the Columbia River Basin is affected by many past and present influences, including human population growth and associated pollutants, water withdrawal for municipal and industrial water and irrigation (and irrigation return flows), dam structures and operations (Federal and non-Federal), and land use practices including mining, domesticated livestock, agriculture, industry (pulp and paper mills), logging (silviculture and forest management), and recreation (e.g., shoreline erosion). New pollutants are continually being identified, such as pharmaceuticals (Nielsen et al. 2014); the existing National Pollutant Discharge Elimination System programs regulate certain identified compounds from point sources, but other pollutants may also be present and unaccounted for. Nonetheless, surface water in the Columbia River Basin supports a wide variety of resident and anadromous fish and other aquatic organisms and wildlife.

The 14 Federal dams within the CRSO study area have affected water and sediment quality due to the creation of reservoirs throughout the system. Prior to the construction of these and other dams, the Columbia River and its tributaries were free-flowing, natural rivers. These rivers experienced seasonal flow and temperature changes. The seasonal peak flows would have moved sediment downstream over time. Water depths would have been comparatively shallow (more shallow than the current reservoirs) which has implications for water velocity, water temperature, and ecological processes. Water in the river was fully mixed as the water flowed downstream. The river conditions dictated the water and sediment quality, which in turn dictated the habitat and species found in the habitat.

The Corps and Reclamation constructed the 14 Federal dams in the Columbia River System and manage the water flowing through the dams for the various authorized purposes. The dam structures and operations reduce river velocity, dampening the hydrograph relative to the undammed river condition. The dams interrupt the connectivity of the river, creating a series of reservoirs that act more like lentic (lake) rather than lotic (riverine) systems, ultimately changing water quality processes.

In general, large dams have an influence on the riverine ecosystem downstream of the structure (Ward and Stanford 1983; Nillson and Berggren 2000). Dams alter flow regime, temperature, oxygen dynamics, sediment dynamics, and channel geomorphology (shape and function) (Shields et al. 2000; Stanford and Ward 2001). Depending on the mode and pattern of operation, dams function to reduce frequent peak flows and raise baseflow stage and discharge in the stream below. Reduction in peak flows acts to decouple a frequent flood or overbank event from the historical floodplain or riparian zone, which converts a floodplain river to a reservoir river (flood pulse concept, Junk et al. 1989). When a frequent flood event is decoupled from the adjacent floodplain, important natural water quality processes and functions are compromised, including nutrient cycling and transport, contaminant sequestration and sometimes transformation, carbon export and food chain support, and feeding and breeding opportunities for aquatic organisms. Because current dam operations are dependent on runoff conditions, in general, more water is stored and released during high-flow years compared to low-flow years, resulting in variation in water quality conditions from season to season and year to year. During periods of high spill resulting in higher downstream velocities, fine sediment can be resuspended (as wash load) and larger-sized gravel and cobbles are mobilized, which redistributes bedforms and associated aquatic habitat, may cause accelerated sedimentation, and sometimes removes established vegetation within the stream channel. In places, shoreline retreat caused by mass wasting triggered by fluctuating reservoir levels may also occur.

Some reservoirs within the Columbia River Basin stratify. Stratification refers to the different vertical layers which develop in the water column due predominantly to solar warming of the surface (top layers) of the water and subsequent changes in the water's density. Generally, because of this vertical temperature and density gradient, three layers form: epilimnion (top), metalimnion or thermocline (middle), and hypolimnion (bottom) (https://www.nwd.usace.army.mil/CRSO/Documents/). As a result of thermal stratification, water column stability typically increases and mixing between layers is reduced, isolating various physical and biotic processes and leading to differences in concentrations of nutrients and other chemicals between the layers.

Hungry Horse, Libby, and Dworshak dams have deep storage reservoirs that retain water for several months, allowing for stratification. This stratification provides the ability to operate these dams, through selective withdrawal, to support downstream water temperature objectives. Grand Coulee is also considered a storage project, but it is unique in the fact that it has relatively low retention times due to the large amount of flow through the reservoir. This short retention time results in very weak thermal stratification. The other CRS dams (Albeni Falls, Grand Coulee, Chief Joseph, McNary, John Day, The Dalles, Bonneville, Lower Granite, Little Goose, Lower Monumental, and Ice Harbor) have relatively short retention times (only a few days or weeks) and more uniform water temperatures from the surface to the bottom; selective withdrawal is not useful at these dams since they lack strong stratification.

### 3.4.1 Area of Analysis

The area considered in this water and sediment quality evaluation consists of the Columbia River and tributaries (Snake, Clearwater, Pend Oreille, Flathead, and Kootenai Rivers) from the U.S.-Canada border to downstream of Bonneville Dam. This includes the Federal dams of Hungry Horse, Libby, Albeni Falls, Grand Coulee, Chief Joseph, Dworshak, Lower Granite, Little Goose, Lower Monumental, Ice Harbor, McNary, John Day, The Dalles, and Bonneville (Figure 3-106).

The water quality analysis for this EIS focused on the area of largest impact both upstream (in the reservoir) and downstream (in the tailrace) of each CRS dam. Operations of the CRS dams have negligible impacts on water and sediment quality in the tidally influenced portion of the Columbia River downstream of Bonneville Dam. These estimates are supported by results that are described in Sections 3.4.3.3 through 3.4.3.6. The descriptions of water quality and potential effects in Lake Koocanusa apply to the reservoir in Canada as well as the United States. Elsewhere in the Canadian portion of the basin downstream of CRS projects, effects to water quality from the CRSO alternatives would not be expected.

In general, it is known that the dams within the Columbia River basin disrupt the movement of sediment, blocking most material from moving downstream of Bonneville Dam, except for small amounts of fine suspended material that are carried to the ocean. It is also recognized that the presence of the dams may impact the lower Columbia River and estuary, simply because the natural processes in the river system have been disrupted by the dams; but the effects of dam construction are not analyzed in this EIS. Other downstream conditions, such as the water and sediment quality in the Portland, Oregon, area, are affected by factors outside the scope of this study, and those downstream conditions may also impact these resources. Existing dredging operations are not considered in this evaluation and are instead covered under other Corps NEPA documents (Corps 1998, 2002).

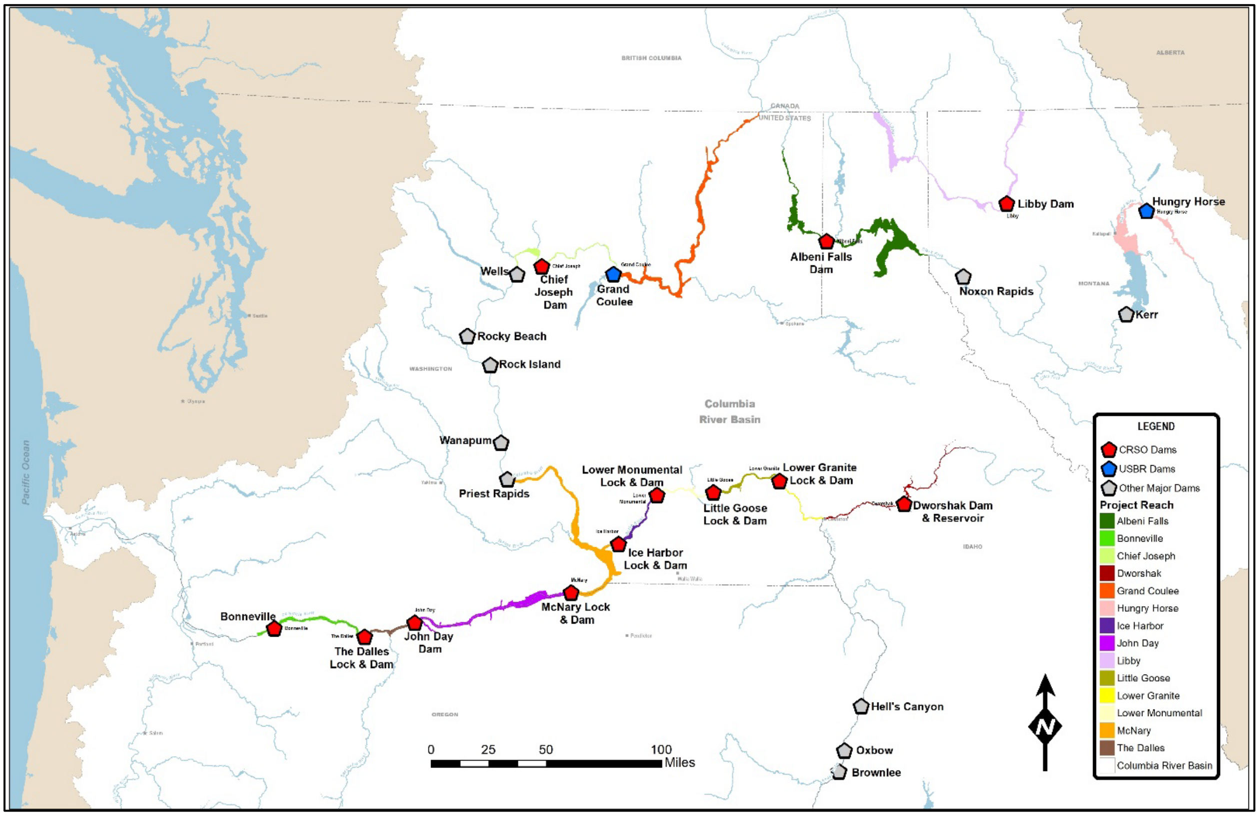


**Figure 3-106. Water Quality Study Area Map**

Note: Colored areas represent the study reaches included in this study.

### 3.4.2 Affected Environment

For this EIS analysis, water quality parameters have been separated into three major categories: (1) water temperature; (2) total dissolved gas (TDG); and (3) other physical, chemical, and biological conditions. This information is summarized in the paragraphs below for each MO.

#### *3.4.2.1 Water Quality*

The Clean Water Act (CWA) is the primary law governing surface water quality in the United States with the goal of restoring and maintaining the chemical, physical and biological integrity of waters (lakes, rivers, streams, wetlands, estuaries and coastal zones) throughout the nation (33 U.S.C. § 1251 et seq.). Under Section 303(d) of the CWA, the states, territories and authorized tribes are required to identify and list impaired waters that do not meet these goals (33 U.S.C. § 1313). The 303(d) list is a report or summary of the impaired waters that are categorized as a Level 5, meaning that water quality standards have not been met for one or more pollutants, and there is no total maximum daily load (TMDL) or pollution control program in place. Multiple waterbodies within the CRSO study area are 303(d) listed. EPA is currently in the process of developing a temperature TMDL.  This is discussed further in Appendix D.

Water quality standards (WQSs) are the legal basis for controlling pollutants entering the waters of the United States. The WQSs describe the desired condition of a water body and the purpose of the condition. The states within the CRSO study area have established their own WQSs and monitoring programs in response to the CWA. Several tribes also have U.S. Environmental Protection Agency (EPA)-approved water quality standards and monitoring programs that apply to portions of the river, including the Confederated Tribes of the Colville Reservation, the Kalispel Tribe of Indians, and Spokane Tribe of Indians. These standards vary by water body and location and protection for various designated uses. Current (2016) state and tribal TDG and water temperature standards are used as the metrics to which all MO analysis results are compared.

TDG saturations[1] in rivers can fluctuate due to a variety of natural and human-caused influences.  Natural influences include total flow, wind, air temperature, barometric pressure, and incoming TDG from upstream and tributaries.  TDG saturation can also increase when dams release water through spillways and other non-turbine outlets. Spilling water at a dam results in increased TDG levels in downstream waters by plunging the aerated spill water to depths where hydrostatic pressure increases the solubility of atmospheric gases. Elevated TDG saturations generated by spill releases from dams are of concern because high saturations can promote the potential for gas bubble trauma in downstream aquatic biota (Weitkamp and Katz 1980; Weitkamp et al. 2002).

Spill operations may be necessary at individual CRS projects in circumstances when river flows exceed powerhouse hydraulic capacity, turbine outages occur, when powerhouse capacity is available but there is no demand for the additional electricity, or when North American Electric Reliability Corporation (NERC)/Western Electricity Coordinating Council (WECC) requirements apply. These events may limit the co-lead agencies' ability to pass water through the powerhouse and, in some cases, may result in additional spill, which can impact TDG levels. The state and tribal water quality standards for TDG are 110 percent throughout the Columbia River Basin.  To date, the states of Oregon and Washington have provided either standard modifications or criteria adjustments on a short-term basis for the benefit of juvenile fish that are passing the lower four Snake River and lower four Columbia River projects during the juvenile fish passage spill season, which runs from April through August. During this season, the lower eight dams are operated in accordance with applicable biological opinions and within

[1] TDG levels are measured at specific gages throughout the CRS and are representative of the TDG levels in the rivers.

these modified TDG standards. The state and tribal water quality standards for TDG are 110 percent throughout the Columbia River Basin with the exception of the lower four Snake River and lower four Columbia River projects during the juvenile fish passage spill season, which runs from April through August. During the juvenile fish passage spill season, the lower eight dams are operated in accordance with applicable biological opinions to meet modified TDG standards.[2]

Water temperature is one of the most important physiochemical constituents of surface water and has been modeled as part of the CRS EIS analysis. It controls the rate of all chemical reactions, directly affects fish and benthic macroinvertebrate growth and reproduction, and can be acutely toxic (fatal) to fish if drastic temperature changes occur or if temperatures exceed 25°C for salmon and steelhead.

Water temperatures in many reaches do not meet the regulatory standards in the summer and early fall. System operations can impact both water temperature and TDG in the Columbia River Basin, and given this the impact, the analysis in the CRSO EIS focuses on how both parameters may change with a change in operation as described in the MOs as compared to the No Action Alternative.

**WATER TEMPERATURE**

Hungry Horse Dam is outfitted with a selective withdrawal system (SWS) that allows water to be drawn from various elevations in the reservoir to meet downstream water temperature objectives. The SWS can operate over a pool elevation range from full (3,560 feet) down 160 feet (3,400 feet). However, major modification to the structure(s) is required to enable function over the lower 60 feet of this range, including removal of the upper and intermediate stationary gates.

The SWS at Hungry Horse Dam is operated from approximately June through October to release warmer water, to mimic temperatures similar to those in the Middle and North Fork Flathead Rivers. During winter and spring months, the reservoir's water column is well mixed, with temperatures throughout the water column being nearly equal from top to bottom (isothermal), making selective withdrawal operations ineffective.

Lake Koocanusa is the 90-mile-long reservoir formed by Libby Dam. The thermal conditions in Lake Koocanusa at Libby Dam typically lag seasonal weather conditions by several months due to the long residence time and thermal inertia (massive volume of water that slows warming and cooling within the reservoir). The heat contained in the reservoir during the summer is carried over into the fall and winter months. In general, thermal conditions at Libby Dam typically reach minimum temperatures during late March or early April and are characterized by a uniform temperature near 39.2°F (4°C). However, during cold winters surface water

[2] The Corps managed to 120 percent and 115 percent (the Washington TDG standard) in 2016, at the time of the Notice of Intent to Prepare the EIS. It should be noted that both Oregon and Washington have begun a water quality standards change process during 2019 for juvenile fish passage spill up to 125 percent TDG in the tailrace during the spring juvenile downstream fish passage season; however, the summer juvenile fish passage spill TDG standard will not change.

temperatures can be in the low 30s°F (0°C to 2°C) range, with surface icing occurring on the shallower upper half of the reservoir. Historical data suggests that the onset of thermal stratification typically begins in late April and May, and is weak and often short lived as weather systems disrupt the thermal structure. Full reservoir mixing and isothermal conditions (i.e., thermal destratification from the loss of heat, at the surface of the lake, back to the atmosphere) generally begins in December.

Libby Dam was designed with a selective withdrawal system (SWS) to manage release water temperatures downstream in the Kootenai River when thermal stratification develops in the reservoir. The selective withdrawal system is operated to provide as close to natural water temperatures as possible downstream in the Kootenai River throughout the year. However, given the presence of a large deep reservoir with stored latent heat as the source of water to the river, outflow temperatures can be cooler in the spring and warmer in the late fall compared to the natural pre-dam Kootenai River. Given this, the selective withdrawal system is operated to follow as best as possible a temperature rule curve developed from pre-dam daily temperatures collected in the Kootenai River from 1967 to 1972 by the Corps and Montana Fish, Wildlife & Parks.

Albeni Falls Dam is located in northern Idaho on the Pend Oreille River about 28 miles downstream of Lake Pend Oreille. Although Lake Pend Oreille is a natural lake, Albeni Falls Dam regulates the upper 11.5 feet of the lake. Albeni Falls Dam has little ability to manage water temperatures in the Pend Oreille River, and water temperature changes in Lake Pend Oreille and the Pend Oreille River are mainly influenced by atmospheric conditions and weather patterns. Lake Pend Oreille is the fifth deepest lake in the United States and exhibits strong thermal stratification regardless of the runoff year. However, a shallow low-water outlet channel acts as a barrier to the transport of much colder deep water from Lake Pend Oreille into the Pend Oreille River resulting in warmer lake surface waters entering the river. The Pend Oreille River TMDL (2011 revised) addresses elevated water temperatures in the summer. Winter water temperatures can be in the low 30s°F (0°C to 2°C) range, with some surface icing during colder winters.

At Grand Coulee Dam, there is little opportunity to manage downstream water temperatures as Lake Roosevelt is weakly stratified. This results in Grand Coulee releasing the coolest water possible in the summer months, based on constraints for generation reliability, voltage stability, and TDG standards. Because of the weak stratification, discharged water temperatures lag the warming/cooling trends observed in the inflow, at the U.S.-Canada border, and tend to be cooler in the spring and warmer in the fall than inflowing conditions. Portions of Lake Roosevelt is currently listed as a Category 5 reach on the state of Washington's 303(d) list for temperature.

Chief Joseph Dam is a run-of-river project located downstream of Grand Coulee Dam. Rufus Woods Lake, the 50-mile-long reservoir formed by Chief Joseph Dam, has an average water retention time (the amount of time water remains in the reservoir) ranging from about 1 to 8 days. Little to no thermal stratification occurs in Rufus Woods Lake, and water temperatures released from Grand Coulee Dam are passed downstream with little change due to the high flows and short retention time in the reservoir. In general, historical hourly temperatures are greater than 60.8°F (16°C) from about the middle of July through late October, and greater than 63.5°F (17.5°C) from about the beginning of August through the end of September. Rufus Woods Lake falls under the state of Washington's 303(d) list Category 5 for temperature due to high water temperatures in the late summer.

Dworshak is a deep, cold-water reservoir that exhibits strong thermal stratification regardless of the runoff year. Summer releases from the project are used to reduce water temperatures downstream in the lower Snake River (Lower Granite, Little Goose, Lower Monumental, and Ice Harbor Dams) where temperatures historically exceeded the current state of Washington standard of 68°F (20°C), even before the dams were constructed (Corps 2002). Historical temperatures in the lower Snake River Basin prior to the construction of the lower Snake River dams and the Hells Canyon Complex show that temperatures in the free-flowing lower Snake River often exceeded 68°F (20°C) in July and August and occasionally exceeded 25°C. These measurements were taken near the mouth of the Snake River from 1955 to 1958 (Peery and Bjornn 2002). The most noticeable effect can be seen at Lower Granite Reservoir where the tailwater water temperatures are managed to meet, or be less than, the state water quality standard during the summer. The cooling effect in the lower Snake River diminishes at each successive downstream reservoir and the frequency of exceedances above the standard increases. Winter water temperatures are typically in the low 30s°F (0 to 2°C) range, with some surface icing during colder winters.

The four lower Columbia River reservoirs (McNary, John Day, The Dalles, and Bonneville) are on the state of Washington's and Oregon's 303(d) due to elevated water temperatures above the standard of 68°F (20°C). All four reservoirs show weak to no surface warming during the summer months, largely due to the short residence time, wind, and flow-induced turbulent diffusion and convective mixing that occur in the reservoirs. The management of water temperatures in a manner similar to the strategies used on the lower Snake River is not effective in the lower Columbia River because there is not an upstream source of very cold water. Therefore, access to off-channel thermal refugia is critical for the migration and spawning success of anadromous fish (EPA 2020).

**TOTAL DISSOLVED GAS**

Libby and Hungry Horse Dams are both considered high head (tall) dams that tend to generate elevated TDG even when small discharges are released through the dams' non-turbine outlets. Spill at Libby is infrequent, so TDG exceedances are not as commonly seen as in other parts of the CRSO study area. Spill occurs more frequently at Hungry Horse as compared to Libby.

TDG on the South Fork Flathead River downstream of Hungry Horse Dam, to the confluence with the mainstem Flathead River, is of concern for resident fish species. When outflows exceed powerplant capacity, flows must be spilled through the outlet works (hollow-jet valves) or the spillway, which results in supersaturated gases in the downstream river. Based on the level of saturation and the length of exposure, effects can be acute or chronic and may result in mortality of fish in the system (Monk 1997). In high-flow years, TDG often does not meet the state standard of 110 percent below the dam during the spring and early summer due to the release of large amounts of water through outlets known to produce TDG.

In any given year, additional outages can occur due to regulatory requirements, planned maintenance, or unexpected events/equipment failures, which may limit the ability to pass water through the powerhouse and, in some cases, may result in additional spill. Specifically, Reclamation is planning a Hungry Horse Powerplant Modernization and Overhaul Project in the next 10 years (Reclamation 2018). Maintenance would require outages for one year in the powerplant, limiting the powerplant to two units and reducing the hydraulic capacity to approximately 6 kcfs. This could result in additional spill in this 1 year.

Spillway flows from Libby Dam can impact TDG saturations downstream in the Kootenai River. Spillway releases can result in an abrupt increase in TDG to saturations greater than 120 percent. However, in contrast to Hungry Horse Dam, the Libby Dam spillway is operated less frequently. Given this, downstream TDG saturations are less than 110 percent the majority of the time.

Albeni Falls Dam spill is highly dependent on runoff volumes. Historically, Albeni Falls Dam spills most years. In general, spillway operations between 1 to 50 kcfs at Albeni Falls Dam increase downstream TDG saturations by about 0 to 9 percent of forebay saturation depending on the amount of water spilled, the number of spillway bays operating, forebay TDG saturations, and total head. When spill is greater than about 50 to 60 kcfs powerhouse operations are suspended and the spill gates are opened, allowing the river to flow relatively unimpeded across the dam. Under these free-flow conditions there is little to no increase in downstream TDG saturations.

Spill at Grand Coulee Dam occurs when total flows exceed powerhouse capacity during high flows typically observed in the spring and early summer. Spill can also occur during lack of market conditions when there is no demand for additional electricity and hydropower production is unnecessary. Often in high-flow years water flowing into Lake Roosevelt across the U.S.-Canada border is in excess of 110 percent TDG. When Grand Coulee is required to spill to achieve flow or flood risk management (FRM) elevation requirements spill can exceed 130 percent TDG in some cases. The outlet tubes, and to a lesser extent, the drum gates, at Grand Coulee Dam are known to produce elevated TDG when in operation. When reservoir elevations are greater than 1,266 feet, the 11 drum gates can be used to discharge water downstream. The drum gates generate much less TDG than the outlet tubes and are the preferred outlet when available. The 40 regulating outlets are used to discharge water downstream when the forebay elevation is below 1,266 feet, at which point the drum gates become inoperable.

Spill at Chief Joseph Dam is also highly dependent on runoff volume and hydropower operations. Spill can also occur during lack of market conditions when there is no demand for additional electricity. The spillway is equipped with spillway deflectors to reduce TDG loadings to the Columbia River. Spilling at Chief Joseph Dam, when incoming TDG levels are elevated (greater than 120 percent), can reduce system TDG loading, therefore Chief Joseph Dam can be used to manage TDG saturations in the Columbia River. In general, spill at Chief Joseph Dam results in tailwater TDG saturations ranging from about 110 to 120 percent.

Dworshak Dam operations typically produce TDG that is less than 110 percent the majority of the time. Short-term exceptions, however, do occur when additional water is released for FRM purposes.

The four lower Snake River dams are run-of-river projects and TDG production is highly related to runoff volume and water temperature as documented in the TMDL for Lower Snake River Total Dissolved Gas (Washington State Department of Ecology [Ecology] 2003). The state of Washington has issued a short-term criteria adjustment to its TDG water quality standard to not exceed a 12-hour average TDG of 115 percent in the forebay and 120 percent in the tailwater for the purpose of juvenile fish passage during the juvenile fish spill season (generally April through August[3]). Excursions above these thresholds can occur, but are relatively infrequent due to the spillway deflectors and project operations (e.g., spill pattern and amount of spill) that are monitored and adjusted daily. Additionally, TDG saturation can be elevated not only during high-flow periods such as spring runoff, but also during low-flow conditions when the air temperatures are high.

The four lower Columbia River dams are operated for downstream fish passage during the fish passage spill season (April to August). These spill operations are managed to keep TDG saturation levels at or below modified/adjusted state water quality standards for the states of Washington (see above) and Oregon of 120 percent in the downstream tailwater. For the most part, TDG exceedances above these thresholds are minimal during the juvenile fish passage season, which can be attributed to structural enhancements (e.g., spillway deflectors) and operational strategies (e.g., tailoring spill to the configuration of each dam and its associated bathymetry, limiting spill, implementing spill patterns) that have been implemented over the years. Nonetheless, exceedances of the standards do occur under some river and meteorological conditions and there is a TDG TMDL that covers all four lower Columbia River reservoirs (Ecology 2002).

**OTHER PHYSICAL, CHEMICAL, AND BIOLOGICAL PROCESSES**

Hungry Horse Reservoir is considered oligotrophic, meaning it has low concentrations of nutrients required for primary productivity, but is well oxygenated throughout the water column. Due to low food availability (productivity) in the reservoir, resident fish rely on terrestrial insects near the lake’s shore to supplement their diet. Pollutants tend to be relatively low in the Hungry Horse Reservoir and no known pollution problems exist in the reservoir.

Lake Koocanusa would be classified as an oligotrophic to lower mesotrophic (intermediate concentrations of nutrients) water body based on summer concentrations of total phosphorus, chlorophyll a, and transparency (turbidity). The reservoir experiences weak thermal stratification and is well oxygenated throughout the entire water column. Total phosphorus

[3] *Supra* note 8.

concentrations are low and follow a seasonal pattern of increasing during spring runoff and decreasing during the summer and fall. Total phosphorus concentrations are typically two to five times greater at the U.S.-Canada border compared to the forebay, suggesting that Lake Koocanusa acts as a phosphorus sink. Concentrations of nitrate have been increasing throughout Lake Koocanusa since the early 2000s. The major change in the Lake Koocanusa watershed since 2000 is an increase in coal mining operations in the Elk and Fording Rivers watershed in British Columbia, and a corresponding increase in nitrate loading from the waste spoils runoff. Estimates are that the total amount of waste spoils from coal mining operations in British Columbia increased tenfold from 1997 to 2016. In addition, USGS has estimated that increased coal mining in the Elk and Fording Rivers has increased selenium loading to Lake Koocanusa fivefold over the past 20 years (USGS 2014). In general, total selenium concentrations are greatest in the hypolimnion. There does not appear to be a substantial seasonal trend in the data, but concentrations are generally higher in the spring and fall and lower in the summer.

For both Lake Pend Oreille and the Pend Oreille River, in general, summer total phosphorus and nitrate concentrations are low, water clarity is high, and algal growth is moderate. The lake and river are well oxygenated throughout the water column. A nearshore TMDL for nutrients was developed for Lake Pend Oreille in 2002 in response to an increasing trend in nuisance algal growth in the nearshore areas (IDEQ 2015).

Lake Roosevelt is classified as oligotrophic based on chlorophyll a, total nitrogen, total phosphorus, and Secchi depth measurements; however, some variation of this classification does exist both spatially and temporally. One example includes the area of reservoir at the mouth of the Spokane River, which is considered mesotrophic due to the influence of the nutrient-rich Spokane River. The increase in primary productivity due to this nutrient load tends to be localized and does not cause widespread issues for fish.

Historically, pollution from mining and smelting, as well as the atmospheric deposition of mercury, has impacted water quality in Lake Roosevelt. Metals have contaminated bed sediments, and mercury cycling—the process that converts insoluble mercury in the sediment and water into a soluble form (methylmercury)—has become more of a concern. The presence of these pollutants has contributed to fish consumption advisories due to bioaccumulation. These pollutants have likely migrated downstream through Lake Roosevelt. Trace elements have been found in Rufus Woods Lake sediments, suggesting that high flow events may push metal contaminants past Grand Coulee Dam at times (https://www.nwd.usace.army.mil/CRSO/Documents/). Additionally, dioxin discharge from pulp and paper mills and other sources has occurred in the system. EPA issued a TMDL for dioxin from RM 0 to RM 745 (below Grand Coulee Dam) in 1991, as well as for portions of the Snake River.

Rufus Woods Lake is a well-oxygenated near neutral to slightly basic pH waterbody with low to moderate nutrient concentrations. Small increases in total phosphorus and ammonia concentrations measured downstream of aquaculture facilities in Rufus Woods Lake suggest that these facilities may be a source of these nutrients. Rufus Woods Lake experiences annual harmful algae blooms (HABs) consisting of free-floating surface mats or clumps of algae containing the cyanobacteria *Oscillatoria* and the cyanotoxin anatoxin-a, which is a neurotoxin that can cause severe illness or death in animals and humans if ingested. These mats of algae are found throughout Rufus Woods Lake upstream and downstream of the aquaculture facilities. The increase in HABs is not attributed to the aquaculture facilities. These blooms are a fairly recent water quality issue, and remain unexplained, although HABs are typically caused by excess nutrient loads and enhanced by increased stream and air temperatures. Blooms also occasionally form in other areas of the Columbia, particularly in backwaters. There was a documented exposure (rash) for workers in contact with HABs on the Columbia in Grant County in 2009, for example (Ecology 2009).

Dworshak is a long, relatively narrow reservoir with historically low nutrient concentrations. A lake fertilization project began in 2007 with the goal of increasing productivity by changing the nitrogen to phosphorus ratios in the reservoir, thereby promoting the growth of phytoplankton species that are edible by zooplankton, resulting in improved forage base for fish. Some changes, both increases and decreases, have been documented for several of the chemical and biological parameters that are being monitored under the current lake fertilization project (https://www.nwd.usace.army.mil/CRSO/Documents/). Many of these changes have occurred in areas that are fertilized, as well as reaches that are not fertilized. As the program continues, additional data should help identify whether the observed shifts are due to the fertilization program, changes related to the inflows, natural aging of the lake, or other unidentified causes.

The water quality characteristics of the lower Snake River are, to a large extent, influenced by the inflowing Snake River above the confluence with the Clearwater River. The concentrations of soluble ions and nutrients are lowest during high runoff events when suspended solids are highest. There are usually no significant differences in the concentrations of these constituents, as well as chlorophyll a and algal biovolume, from one reservoir to the next. This is likely due to the relatively short hydrologic residence time of each impoundment.

Within the lower Columbia River, information on other water quality issues is limited. High pH and/or dissolved oxygen in limited portions of the reach from The Dalles to Bonneville Dams resulted in the inclusion of these parameters in the Washington or Oregon 303(d) lists for those stretches. Additionally, some portion of all four reservoirs contain other water quality impairments (mercury and polychlorinated biphenyls [PCBs] have fish consumption advisories and are on 303(d) lists; dioxin has a TMDL). The lower Columbia River contains a wide variety of human-sourced compounds, including metals and organic compounds. Continued pollutant and nutrient loading is expected due to farming activities, industry, and urban and agricultural runoff.

#### ***3.4.2.2 Sediment Quality***

Sediment in the Columbia River Basin is variable in size and composition. Within rivers, sediment originates in the upland areas and riverbanks, as erosion and materials washed or discharged into the river. Coarse-grained material (rock, stone, coarse sand) settles and moves only with the highest flows. Finer-grained material (clay, silt) tends to wash further down the river. In all cases, when the water slows or stops, such as in large reservoirs behind dams, the solids washed along by the water settle out and become the sediment at the bottom of the river.

Sediment in some areas impedes use of tribal fishing access sites and has negative impacts on cold-water refuges and other important habitat. Sedimentation can also impact navigation when it builds up in shipping channels. Areas commonly dredged include the confluence of the Snake and Clearwater Rivers, and other navigation points such as lock approaches and docking areas. The Corps maintains the navigation channel by dredging and by other activities, such as those listed in the Programmatic Sediment Management Plan (Corps 2014) and other documents. Sediment is characterized following applicable guidance and regulations prior to the implementation of dredging projects.

Sediment can carry pollutants. Naturally occurring metals (e.g., mercury) are expected to be present in the sediment, but unnaturally high levels of metals, nutrients, or organic compounds that wash into the river can bind to the sediment and remain at the bottom of the river. These pollutants can be mixed back into the water at a later time when the sediment is disturbed, or they can remain in the river or reservoir and impact aquatic organisms that live in or near the sediment.

Within the Columbia River Basin, sediment quality varies by location. The uppermost end of the system, such as the area near Hungry Horse Dam, tends to have fewer human influences and thus less sediment-based pollution.  As one moves downstream to more populous areas, sediment pollution is more common.  In addition, some reservoirs have known sediment pollution problems related to past industrial discharges from upriver sources. For example, in Lake Roosevelt, an estimated 10 to 14 million tons of slag-related contaminants are can be found in the sediments due to smelter operations. Sediment does not easily wash away from reservoirs, and the quality of the sediment tends to reflect the land uses and past environmental practices of the land users.

General issues throughout the Columbia River Basin include metals, which are particularly high in some reservoirs, and pesticides. Pesticides are generally present in low concentrations, however many of these compounds are toxic to aquatic organisms, bioaccumulate, and persist in the environment for decades. Other notable pollutants found in sediment within the basin include radionuclides, dioxins, and petroleum-based compounds. As with water pollutants, the sediment pollutants reflect the land uses and practices within the basin, including urban development, agriculture, mining, and other industrial activities. In summary, the contaminants of concern in sediment include metals, mercury, PCBs, dioxins, pesticides, and other organic compounds (mostly from human sources). Sediment quality at individual reservoirs, including potential sources of pollutants and historical issues, is discussed at length in separate technical documents that can be found on the CRSO website (https://www.nwd.usace.army.mil/CRSO/Documents/).

### 3.4.3 Environmental Consequences

#### *3.4.3.1 Methodology*

Changes to water and sediment quality for each alternative were assessed using both quantitative (numerical) and qualitative methods. Modeling was used to simulate the effects on water temperature and TDG in the Columbia, Snake, and Clearwater River Systems, while qualitative methods were used to predict effects to other physical, chemical, and biological processes such as dissolved oxygen.

The analysis used the CE-QUAL W2 and Hydraulic Engineering Center River Analysis System software (HEC-RAS) numerical models which are described further below:

- CE-QUAL-W2 model: The CE-QUAL-W2 model (Version 4.2) was used to simulate reservoir water temperature and TDG both by depth and distance up and downstream.
- HEC-RAS model: The HEC-RAS model (Version 5.0.3) was used to simulate up and downstream river (non-reservoir) water temperatures in the Snake, Clearwater, and middle Columbia Rivers.

Portions of the study area were analyzed with the CE-QUAL W2 and HEC-RAS models linked together. This is referred to as the "system model." The portion of the CRSO study area considered in the system model included an area that extended from the Columbia River mainstem at the U.S.-Canada border to Bonneville Dam. In the Snake River Basin, the system model included the North Fork of the Clearwater River from Dworshak Reservoir, the mainstem Clearwater River downstream of Orofino, Idaho, and the Snake River from Anatone, Washington, to the mouth of the Snake River. The system model included the 11 Federal dams in the study area: Grand Coulee, Chief Joseph, Dworshak, Lower Granite, Little Goose, Lower Monumental, Ice Harbor, McNary, John Day, The Dalles, and Bonneville. It also included five non-CRS projects (Wells, Rocky Reach, Rock Island, Wanapum, and Priest Rapids) on the Columbia River mainstem to more accurately describe the river conditions (Figure 3-107); however, the water quality at the non-CRS dams is not discussed in this section.

The system model required reservoir and river operations data and meteorological data such as wind speed and direction, air temperature, and barometric pressure inputs to predict water quality conditions. The reservoir and river operations data[4] used in the system model included total discharge, spillway and powerhouse operations, miscellaneous discharge, and reservoir/tailwater elevation data.

Water quality modeling in the system model was conducted over a 5-year period (2011 to 2015) to represent a wide range of environmental responses to hydrology (wet, dry, average) and weather conditions (hot, cold, average). These years are represented as the following:

- 2011 = HF/LT (high inflow/low temperature),

[4] Reservoir and river operations data were derived from the H&H ResSim and HydSim models, as described in Section 3.2.

- 2012 = AF/LT (average inflow/low temperature),
- 2013 = LF/AT (low flow/average temperature),
- 2014 = AF/AT (average flow/average temperature), and
- 2015 = LF/HT (low flow/high temperature).

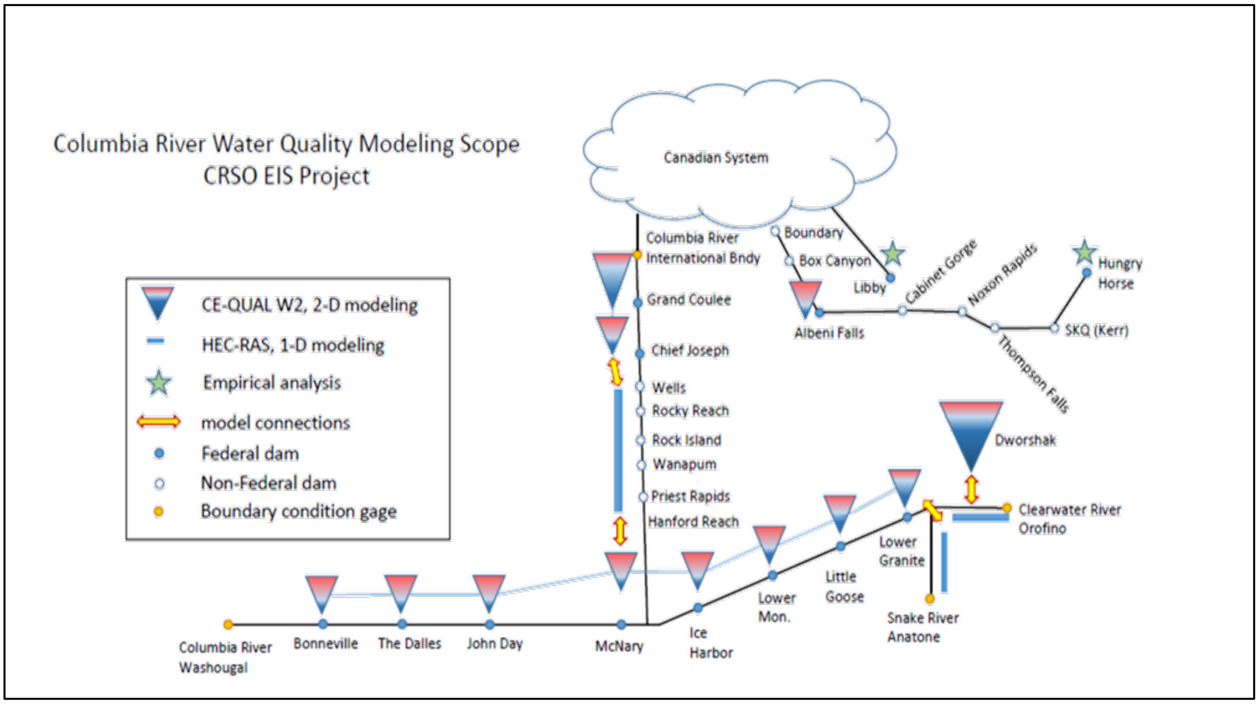

**Figure 3-107. Columbia River System Operations Environmental Impact Statement Water Quality Modeling Framework**

After running the system model, the simulated water temperature and TDG data were compared to state, federal and tribal temperature and TDG standards to quantify the effects associated with each alternative. This information was also used to inform effects to other resources such as anadromous and resident fish (Section 3.5), wildlife (Section 3.6), tribal uses (Section 3.17), and recreation (Section 3.11).

To analyze effects associated with actions at Albeni Falls Dam, the CE-QUAL W2 model was run separately from the system model because the Albeni Falls Dam is located on the Pend Oreille River approximately 100 river miles upstream from where the Pend Oreille River joins the Columbia River. Moreover, downstream of the Albeni Falls Dam, the Pend Oreille River is influenced by two non-Federal U.S. dams and two Canadian dams before flowing into the Columbia River. The Albeni Falls water quality modeling was used to simulate effects from the operation of Albeni Falls Dam, only, and not effects from the operation of non-CRS dams such as Boundary or Box Canyon, which fall outside the scope of this EIS. The Albeni Falls modeling addressed the area that extends from the outlet of Lake Pend Oreille near Sandpoint, Idaho, downstream to Albeni Falls Dam. The model simulated water temperatures, which were compared to state and Federal temperature standards. TDG production at Albeni Falls Dam was addressed qualitatively because a reliable model could not be developed due to a lack of direct relationship between discharge from the dam and TDG.[5]

For the Libby and Hungry Horse Dams, updated and peer-reviewed CE-QUAL W2 models either did not exist or were too outdated to be updated for use in this EIS. Instead, analysis tools that relied on observational data were developed to predict TDG generation from dam operations. The TDG analysis used TDG production equations that were derived from observational data to predict TDG generated under the various flow regimes for each alternative. A qualitative assessment was used to evaluate whether the MOs would likely adversely impact the ability to continue managing downstream water temperatures using the selective withdrawal systems that exist at both Libby and Hungry Horse Dams.

For each of the regions in the study area, sediment quality effects were evaluated qualitatively, using existing field data and information from past studies (white paper; i.e., CH9). There was no overall model describing sediment quality; however, sediment movement information from Section 3.3, *River Mechanics*, and the associated white paper; i.e., CH9 were used to inform the sediment quality analysis. For more information on these models and geomorphology and analysis, refer to Appendix D, *Water and Sediment Quality Appendix*, and Appendix C, *River Mechanics Technical Appendix*.

#### *3.4.3.2 Impact Framework*

A framework was developed to define the overall level of water temperature and TDG impact for each CRSO EIS alternative as compared to the No Action Alternative.  For water temperature, the level of impact (negligible, minor, moderate, or major) was defined based on the absolute change in the maximum and minimum water temperatures as averaged over the 5-year simulation period (2011-2015).  If the absolute change in water temperature between the MO Alternative and No Action Alternative was less than 0.4 degree Fahrenheit, the water temperature impact was considered negligible. If the absolute change in average minimum and maximum values was greater than 0.4 degree Fahrenheit, but less than 2 degrees Fahrenheit , the impact was considered negligible, minor or moderate based on the time of year (season) the impact occurred and whether the impact increased the number of days that State water quality standard (WQS) criteria was not met and by how much.  Absolute water temperature changes of >2 degrees Fahrenheit, or an increase in water temperature WQS exceedances of greater than 10 days, were considered a major impact (Figure 3-108).

For total dissolved gas, the following decision criteria was used to determine level of impact:

- Negligible: <=1% change in the 5-year average maximum TDG as compared to the No Action Alternative.
- Minor: >=1% but <2% change in the 5-year average maximum TDG as compared to the No Action Alternative.

[5] Studies indicate that a direct relationship between spillway discharge and the amount of TDG in the water is not consistently observed at Albeni Falls (Schneider et al. 2007). Developing a reliable model to estimate TDG saturations in the Pend Oreille River downstream of Albeni Falls Dam was not possible because of this lack of a spillway discharge versus TDG production relationship.

- Moderate: >=2% but <3% change in the 5-year average maximum TDG as compared to the No Action Alternative.
- Major: >=3% change in the 5-year average maximum TDG as compared to the No Action Alternative.

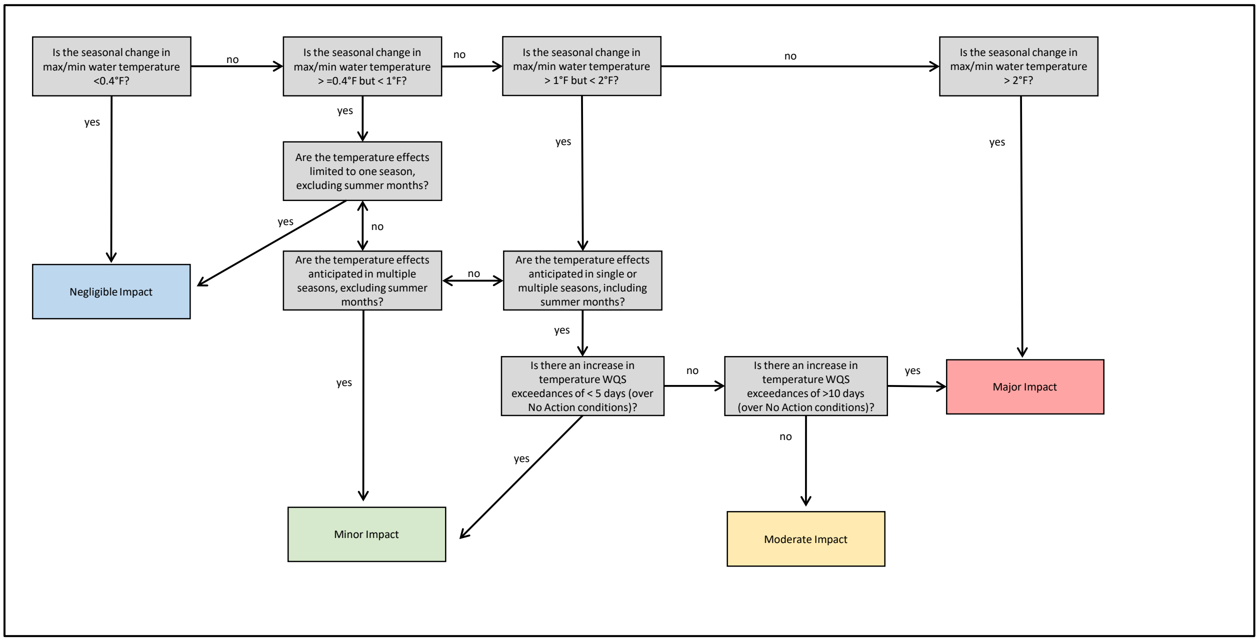

**Figure 3-108. Water Temperature Impact Framework and Decision Criteria**

These descriptors are used to summarize the overall impact of each EIS Alternative as described in the sections below.

For more detailed results, please refer to the Water Quality Technical Appendix D.

#### *3.4.3.3 No Action Alternative*

Water and sediment quality under the No Action Alternative would be expected to continue in a similar manner as that described in Section 3.4.2, *Water Quality Affected Environment*.

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Water Quality**

***Water Temperature***

In Region A, the use of the SWS at Hungry Horse and Libby Dams would continue under the No Action Alternative and, therefore, water temperatures at both projects are expected to be similar to those described in the Affected Environment (Section 3.4.2). Water temperatures in Lake Pend Oreille and the Pend Oreille River would remain unchanged and would also reflect conditions as described in the Affected Environment.

#### *Total Dissolved Gas*

TDG often does not meet the state of Montana's standard of 110 percent below Hungry Horse Dam during high-flow years when flow exceeds powerhouse capacity and water is released through the dam outlets known to produce TDG. This is expected to continue under the No Action Alternative in high-flow years. In years that follow a very dry year in which Hungry Horse Reservoir water levels are well below the end of September elevations, minor reductions in TDG would be observed due to the reduced spill associated with lower reservoir water levels. Any spill operations conducted at Libby Dam would continue to cause elevated TDG downstream. Libby Dam is not expected to spill frequently under the No Action Alternative, so downstream TDG saturations are anticipated to typically remain less than 110 percent.

Albeni Falls Dam spill is highly dependent on runoff volumes and, historically, Albeni Falls Dam has spilled most years. Under the No Action Alternative, these spillway operations are expected to continue in a manner similar to that described in the Affected Environment (Section 3.4.2).

#### *Other Physical, Chemical, and Biological Processes*

Under the No Action Alternative, nutrients or pollution would remain relatively low in Hungry Horse Reservoir. If coal production in the Kootenai River watershed above Libby Dam continues to increase, as it has over the past 20 years, this increase will lead to greater selenium and nitrate loadings into Lake Koocanusa and the Kootenai River downstream of Libby Dam. Though separate from the operation of Libby Dam, the continued increase in nitrate loadings to Lake Koocanusa could make the lake susceptible to increased algae blooms including potential nuisance species under the No Action Alternative.

Current water quality conditions of Lake Pend Oreille and the Pend Oreille River are expected to continue under the No Action Alternative. If nutrients continue to increase in the nearshore areas, it is likely that nuisance aquatic growth would further impair beneficial uses in the future.

### Sediment Quality

Similar to water quality, under the No Action Alternative, sediment-related processes and projects would continue to occur much as they do now as described in the Affected Environment (Section 3.4.2).

Sediment accumulation behind the dams in Region A would continue under the No Action Alternative. Sediment that has accumulated behind the dams would remain a source of contamination to benthic and aquatic organisms in Libby Reservoir due to upstream mining activities. No known pollutants exist in Hungry Horse Reservoir or directly downstream of the dam.

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Water Quality

#### Water Temperature

Lake Roosevelt at Grand Coulee has relatively short water retention times (i.e., the water does not stay in the reservoir for long) due to the large amount of flow through the reservoir. This short retention time results in water temperatures being fairly uniform across reservoir depths and at the dam's penstock intake depths. Because of the nearly uniform water temperature in the reservoir, there is not a cold water layer from which to draw from during the summer. This results in Grand Coulee Dam releasing the coolest water possible in the summer months, based on constraints for generation reliability, voltage stability, and TDG standards. Lake Roosevelt does, however, exhibit the typical water temperature lag that is commonly seen in impounded waterbodies. The reservoir tends to be cooler in the spring and warmer in the fall as compared to undammed rivers. This pattern would continue in the future under the No Action Alternative.

Chief Joseph Dam is a run-of-river project located downstream of Grand Coulee Dam. Little to no thermal stratification (i.e., different water temperature layers) occurs in Rufus Woods Lake, and water temperatures released from Grand Coulee Dam are passed downstream with little change due to the high flows and short retention time in the reservoir. Under the No Action Alternative, these conditions are expected to continue.

#### *Total Dissolved Gas*

TDG often does not meet state water quality standards at the international border, or downstream of Grand Coulee or Chief Joseph Dams, during high-flow years when a spill occurs. TDG produced by the operation of Grand Coulee and Chief Joseph Dams is expected to remain unchanged and reflect conditions as described in the Affected Environment (Section 3.4.2). Spill would still be necessary when total flows exceed powerhouse capacity or for hydropower (lack of market) reasons. The Chief Joseph spillway would still be equipped with flow deflectors to reduce TDG in the Columbia River. Spill operations at Chief Joseph Dam that are used to manage TDG saturations in the Columbia River are not expected to change under the No Action Alternative.

#### *Other Physical, Chemical, and Biological Processes*

Lake Roosevelt's in-reservoir processes would continue under the No Action Alternative (see Appendix D). The rate of bioaccumulation of contaminants within the reservoir is anticipated to remain relatively unchanged from what is currently observed.

In recent years, there has been an increase in harmful algae blooms in Rufus Woods Lake that are not attributed to the aquaculture facilities. These blooms are a fairly recent water quality issue, which remain unexplained, but are expected to continue in the future under the No Action Alternative.

**Sediment Quality**

Similar to water quality, under the No Action Alternative, sediment-related processes and projects would continue to occur much as they do now, as described in the Affected Environment (Section 3.4.2).

Sediment accumulation behind the dams in Region B would continue under the No Action Alternative. Sediment that has accumulated behind the dams would remain a source of contamination to benthic and aquatic organisms. Some pesticides or other compounds may slowly degrade over time; however, metals and the bulk of organic pollutants would remain in the accumulated sediment. Contaminants of concern in the sediment would continue to include metals, mercury, PCBs, dioxins, pesticides, and other organic compounds (mostly from human sources).

**REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS**

**Water Quality**

***Water Temperature***

Dworshak is a deep, cold water reservoir that exhibits strong thermal stratification regardless of the quantity of water entering the reservoir (i.e., runoff year). As such, under the No Action Alternative, sufficient cold water that is less than 52°F is expected to continue to be available to moderate lower Snake River temperatures during the summer (see Appendix D).

Water temperatures at the lower Snake River projects as described in Section 3.4.2 would continue under the No Action Alternative. As noted earlier, historical temperatures in the lower Snake River Basin prior to the construction of the lower Snake River dams and the Hells Canyon Complex show that temperatures in the free-flowing lower Snake River often exceeded 68°F (20°C) in July and August and occasionally exceeded 25°C. The effects of the Dworshak Dam summer cool water releases are expected to continue to influence water temperatures in the lower Snake River. The most noticeable effect of the cool water releases would be noted at Lower Granite Reservoir where water temperature stratification is expected to occur during the summer and tailwater temperatures would usually be held at less than 68°F during the summer (see Appendix D). The cooling effect from the Dworshak water releases would diminish at each successive downstream reservoir after Lower Granite and the frequency of water temperatures exceeding water temperature standards would increase downstream of Lower Granite Dam. Winter water temperatures would continue to be in the low 30°F range, with some surface icing during colder winters.

#### *Total Dissolved Gas*

Under the No Action Alternative, TDG is anticipated to be less than 110 percent the majority of the time below Dworshak Dam, although short-term exceptions would likely occur when flows exceed powerhouse capacity.

The four lower Snake River dams are run-of-river projects, and TDG production is highly related to runoff volume. Excursions above the WQSs in place in 2016 (115 percent forebay and 120 percent tailwater) are expected to continue during the fish spill season (April through August) at a frequency of that observed in recent years.  Additionally, because expressed TDG saturation is temperature dependent, elevated TDG saturation would also be expected to occur during low-flow conditions when the air temperatures are high.

#### *Other Physical, Chemical, and Biological Processes*

Dworshak Reservoir nutrient fertilization occurs annually and is expected to continue under the No Action Alternative. As the program continues, additional data should help identify whether the observed shifts in water quality are due to the fertilization program or changes related to the inflows, natural aging of the lake, or other unidentified causes.

The lower Snake River contains a variety of human-sourced compounds, including metals and organic compounds. Continued pollutant and nutrient loading is expected due to farming activities, industry, and urban and agricultural runoff. In addition, models suggest that the current moderate to high levels of nutrients (i.e., mesotrophic to eutrophic conditions) in the lower Snake River reservoirs is unlikely to change under the No Action Alternative. Thus, it is expected that the current water quality impairments would continue under the No Action Alternative.

### Sediment Quality

Sediment-related processes and projects would continue to occur in a similar manner as described above for Region B. Additionally, sediment management activities in the lower Snake River (as described in the Programmatic Sediment Management Plan (Corps 2014) and other documents) would continue as currently planned under the No Action Alternative. Areas that historically have required dredging (lock chamber approaches, harbor and port berthing areas and entrances) would still experience shoaling (buildup of sediment in shallow areas). The Federal Navigation Channel (FNC) and private dockface/berthing area dredging to maintain navigation would still occur.

## REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

### Water Quality

#### *Water Temperature*

The four lower Columbia River reservoirs (McNary, John Day, The Dalles, and Bonneville) would continue to show weak to no water temperature stratification during the summer months. This would largely be due to the short time water is in the reservoirs and water mixing[6] that occurs in the reservoirs. Exceedances of water temperature standards in Region D occur during the summer under a range of river and meteorological conditions and would be expected to continue to occur under the No Action Alternative (see Appendix D).

#### *Total Dissolved Gas*

The lower Columbia River dams in Region D are operated as run-of-river projects (albeit John Day has a small amount of storage), and TDG production is highly related to runoff volume. A similar frequency of TDG exceedances above the WQS in place in 2016 (115 percent forebay and 120 percent tailwater) are expected to continue to occur during the juvenile fish passage spill season under the No Action Alternative. Additionally, because TDG saturation is temperature dependent, elevated TDG would be expected to occur during low-flow conditions when the air temperatures are high.

#### *Other Physical, Chemical, and Biological Processes*

The lower Columbia River contains a variety of human-sourced compounds, including metals and organic compounds. Continued pollutant and nutrient loading is expected due to farming activities, industry, and urban and agricultural runoff. In addition, data suggests that the moderate to high levels of nutrients (i.e., mesotrophic to eutrophic conditions) in these reservoirs is unlikely to change under the No Action Alternative. Thus, it is expected that the current water quality impairments in the lower Columbia River would continue under the No Action Alternative.

### Sediment Quality

Sediment-related processes and projects would continue to occur in a similar manner as that described above for Region C.

## SUMMARY OF EFFECTS

Water and sediment quality under the No Action Alternative would be expected to continue in a similar manner as that described in Section 3.4.2, *Water Quality Affected Environment*.

[6] Water mixing may occur from wind, water flows, or sinking cold water (i.e., convective mixing).

Although the effects of the No Action Alternative differ across the various projects in terms of water and sediment quality, they can generally be categorized as follows.

In Region A, TDG does not always meet the state of Montana's standard of 110 percent below Hungry Horse Dam during high-flow years when flow exceeds powerhouse capacity and water is released through the dam outlets known to produce TDG. This is expected to continue under the No Action Alternative in high-flow years. Any spill operations conducted at Libby Dam would continue to cause elevated TDG downstream. Increases in nitrate loadings to Lake Koocanusa and the Kootenai River could lead to increased algal blooms and associated nuisance species. Contaminated sediment accumulation behind Libby Dam in Region A would continue under the No Action Alternative.

In Region B, water temperature lags associated with Lake Roosevelt would continue, and water temperatures released from Grand Coulee Dam would be passed downstream and through Lake Rufus Woods with little change due to high flows and short retention times. TDG produced by the operation of Grand Coulee and Chief Joseph Dams is expected to remain unchanged. Algae blooms in Rufus Woods Lake would be expected to continue.

In Region C, thermal stratification at Dworshak reservoir and the release of cold water to moderate lower Snake River temperatures would be expected to continue. TDG would be anticipated to be less than 110 percent the majority of the time below Dworshak Dam, while a similar frequency of TDG exceedances above WQS in place in 2016 (115 percent forebay and 120 percent tailwater) are expected to continue in the lower Snake River. Continued pollutant and nutrient loading is expected due to farming, industry, and urban and agricultural runoff in the lower Snake River.

In Region D, little to no water temperature stratification would occur during the summer months, and exceedances of water temperature standards would continue under a range of river and meteorological conditions. Similar frequencies of TDG exceedances above current standards are expected to continue during the juvenile fish spill season (April through August). Continued pollutant and nutrient loading is expected due to farming, industry, and urban and agricultural runoff.

### *3.4.3.4 Multiple Objective Alternative 1*

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Water Quality**

***Water Temperature***

In general, the water temperature response at the Libby and Hungry Horse Dams are expected to be similar to the No Action Alternative. However, slight changes in water temperatures downstream of Libby Dam could occur due to the *December Libby Target Elevation* and *Modified Draft at Libby* measures. With these measures, water temperatures downstream of

Libby Dam could be warmer in the winter and colder in the early spring as compared to the No Action Alternative.

There are no changes to operations expected at Albeni Falls Dam under MO1, so the temperature conditions in Lake Pend Oreille and the Pend Oreille River are expected to remain unchanged under MO1 and reflect conditions as described in the No Action Alternative.

***Total Dissolved Gas***

In general, MO1 would have little to no impact on TDG conditions below Libby, Hungry Horse, and Albeni Falls Dams as compared to the No Action Alternative.

TDG below Hungry Horse Dam under MO1 is expected to be relatively similar to the No Action Alternative in most years. The winter and spring operations at Hungry Horse Dam are not specifically targeted by any of the MO1 measures, but due to changes in reservoir elevations at the end of September from *the Hungry Horse Additional Water Supply* measure and the *Sliding Scale at Libby and Hungry Horse* measure, winter and spring reservoir elevations and outflows would be impacted. In the years that follow a very dry year, in which Hungry Horse Reservoir water levels are well below the summer flow augmentation elevation objectives at the end of September, minor reductions in TDG would be observed due to the reduced outflow and spill the following spring associated with lower reservoir water levels.

Libby Dam is operated to minimize spill. Under MO1, Libby Dam's draft and refill operations would be modified, resulting in a minor increase in spill compared to the No Action Alternative. For the 80-year period from 1928 to 2008, model results predict 6 years with spill under MO1 compared to 2 years when spill would occur for the No Action Alternative. In those years identified as having spill at Libby Dam, the model predicts 35 days with TDG exceeding 110 percent for MO1 versus only 8 days with TDG exceedances under the No Action Alternative. Regardless, Libby Dam is not expected to spill frequently under MO1, so downstream TDG saturations should remain less than 110 percent the majority of time.

Albeni Falls Dam spill is highly dependent on runoff volumes. Historically, Albeni Falls Dam spills most years. Because there is no change in Albeni Falls Dam operations between MO1 and the No Action Alternative, spillway operations and TDG conditions under MO1 are expected to remain unchanged.

***Other Physical, Chemical, and Biological Processes***

Negligible impacts to the physical, chemical, or biological processes at Hungry Horse Reservoir and the South Fork Flathead River downstream of the dam, are expected as compared to the No Action Alternative. Although the operational measures *Hungry Horse Additional Water Supply* and *the Sliding Scale at Libby and Hungry Horse* could result in deeper reservoir drawdowns, stratification that would influence nutrient levels in Hungry Horse Reservoir are not expected to change. There may be some reductions to primary and secondary productivity in the reservoir due to changes in outflows and storage, but effects would be negligible as compared to the No Action Alternative.

MO1 would result in changes to water levels in Lake Koocanusa that may impact physical, chemical, and biological water quality parameters when compared to existing conditions and the No Action Alternative. Parameters of concern in Lake Koocanusa that may be altered by MO1 include changes to nutrients (such as phosphorus and nitrogen), selenium, and phytoplankton. Although unrelated specifically to MO1, coal production in the Kootenai River watershed above Libby Dam may continue to increase, as it has over the past 20 years. This increase, together with changes in reservoir elevations and the amount of time water spends in the reservoir under MO1, may lead to greater quantities of selenium and nitrate in Lake Koocanusa and the Kootenai River downstream of Libby Dam. The shorter residence time (amount of time that water stays in the reservoir) may also allow phosphorus to move farther down reservoir before settling out or transforming. This increase in nutrients available in the reservoir could make the lake more susceptible to increased phytoplankton blooms including potentially toxic species under MO1.

Water quality conditions of Lake Pend Oreille and the Pend Oreille River described for the affected environment and the No Action Alternative are expected to continue under MO1.

**Sediment Quality**

Operational changes at Libby and Hungry Horse Dams under MO1 are not expected to affect sediment movement downstream in the Kootenai and Flathead Rivers, respectively. MO1 would not impact Albeni Falls Dam operations and would not affect sediment sources or movement.

**REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS**

**Water Quality**

***Water Temperature***

The water temperature in Lake Roosevelt would not likely be affected by upstream flow changes or by the five operational measures (*Update System FRM Calculation, Planned Draft Rate at Grand Coulee, Grand Coulee Maintenance Operations, Winter System FRM Space,* and *Lake Roosevelt Additional Water Supply*) called for under MO1.

For Columbia River temperatures downstream of Grand Coulee Dam, model results suggest there would be a negligible change in water temperatures, on average. The number of days that water temperatures would exceed Washington State WQSs would be reduced by 1 day per year, on average. Changes to Grand Coulee Dam outflows would be carried through Rufus Woods Lake, Chief Joseph Dam, and downstream. These flow changes are relatively small and would result in a negligible change in Rufus Woods Lake elevations when compared to the No

Action Alternative. As such, Chief Joseph Dam tailwater temperatures under MO1 would be similar to the No Action Alternative.

### *Total Dissolved Gas*

Downstream of Grand Coulee Dam, major reductions in TDG, as compared to the No Action Alternative, would occur due to the MO1 measures that call on more operational flexibility for FRM (*Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Grand Coulee Maintenance Operations*, and *Winter System FRM Space*) and the water supply measure (*Lake Roosevelt Additional Water Supply*). The major maintenance measure (*Grand Coulee Maintenance Operations*), which is expected to temporarily reduce the powerhouse capacity of Grand Coulee Dam and increase the magnitude of spill and TDG in some situations, was balanced by improvements to TDG associated with the other Grand Coulee measures. TDG effects anticipated at Grand Coulee would be carried downstream of Chief Joseph Dam and Reservoir. During high flow years, the spillway deflectors at Chief Joseph Dam would provide reductions (degassing) of elevated TDG levels generated from upstream Canadian dam and Grand Coulee Dam operations. TDG effects downstream of Chief Joseph Dam under MO1 are negligible.

### *Other Physical, Chemical, and Biological Processes*

Qualitative analysis suggests that, when compared to the No Action Alternative, MO1 could have minor effects to physical, chemical, and biological processes in Lake Roosevelt. The slower drawdown from the *Planned Draft Rate at Grand Coulee* measure could provide minor reductions in local landslides and associated high turbidity, and thereby improve water quality. However, water level fluctuations in the reservoir (due to the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, and *Winter System FRM Spa*ce measures) may increase methylmercury in the waterbody. The MO1 measures would not change the number of times portions of the reservoir banks and margins are covered with water (inundated), but the MO1 measures would result in earlier and longer exposure of sediments. This longer sediment exposure may increase the amount of mercury that is converted to methylmercury upon rewatering the area. Methylmercury is the more toxic form of mercury that bioaccumulates in fish tissue. Minor changes to water retention times passing through the reservoir from February through July are not expected to result in changes to algae blooms, pH, or dissolved oxygen conditions. No additional physical, chemical, or biological water quality effects are expected to occur in the Columbia River immediately below Grand Coulee Dam.

Chief Joseph Dam and Rufus Woods Lake elevations and flows under MO1 are predicted to be similar to the No Action Alternative. As such, the water quality of Rufus Woods Lake under MO1 would be similar to the No Action Alternative. The harmful algae blooms described for the affected environment and the No Action Alternative would be expected to continue in the future under MO1.

#### Sediment Quality

Minor increases in the mobilization of sediment and shoreline erosion is expected within Lake Roosevelt due to changes in elevations under MO1 from the *Update System FRM Calculation, Planned Draft Rate at Grand Coulee, Grand Coulee Maintenance Operations, Winter System FRM Space,* and *Lake Roosevelt Additional Water Supply* measures. However, it is not anticipated that additional sediment would pass the dam; expected effects would occur within the reservoir. In comparison to the No Action Alternative, MO1 flow changes at Chief Joseph Dam would be minor, and no effects to sediment sources or movement would be expected.

### REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

#### Water Quality

##### *Water Temperature*

Under MO1, Dworshak Reservoir would continue to thermally stratify during the summer, and outflow water temperatures would remain less than the Idaho State water quality standard of 55.4°F. Water temperatures in the lower Snake River would increase during August, due to the *Modified Dworshak Summer Draft* measure. Under MO1, cool water would be discharged into the lower Snake River from June 21 to August 1. During August, total Dworshak outflows would be reduced to preserve cold water for release again in September. This modified Dworshak operation would result in a moderate increase in water temperatures in the lower Snake River, on average. It is not anticipated that fish ladder water temperature improvements at Lower Monumental and Ice Harbor Dams (*Lower Snake Ladder Pumps*) would have any meaningful impact to downstream river water temperatures. These structural changes would be anticipated to effect fish ladder conditions only.

##### *Total Dissolved Gas*

Implementing MO1 would lead to negligible changes to TDG saturation below Dworshak Dam for most flow and temperature conditions. There are two measures within MO1 that would modify juvenile fish passage spill operations in the lower Snake River; the *Block Spill Test (Base + 120/115%) Measure* and the *Summer Spill Stop Trigger.* The *Block Spill Test* calls for a spill test to evaluate the latent mortality hypothesis; spill operations switch between performance (base) spill and a test spill operation within a given season. The *Summer Spill Stop Trigger* calls for the early end to summer juvenile fish passage spill operations at the lower Snake River projects. Ending dates vary from August 6 to 21, depending on the dam. Due to the within-season switch between operations at the dams, in conjunction with an assumed higher amount of lack of load/lack of market spill, model results showed a negligible difference in TDG levels under MO1, even with these operational measures, as compared to the No Action Alternative.

#### *Other Physical, Chemical, and Biological Processes*

Having water stay longer in Dworshak Reservoir during August under the *Modified Dworshak Summer Draft Measure* could lead to additional blue-green algae growth. However, liquid fertilizer is currently added (and would be expected to continue) to the reservoir to manage the nitrogen to phosphorus ratio (nutrient balance). The continuation of the nutrient balancing would be expected to prevent the formation of hazardous algal blooms as a result in the change to Dworshak operation under MO1.

Increased water temperatures (as described above), along with higher concentrations of soluble nutrients and a longer time water stays in reservoirs in the lower Snake River during August, would likely foster additional growth of cyanobacteria (blue-green algae) in swim areas and boat basins.

### Sediment Quality

MO1 includes structural changes aimed at improving juvenile fish passage in Region C; these proposed measures would not affect sediment sources or movement because they do not change the overall flow range experienced in the river, and the measures would not result in disturbance of the sediment held deep within the reservoir. The proposed operational changes generally have a goal of improving flexibility in operation and of improving in-stream (flow and temperature) conditions for fish; changing the timing of operational flows or the temperature characteristics would not affect sediment sources. MO1 is not expected to affect land use throughout the basin, including upland recreation, FRM, agricultural, timber, or mining activities, and is not expected to change population growth patterns in the area of any of the affected reservoirs. Overall, MO1 is not expected to affect sediment movement within Region C.

## REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS

### Water Quality

#### *Water Temperature*

Under MO1 and as with the No Action Alternative, the four lower Columbia River reservoirs (McNary, John Day, The Dalles, and Bonneville) would continue to show weak to no water temperature stratification during the summer months largely due to the time water is in the reservoirs and water mixing that occurs in the reservoirs. Maximum tailwater temperatures and the frequency of water temperature standard exceedances would be similar for MO1 and the No Action Alternative over a range of river and meteorological conditions; negligible effects are anticipated.

#### *Total Dissolved Gas*

Similar to that described for the lower Snake River projects in Region C, the measures within MO1 that modify spill would have a negligible effect on TDG levels under MO1 as compared to the No Action Alternative for the lower Columbia River projects.

#### *Other Physical, Chemical, and Biological Processes*

For Region D, MO1 would have no change on the physical, chemical, or biological water quality impairments.

### Sediment Quality

Overall, sediment quality within Region D would change little from the No Action Alternative as the structural measures, operational changes, nor would land use under MO1 impact sediment sources or movement.

## SUMMARY OF EFFECTS

Although the effects of MO1 differ across the various projects in terms of water and sediment quality, they can generally be categorized as follows:

In Region A, MO1 is expected to have negligible to minor effects to water temperatures and TDG conditions at the projects when compared to what would occur under the No Action Alternative. There would be a minor increase in spill and associated TDG levels at Libby Dam due to the project's draft and refill operations. Minimal changes to the physical, chemical, or biological processes in most locations in Region A would occur.  Elevated concentrations of selenium and nitrate-nitrogen in Lake Koocanusa and the Kootenai River downstream may occur due to the increased reservoir elevations that may concentrate these contaminants. Lastly, MO1 would not impact turbidity or sediment concentrations in the region. Overall, these effects are expected to be negligible to minor.

In Region B, MO1 is expected to have negligible effects on water temperatures when compared to the No Action Alternative. Major reductions in TDG would occur downstream of Grand Coulee due to the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Grand Coulee Maintenance Operations*, and *Winter System FRM Space* and *Lake Roosevelt Additional Water Supply* measures. Slight increases in mercury solubility in Lake Roosevelt may occur, but there would be little to no additional changes compared to the No Action Alternative to the physical, chemical, and biological processes elsewhere. The minor additional mobilization of sediment is expected to occur in Lake Roosevelt, but no additional changes to sediment quality are anticipated. Overall, these effects are expected to be negligible to minor. Negligible impacts are expected in Lake Rufus Woods or downstream of Chief Joseph Dam.

In Region C, MO1 is expected to increase the number of days that water temperatures would exceed Washington State water quality standards in the lower Snake River due to the *Modified Dworshak Summer Draft* measure.  Major impacts would be expected in the Lower Granite tailwater with an additional 18 days of exceedances per year on average, as compared to the No Action Alternative. Negligible impacts would be expected in the Ice Harbor tailwater with an additional 5 days of exceedances per year, on average as compared to the No Action Alternative. Increased water temperatures may result in additional growth of blue-green algae in the region. Little to no changes in TDG concentrations and sediment movement would occur. Overall, the effects to water quality would be moderate for water temperature and negligible to minor for TDG and other water quality parameters.

In Region D, MO1 is expected to result in little to no change to water temperatures, TDG, sediment quality, or other water quality parameters when compared to the No Action Alternative. These effects are expected to be negligible.

For further details, please refer to the Water Quality Technical Appendix D.

#### *3.4.3.5 Multiple Objective Alternative 2*

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Water Quality**

***Water Temperature***

Under MO2, the SWSs at Hungry Horse and Libby Dams would continue to be operational. However, thermal stratification must be present in the forebay for the SWSs to achieve temperatures as close as possible to downstream water temperature objectives, critical for resident fish species. The onset of thermal stratification is difficult to predict and can vary from year to year due to reasons such as inflow volumes, inflow temperatures, reservoir drawdown elevation, discharge volumes, and weather conditions. Historical temperature data suggests that holding the reservoir water levels higher in the winter results in colder reservoir water temperatures and difficulty for the SWSs to achieve desired water temperatures the following spring/early summer.

When Libby and Hungry Horse Reservoirs are drafted deeper, the reservoir volume is less, thereby allowing for greater warming in the spring and summer from warmer inflows and warming air temperatures. Under MO2, lower reservoir elevations are anticipated due to the *Slightly Deeper Draft for Hydropower* measure and would likely be substantial enough to result in a change in Lake Koocanusa and Hungry Horse Reservoir water temperatures and thermal stratification as compared to the No Action Alternative. These lower reservoir elevations are likely to result in slightly warmer reservoir temperatures and earlier thermal stratification during the spring and summer resulting in a greater ability for the SWSs to achieve downstream temperatures when compared to the No Action Alternative.

Downstream of Libby Dam, higher November and December outflows may delay the natural cooling of the Kootenai River downstream of the dam. The higher outflows in November and December are caused by the combination of the *Slightly Deeper Draft for Hydropower* measure with the *December Libby Target Elevation* measure. When combined, these measures result in a reservoir elevation of 2,400 feet NGVD29. This deeper draft to 2,400 feet NGVD29 at the end of December, and the subsequent reservoir levels through the winter, however, may allow for the reservoir to warm earlier in the spring, providing for earlier (and beneficial) warming to water temperatures downstream of the dam.

Operations specific to Albeni Falls would change little under MO2 as compared to the No Action Alternative. However, upstream flow changes, such as those called for under MO2 at Hungry Horse Dam, would result in flow changes in the Flathead River that would be evident downstream through the Pend Oreille Basin. These operational changes would result in minor temperature changes downstream of Albeni Falls Dam, ranging from a decrease of about 0.9 degree Fahrenheit to an increase of about 2.7 degrees Fahrenheit , with the greatest differences occurring during the winter months (January/February).

***Total Dissolved Gas***

MO2 would modify Libby Dam's drawdown and refill operations, resulting in a small increase in spill compared to the No Action Alternative. For the 80-year period from 1928 to 2008, model results predict that spill would occur in 6 years under MO2 versus only occurring in 2 years for the No Action Alternative. In those spill years, MO2 would have 27 days with TDG exceeding 110 percent while only 8 days would exceed the TDG standards under the No Action Alternative. Regardless, Libby Dam is not expected to spill frequently under MO2, so downstream TDG saturations should remain less than 110 percent the majority of time.

The *Slightly Deeper Draft for Hydropower* measure allows for greater operational flexibility and would result in deeper winter drawdowns at Hungry Horse Reservoir. This, in turn, would reduce spring outflows and spill in some cases. As a result, the number of days that TDG below the dam would be greater than 110 percent under MO2 is expected to be lower than the No Action Alternative in most years.

Albeni Falls Dam spill is highly dependent on runoff volumes. Historically, Albeni Falls Dam spills most years. Because there are little changes in Albeni Falls Dam operations between MO2 and the No Action Alternative, spillway operations under MO2 are expected to remain unchanged.

***Other Physical, Chemical, and Biological Processes***

The modified operations under MO2 would result in changes in the drafting depth, water elevations, and retention times of Lake Koocanusa and Hungry Horse Reservoir. This could lead to higher flushing rates and reductions in primary and secondary productivity in the reservoirs. Water quality chemical and biological parameters of concern in Lake Koocanusa that may be impacted by MO2's shorter residence times include nutrients such as phosphorus and nitrogen, suspended sediments, metals such as selenium, and phytoplankton.

Water quality conditions of Lake Pend Oreille and the Pend Oreille River described for the affected environment and the No Action Alternative are expected to continue under MO2.

**Sediment Quality**

MO2 includes operational changes that would result in water level changes at some reservoirs. These changes would have little overall effect on sediment within Region A. Additional shoreline erosion could occur at some reservoirs that have large water elevation fluctuations; however, the sediment that erodes would be trapped within the reservoirs and would not move downstream. MO2 is not expected to affect land use throughout the basin, including upland recreation, FRM, agricultural, timber, or mining activities, and it is not expected to change population growth patterns in the area of any of the affected reservoir. The contaminants of concern in the sediment are expected to remain the same. Overall, MO2 is expected to have little impact on sediment conditions within Region A in comparison to the No Action Alternative.

**REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS**

**Water Quality**

***Water Temperature***

The Grand Coulee Dam area, comprised of Lake Roosevelt above the dam and the Columbia River below, are affected by five operational measures (*Slightly Deeper Draft for Hydropower, Update System FRM Calculation, Planned Draft Rate at Grand Coulee, Grand Coulee Maintenance Operations, Winter System FRM Space*).  These measures would result in an earlier and sometimes deeper drawdown of Lake Roosevelt and changes to inflow due to changes in operations at the upstream projects. Many of the measures would be implemented in the winter when the reservoir is nearly the same temperature (i.e., isothermal) so downstream temperatures during the winter would not be affected. The carry-over effects from these measures, however, may reduce the cold water mass that tends to cool inflowing water from upstream sources in the spring and early summer. This could result in minor warming in the spring and early summer, especially in LF/HT years (see Section 3.4.3.1 for definitions). Overall, MO2 is expected to have negligible effects on water temperature.

Flow changes observed at Grand Coulee Dam would move downstream through Rufus Woods Lake and Chief Joseph Dam. Water temperatures under MO2 at Chief Joseph Dam tailwater would be similar to, or slightly cooler than, the No Action Alternative with the majority of temperature differences in the ±1 to 2 degrees Fahrenheit range. However, for the AF/AT and LF/HT scenarios (see Section 3.4.3.1 for definitions), spring and early summer water temperatures would be 1 to 2 degrees Fahrenheit warmer under MO2. Tailwater temperatures under MO2 are predicted to exceed the Washington State water quality standard of 63.5°F, as measured by the 7-day average of the daily maximum temperature throughout the months of August and September; these exceedances occur under No Action as well. In general, MO2 water temperature changes at Chief Joseph Dam would be negligible.

#### *Total Dissolved Gas*

The *Grand Coulee Maintenance Operation* measure, in isolation, could result in substantial increases in spill and TDG, and in some cases, produce TDG in excess of 130 percent; however, this effect is largely offset in the spring and early summer by other measures, such as the *Slightly Deeper Draft for Hydropower* measure that would result in lower reservoir elevations in late winter/early spring. Compared to the No Action Alternative, MO2 results in a reduction in TDG, particularly in May and June, in the Columbia River below Grand Coulee Dam. MO2 model results indicate that TDG would decrease, particularly in average flow years, from May 1 to mid-June by 5 percent to 10 percent. This effect is considered a major reduction using the logic presented in Section 3.4.3.2.

At Chief Joseph Dam, forebay and tailwater TDG saturations are predicted to be similar to or slightly less than the No Action Alternative under MO2 for a wide range of flow and air temperature conditions. Overall TDG impacts under MO2, as compared to the No Action Alternative, are negligible.

#### *Other Physical, Chemical, and Biological Processes*

At Grand Coulee, operational measures including the *Winter System FRM Space, Deeper Draft for Hydropower*, and the influence from upstream projects would result in an increase in outflows from November to January. In January through March, the *Planned Draft Rate at Grand Coulee* would likely cause Lake Roosevelt to be drafted more slowly in some cases, potentially reducing local landslides (which can cause turbidity) and thereby improve water quality. However, earlier and deeper reservoir drawdowns at Grand Coulee could result in the longer duration and exposure of reservoir shoreline sediment and increase the potential for mercury solubility in the reservoir water (although the measures would not change the number of occurrences of repeated inundation and exposure of sediment in comparison to the No Action Alternative). Increased exposure has the potential to increase mercury methylation rates, which could lead to greater buildup of mercury quantities in aquatic organisms (i.e., bioaccumulation) (Willacker 2016), among other potential contributing factors. No notable effects are likely to occur in the Columbia River immediately below Grand Coulee Dam.

Chief Joseph Dam and Rufus Woods Lake elevations and flows under MO2 are predicted to be similar to the No Action Alternative. As such, the water quality of Rufus Woods Lake under MO2 would be similar to the No Action Alternative. The harmful algae blooms described for the affected environment and the No Action Alternative would be expected to continue in the future under MO2.

### Sediment Quality

Similar to that described for Region A, MO2 includes operational changes that would result in water level changes at some reservoirs, but the changes would have little overall effect on sediment within Region B. Overall, MO2 is expected to have little impact on sediment conditions within Region B.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Water Quality

#### *Water Temperature*

Deeper drawdowns of Dworshak Reservoir from the *Slightly Deeper Draft for Hydropower* measure, ranging from 12 to 38 feet in the spring, could lead to slower warming of the surface waters because the smaller surface area would result in less warming by the sun in the early spring. Near-full pool would be reached by July, and thermal stratification for the remainder of the year would not change. Average outflow temperatures would be approximately 0.8 to 1.6degrees Fahrenheit warmer in May, June, and July during AF/AT conditions (see Section 3.4.3.1 for definitions). Mean monthly temperature changes for April through September for the other flow and weather conditions modeled would range from -0.5 to 0.6 degree Fahrenheit. However, maximum temperatures would remain less than 52°F throughout the year, and overall water temperature effects downstream of Dworshak Dam under MO2 would be negligible using the logic presented in Section 3.4.3.2.

MO2 water temperatures in the lower Snake River would result in moderate to minor changes as modeled, compared to the No Action Alternative. Under MO2, ResSim modeling assumptions did not represent the intended operations and instead showed the reservoir would have a decreased refill probability, refilling to within 0.5 feet of the normal full reservoir elevation in about 48 percent of years.  It is likely that in real-time operations, the refill probability for Dworshak Reservoir under MO2 would be higher than shown in modeled results, and more closely aligned to the No Action Alternative. Therefore, effects to water temperatures are considered negligible in Region C.

#### *Total Dissolved Gas*

TDG saturation downstream of Dworshak Dam would remain below 110 percent for most of the year, with a few exceptions. Some increases in downstream TDG occurred in the modeling results during high-flow years due to the modeling assumption that increased outflow in the spring. The spring modeling assumption did not represent the desired operation as defined in the *Slightly Deeper Draft for Hydropower* measure. In actual operations, spill would be consistent with water quality criteria, and these impacts would be avoided, when possible, during implementation of this measure. Overall effects are anticipated to be negligible for TDG.

The *Spill to Near 110 Percent TDG* measure limits juvenile fish passage spill at the lower Snake and Columbia dams to 110 percent TDG as measured in-river, including tailraces and downstream forebays except when higher minimum spill levels are required for powerhouse surface passage routes, for spillway weirs, and/or for adult attraction. Additionally, spill during high flow and flood events would not be restricted to a cap of 110 percent TDG, but rather set to levels necessary for safety. Lack-of-market spill would also continue, and would follow the spill priority list. TDG in the lower Snake River downstream of Lower Granite Dam would be greater than 110 percent from April through July during most flow and meteorological conditions due to lack-of-turbine spill and/or spill for lack-of-market. Maximum TDG values would still exceed 120 and 125 percent during May, June, and July. However, because spill for juvenile fish passage would no longer occur during August under MO2, there would be a minor decrease in the amount of time that TDG levels exceeded 110 percent in August. Overall impacts to TDG in the lower Snake River under MO2 would range from minor to negligible.

***Other Physical, Chemical, and Biological Processes***

The lower water elevation of the Dworshak Reservoir from April through June would result in a smaller surface area and consequently slower warming of the surface by the sun. Additionally, shallower water depths at the upper end of the reservoir would lead to faster water travel times and delayed primary production.

Water quality conditions, as described for the affected environment and the No Action Alternative, are expected to continue under MO2 for the lower Snake River.

**Sediment Quality**

Similar to that described for Region A, MO2 includes operational changes that would result in water level changes at some reservoirs, but the changes would have little overall effect on sediment within Region C for the same reasons discussed above in the Region A discussion under MO2.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Water Quality**

***Water Temperature***

Under MO2 and as with No Action Alternative, the four lower Columbia River reservoirs (McNary, John Day, The Dalles, and Bonneville) would continue to show weak to no temperature stratification during the summer months largely due to the time water is in the reservoirs and water mixing that would occur in the reservoirs. Maximum tailwater temperatures and the frequency of water temperature standard exceedances would be similar for MO2 and the No Action Alternative over a range of river and weather conditions. Impacts are expected to be negligible.

***Total Dissolved Gas***

MO2 model results generally show a decrease in forebay and tailwater TDG saturations and in the frequency of exceedances of current state TDG standards of 110 percent as compared to the No Action Alternative. MO2 effects on TDG would be minor at McNary and John Day Dams, moderate at The Dalles Dam, and negligible at Bonneville Dam based on the logic presented in Section 3.4.3.2.

***Other Physical, Chemical, and Biological Processes***

Water quality conditions, as described for the affected environment and the No Action Alternative, are expected to continue under MO2 for the lower Columbia River.

**Sediment Quality**

Overall, MO2 is expected to have little impact on sediment conditions within Region D and would be similar to the No Action Alternative.

**SUMMARY OF EFFECTS**

Although the effects of MO2 differ across the various projects in terms of water quality, they can generally be categorized as follows.

In Region A, MO2 is expected to result in a greater ability for the selective withdrawal system at Lake Koocanusa and Hungry Horse Reservoir to achieve downstream temperature objectives, compared to the No Action Alternative. In the Albeni Falls reservoir, there would be a small water temperature change ranging from about a 0.9 degree Fahrenheit decrease to an increase of about 2.7 degree Fahrenheit. The small increase in spill at Libby Dam would result in a small increase in the number of days with TDG exceeding 110 percent. Hungry Horse Dam would have fewer days exceeding 110 percent TDG compared to the No Action Alternative, and Albeni Falls TDG levels would remain the same. MO2 may result in some reductions to productivity in Hungry Horse and Libby Reservoirs, but the alternative would not impact turbidity or sediment concentrations in the region. Overall, these effects are expected to be negligible to minor.

In Region B, MO2 is expected to result in slight warming in the spring and early summer under certain flow and air temperature conditions, but in general water temperature effects are negligible. TDG would decrease at Grand Coulee, particularly in average flow years, by 5 to 10 percent. TDG effects downstream of Chief Joseph Dam are negligible. There may be some additional mercury mobilization in Lake Roosevelt, but no additional physical, chemical, or biological water quality parameters are anticipated to change from the No Action Alternative.

In Region C, MO2 is expected to result in negligible water temperature effects. The frequency when TDG would exceed 110 percent would decrease in August in the lower Snake River due to reduced spill for downstream fish passage. All other water quality conditions would be similar to those under the No Action Alternative. Overall, water quality effects in Region C under MO2 are anticipated to be minor to negligible.

In Region D, water temperatures would be similar to the No Action Alternative. TDG saturations and the frequency of exceeding the state TDG water quality standards would decrease under MO2. All other water quality parameters are anticipated to be similar to the No Action Alternative. Overall, there would be a negligible impact to most water quality parameters and a minor to moderate reductions in TDG conditions.

For further details, please refer to the Water Quality Technical Appendix D.

#### *3.4.3.6 Multiple Objective Alternative 3*

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Water Quality**

***Water Temperature***

Under MO3, the SWSs at Hungry Horse and Libby would continue to be operational and therefore, water temperatures management at both projects would continue as that described in the No Action Alternative. Downstream of Libby Dam, higher November and December outflows may delay the natural cooling of the Kootenai River downstream of the dam. The higher outflows in November and December are caused by the *December Libby Target Elevation* measure which, in MO3, calls for a reservoir elevation of 2,400 feet NGVD29 at the end of the December. This deeper draft to 2,400 feet NGVD29 at the end of December and the subsequent reservoir levels through the winter, however, may allow for the reservoir to warm earlier in the spring, providing for earlier (and beneficial) warming to water temperatures downstream of the dam.

There would be no changes to operations expected at Albeni Falls Dam so the temperature conditions in Lake Pend Oreille and the Pend Oreille River are expected to remain unchanged under MO3 and reflect conditions as described in the No Action Alternative.

***Total Dissolved Gas***

MO3 would modify Libby Dam's draft and refill operations resulting in a small increase in spill compared to the No Action Alternative. For the 80-year period from 1928 to 2008, model results predict 5 years when spill would occur under MO3 versus only 2 years when spill would occur for the No Action Alternative. Of those years with spill, there would be 27 days with TDG exceeding 110 percent for MO3 versus 8 days of spill exceeding the 110 percent TDG standard under the No Action Alternative. Regardless, Libby Dam is not expected to spill frequently under MO3, so downstream TDG saturations should remain less than 110 percent the majority of time.

Winter and spring Hungry Horse Dam operations are not specifically targeted by any measures, but due to changes in pool elevations at the end of September from the *Hungry Horse Additional Water Supply* measure and the *Sliding Scale at Libby and Hungry Horse* measure, winter and spring reservoir elevations and outflows would be impacted. Specifically, outflows from October through June would be lower under MO3 than the No Action Alternative. TDG below the dam under MO3 is expected to be relatively similar to the No Action Alternative in most years. The only exception would be for those years that follow a very dry year in which Hungry Horse Reservoir would not reach its normal end-of-September elevation; TDG in these years could be slightly reduced due to reduced outflow and spill (Appendix D).

Albeni Falls Dam spill is highly dependent on runoff volumes. Historically, Albeni Falls Dam spills most years. Because there are little to no changes in Albeni Falls Dam operations between MO3 and the No Action Alternative, TDG levels under MO3 are expected to remain unchanged.

#### *Other Physical, Chemical, and Biological Processes*

The modified operations under MO3 would result in changes in the drafting depth, water elevations and retention times of Lake Koocanusa and Hungry Horse Reservoir. This could lead to higher flushing rates and moderate to major reductions in primary and secondary productivity in the reservoirs. Water quality chemical and biological parameters of concern in Lake Koocanusa that may be impacted by the MO3's shorter water residence times include nutrients such as phosphorus and nitrogen, suspended sediments, metals such as selenium, and phytoplankton.

Water quality conditions of Lake Pend Oreille and the Pend Oreille River described for the affected environment and the No Action Alternative are expected to continue under MO3.

### Sediment Quality

The operational measures related to spill control and timing, fish ladder configuration, spillway configuration, and other changes would not impact sediment movement and would not change existing sediment conditions in the Columbia River in Region A. Proposed changes to the timing and magnitude of operational flows also are not expected to impact sediment movement or existing sediment conditions; the proposed flows would be within the historical range of flows. No changes to sediment quality and current sedimentation patterns in Region A from MO3 are expected.

## REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS

### Water Quality

#### *Water Temperature*

MO3 water temperatures are nearly identical to conditions under the No Action Alternative in Lake Roosevelt and the Columbia River downstream of Grand Coulee Dam, with few exceptions. Many of the MO3 measures (the *Planned Draft Rate at Grand Coulee* measure, the *Update System FRM Calculation measure, Lake Roosevelt Additional Water Supply,* and changes to inflow due to changes to upstream projects) would impact winter and spring storage and outflow; however, the measures are not expected to impact temperatures significantly. Spring/early summer water temperatures downstream of Grand Coulee Dam would increase slightly (on average, 0.3 degree Fahrenheit for the period of May through July) in the driest of years. Overall, negligible water temperature effects below Grand Coulee Dam are expected under MO3.

Changes to Grand Coulee Dam outflows would carry downstream through Rufus Woods Lake and Chief Joseph Dam. Modeled temperatures under MO3 Alternative at Chief Joseph Dam tailwater are similar to, or slightly cooler, than the No Action Alternative with the majority of temperature differences in the ±0.5 to 2 degrees Fahrenheit range. Tailwater temperatures under MO3 are predicted to exceed the Washington State standard of 63.5°F (17.5°C) as measured by the 7-day average of the daily maximum temperature in August and September, similar to No Action Alternative. Water temperature changes downstream of Grand Coulee and Chief Joseph dams are negligible under MO3.

#### ***Total Dissolved Gas***

Downstream of Grand Coulee Dam, major reductions in overall TDG would occur in the spring/early summer due to the *Update System FRM Calculation* and *Lake Roosevelt Additional Water Supply* measures. The operational measure *Grand Coulee Maintenance Operations* reduces the hydraulic capacity through the power plants, and if examined independently, would increase occurrence and magnitude of spill. This measure, however, is largely offset in the spring and early summer by other measures (including effects to inflows from changes in upstream dam operations combined with the Lake Roosevelt Additional Water measure). Additionally, the *Contingency Reserves During Fish Passage Spill* measure would allow reserves to be carried as part of juvenile fish passage spill in the lower Snake and Columbia River projects, potentially allowing Grand Coulee to generate more and hold less units in reserve, thus reducing TDG.

At Chief Joseph Dam, the MO3 forebay TDG saturations are predicted to be similar to the No Action Alternative under a wide range of flow and air temperature conditions. The number of days the tailwater exceeds the 110 percent TDG criteria is predicted to be similar to or slightly lower under MO3 depending on flow and meteorological conditions (Appendix D). TDG effects downstream of Chief Joseph Dam under MO3 are negligible as compared to the No Action Alternative.

#### ***Other Physical, Chemical, and Biological Processes***

Qualitative analysis suggests that, when compared to the No Action Alternative, MO3 could have some slight effects to physical, chemical, and biological processes in Lake Roosevelt. No effects would be likely to occur in the Columbia River immediately below Grand Coulee. Operational measures, including the *Update System FRM Calculations and Planned Draft Rate at Grand Coulee*, would result in a deeper winter draft in some years as early as January. In February and March, the reservoir would likely be drafted more slowly (from the *Planned Draft Rate at Grand Coulee* measure), which could reduce local landslides associated with high turbidity, and thereby improve water quality. Earlier and potentially deeper drafts in some years would not change the number of occurrences of repeated inundation and exposure of sediment in comparison to the No Action Alternative but may result in earlier and longer exposure of sediments. However, earlier and deeper reservoir drawdowns at Grand Coulee could result in the longer duration and exposure of reservoir shoreline sediment and increase the potential for mercury solubility in the reservoir water (although the measures would not change the number of occurrences of repeated inundation and exposure of sediment in comparison to the No Action Alternative). Increased exposure has the potential to increase mercury methylation rates, which could lead to greater buildup of mercury quantities in aquatic organisms (i.e., bioaccumulation) (Willacker 2016), among other potential contributing factors.

Chief Joseph Dam and Rufus Woods Lake elevations and flows under MO3 measures are predicted to be similar to the No Action Alternative. As such, the water quality of Rufus Woods Lake under MO3 would be similar to the No Action Alternative. The harmful algae blooms described for the affected environment and the No Action Alternative would be expected to continue in the future under MO3.

**Sediment Quality**

Similar to those described for Region A, sediment movement and existing sediment conditions would remain the same in Region B under MO3 in comparison to the No Action Alternative.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

**Water Quality**

***Water Temperature***

Water temperature conditions at Dworshak Dam would be very similar under MO3 as compared to the No Action Alternative. Project operations would not change, and outflow temperatures would remain less than 54°F year-round.

Breaching the lower Snake River dams under MO3 would produce a major change in the volume and the amount of heat stored (i.e., heat storage capacity) in the lower Snake River. Water temperatures would respond accordingly, shifting from a reservoir to river system, with rapid warming in the spring and cooling in the fall. Based on modeling results, average August temperatures would be 0.2 degree Fahrenheit less at Lower Granite Dam and 1.8 degrees Fahrenheit cooler at Ice Harbor Dam, as compared to the No Action Alternative (Appendix D). Water temperature differences between impounded (No Action Alternative) and non-impounded river conditions (MO3) would be most notable in the fall and reach largest differences in November when there would be an average reduction in water temperatures of 3.6 degrees Fahrenheit at Lower Granite Dam and an 8.8 degree Fahrenheit decrease at Ice Harbor Dam. Maximum summer water temperatures would range from 72°F at Lower Granite Dam to 76°F at Ice Harbor Dam. The frequency of days when temperatures exceed 68°F would be highest in July and August and occur up to 45 percent of the time at Lower Granite Dam and 100 percent of the time at Ice Harbor Dam during these two months. Summer day/night temperature differences that range from 0.5 to 1.0 degree Fahrenheit under the No Action Alternative would increase to 2.5 to 3.5 degree Fahrenheit, providing nighttime cooling.

***Total Dissolved Gas***

TDG downstream of Dworshak Dam would be very similar under MO3 when compared to the No Action Alternative; effects are negligible compared to the No Action Alternative.

TDG above 120 percent could occur at the Lower Snake River dams during the spring prior to breaching since only three powerhouse units would be available to pass river flow. Remaining flow would go over the spillways, and the amount of TDG produced would depend on the spring inflows, but it could exceed 130 percent.

After breaching the dams, there would be no spill and consequently no resulting TDG at the lower Snake River dams. Plunge pools that could form during development of a stable channel morphology under the new flow regimen could also produce localized TDG greater than 110 percent for short periods of time.

***Other Physical, Chemical, and Biological Processes***

The physicochemical and biological processes in Dworshak Reservoir and downstream of the project would not differ from the No Action Alternative if MO3 is implemented.

Changes would occur to several of the physical and chemical constituents in the lower Snake River during breaching. Effects would be largest during reservoir drawdown and immediately following breaching. Suspended solid concentrations are expected to peak to more than 24,000 mg/L during the first breach (Lower Granite and Little Goose) and 16,000 mg/L during the second breach (Lower Monumental and Ice Harbor). Concentrations greater than 5,000 mg/L would last for 26 and 18 days during the first and second dam breaching events, respectively (Section 3.3, River Mechanics). Because the sediments and the interstitial waters (water between the sediment particles) are deprived of oxygen in the reservoir, they would create an oxygen demand when the oxygen-deprived water and sediment enter the water column during breaching, resulting in very low oxygen and even anoxic (no oxygen) conditions during reservoir drawdown and breach (Annex C). Water column concentrations of nitrogen and phosphorus would also increase as interstitial water is mixed with the river water during breaching, with total ammonia-nitrogen (a gaseous combination of hydrogen and nitrogen) the primary constituent of concern. Ammonia concentrations could exceed the EPA's aquatic life ambient water quality criteria for chronic toxicity as sediment is mixed with river water. Average ammonia elutriate concentrations for the four lower Snake River reservoirs in 1997 (Corps 2002) ranged from 2.5 to 3.6 mg/L, with some individual values exceeding 12 mg/L. Although actual water column concentrations would differ from elutriate concentrations, this data suggests that there is a potential for ammonia toxicity under MO3. A more concise estimate of the magnitude, duration, and frequency of possible in-water ammonia concentrations and resulting toxicity to fish would require additional sediment characterization coupled with fate/transport modeling. Oxygen and nutrient concentrations would normalize as suspended solids decrease to No Action Alternative levels. Intermittent oxygen deficits and nutrient pulses could occur for years after breaching, depending on the hydrologic and biotic processes at the time, and as material from exposed mudflats moves into the river due to slumping or runoff. However, there is uncertainty regarding these longer term (>2 year) effects.

Primary productivity would change from a system based on phytoplankton to attached benthic algae. During, and for some time after breaching, phytoplankton productivity would decrease as a result of increased suspended solids concentrations and reduced light transparency.

Current attached benthic algae communities would be exposed to air and desiccate. The transition phase to return the substrate to sand, cobble, and gravel could take years depending on runoff, location, and precipitation. After a new equilibrium of sediments is established, primary production would be expected to be higher per length of river than it was during impoundment under the No Action Alternative.

Secondary production would also change in the lower Snake River if MO3 were implemented. Zooplankton would become minor components of the food web, and aquatic insect larvae would become the main secondary producers.

**Sediment Quality**

MO3 would include breaching the four lower Snake River dams. This alternative would have a major impact on sediment processes within the Snake River. The dam breaching process would release a large volume of currently shoaled (buildup of sediment into shallow areas) sediment. The release of this sediment would cause both short-term effects (loss of dissolved oxygen, very high suspended solids, smothering of downstream aquatic organisms) and longer-term effects (changes to bioaccumulation of pollutants in aquatic organisms, long-term changes to bank erosion and groundwater discharges, changes to shoaling patterns within the lower Snake River). However, it should be noted that the sediment study did not include existing bridges and therefore does not consider bridge-related scour and deposition potential. Overall, the sediment in the lower Snake River would move downstream during and after the dam breach. The release of the currently shoaled sediment, which contains historical pollutants (pesticides, dioxins, other human-sourced pollutants and naturally occurring mercury in volcanic soils and from atmospheric deposition) would impact sediment quality in the lower Snake River (Appendix D). Future sediment accumulations in the lower Snake River would be limited to backwater areas and would largely accumulate downstream in the Region D (as discussed below). See Section 3.3, River Mechanics, for additional discussion of sediment movement.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Water Quality**

***Water Temperature***

Under MO3 and as with the No Action Alternative, the four lower Columbia River reservoirs (McNary, John Day, The Dalles, and Bonneville) would continue to show weak to no stratification during the summer months, largely due to the time water is in the reservoirs and water mixing. In contrast with the No Action Alternative, day-to-night and day-to-day variability may be greater in the lower Columbia River under MO3, though it would be far less pronounced than that anticipated in the lower Snake River (Region C). Maximum tailwater water temperatures and the frequency of water temperature standard exceedances would be similar for MO3 and the No Action Alternative, with minor effects expected at McNary, John Day, and The Dalles Dams and negligible effects expected at Bonneville Dam (Appendix D).

#### *Total Dissolved Gas*

Under MO3, the *Spring Spill to 120 percent TDG* measure calls for managing juvenile fish passage spill to not exceed a 120 percent TDG saturation at the tailrace of all four lower Columbia River dams from April 10 to June 15; there would be no TDG limit in the forebays under this alternative, resulting in larger amounts of spill at times. Additionally, the *Reduced Summer Spill* measure aims to reduce the duration of summer juvenile fish passage spill at the lower Columbia River dams, ending summer spill on July 31. As a result, MO3 model results show, as compared to the No Action Alternative, similar or higher tailwater TDG saturations April through June and lower TDG saturations in August. At most dams and under most river and weather conditions, forebay TDG saturations would be similar or lower under MO3 as compared to the No Action Alternative, especially in the McNary forebay because it would no longer be receiving elevated TDG from the lower Snake River projects. In general, TDG effects under MO3 would be minor to negligible in the lower Columbia River.

#### *Other Physical, Chemical, and Biological Processes*

Breaching of the lower Snake River dams would result in sediment being transported downstream to the McNary Reservoir, particularly in the years immediately following breaching (near-term). As a result, short-term major negative effects associated with the sediment transport would be expected in the McNary Reservoir (Appendix D). Dissolved oxygen, light attenuation, phytoplankton, zooplankton, and productivity would likely be depressed, while total suspended solids, turbidity, nutrients, organics, and metals would likely increase. Near-term transport of silt- and clay-sized particles downstream of McNary Dam may cause similar effects to the downstream reservoirs, though the effects would likely be much less severe than in the McNary Reservoir because the majority of coarse sediment is expected to be trapped by McNary Dam. The near-term increases in suspended sediment and turbidity (and associated effects) would eventually level off, and more typical seasonal fluctuations would occur long term in the McNary Reservoir and further downstream (Section 3.3, River Mechanics). Long-term increases in the estimated volumes of silt- and clay-sized particles transported to and downstream of the McNary Reservoir, as compared to the No Action Alternative, create the potential for increases in total nutrients, metals, and organic concentrations as these constituents are often associated with finer sediment particles. The magnitude of these long-term effects would reflect inflows after the system equilibrates as well as watershed land use practices and runoff events. The sediment shoaled behind the lower Snake River and McNary Dams has not been sampled in over 20 years, and there is uncertainty in the chemical characteristics of the sediment.

### Sediment Quality

With the exception of the area upstream of and in the McNary Reservoir, there would be no impact to sediment movement or condition in the lower Columbia River in Region D. Sediment movement and existing sediment conditions would remain the same at John Day, The Dalles, and Bonneville Dams in Region D under MO3. As discussed for Region C above, the sediment in the lower Snake River would move downstream during and after the dam breach. The release of the sediment, which contains historical pollutants (pesticides, dioxins, other human-sourced pollutants and naturally occurring mercury in volcanic soils and from atmospheric deposition) would impact sediment quality in the McNary Reservoir. In the future, the majority of the sediment moving through the lower Snake River would accumulate within the McNary Reservoir with a smaller amount of fine-grained suspended material passing through the dam, along the lower Columbia River, and out into the estuary. Future sediment accumulation at the lower Columbia River dams would not be greatly impacted. See Section 3.3, *River Mechanics*, for additional discussion of sediment movement.

**SUMMARY OF EFFECTS**

Although the effects of MO3 differ across the various projects in terms of water quality, they can generally be categorized as follows:

In Region A, MO3 would result in water temperatures that would be similar to the No Action Alternative. TDG levels would be similar to the No Action Alternative, though there may be a slight reduction in spill and associated TDG at Hungry Horse Dam during very dry years. There may be a decrease in primary and secondary productivity in the reservoirs.  Overall, MO3 would have a minor effect on water quality in Region A.

In Region B, MO3 water temperatures would be nearly identical to conditions under the No Action Alternative, with few exceptions. Downstream of Grand Coulee Dam, major reductions in overall TDG may occur in the spring/early summer. The Chief Joseph Dam forebay TDG saturations are predicted to be similar to the No Action Alternative under a wide range of flow and air temperature conditions. Mercury mobilization may occur slightly more frequently in Lake Roosevelt; no other water quality impairments are anticipated.

Region C would have the largest change in water quality under MO3. Breaching the lower Snake River dams under MO3 would produce a major change in the volume and the amount of heat stored in the lower Snake River. Water temperature differences (up to 8.8 degrees Fahrenheit) between impounded (No Action Alternative) and non-impounded (MO3) river conditions would be greatest in the fall.  TDG downstream of Dworshak Dam would be very similar under MO3. Due to the breaching, there would be no spill and consequently no resulting TDG at the lower Snake River dams. However, some elevated TDG would occur during preparation and implementation of dam breaching. Dam breaching would result in elevated suspended solids, particularly during and immediately following breaching, which could temporarily result in low oxygen conditions and elevated ammonia concentrations. Primary and secondary productivity would also temporarily decrease due to the suspended solids. In the long term, primary and secondary productivity is anticipated to be greater compared to the No Action Alternative. The release of sediment during and following the dam breach would also cause both short-term effects (loss of dissolved oxygen, very high suspended solids, smothering of downstream aquatic organisms) and longer-term effects (changes to bioaccumulation of pollutants in aquatic organisms, long-term changes to bank erosion and groundwater discharges, changes to shoaling patterns within the lower Snake River). Overall, MO3 would have a major short-term negative impact on water quality due to the mobilization of sediment during dam breaching.

Over the long term, MO3 would have moderate to major beneficial effects on water quality in Region C through the restoration of natural, river, and water quality processes; a substantial cooling effect in the fall; greater nighttime cooling and respite from warm water temperature conditions in the summer; and a reduction in overall system TDG.

In Region D, day-to-night and day-to-day water temperature fluctuations may be greater under MO3, but the maximum and frequency of water temperatures exceeding state water quality standards would largely remain the same as the No Action Alternative. Region D would have similar, though lesser effects as Region C from the dam breaching. TDG levels would be similar under MO3, though McNary Reservoir would no longer be receiving elevated TDG from the lower Snake River projects. Sediment and contaminants being transported to McNary Reservoir during and following the dam breach would result in reduced dissolved oxygen, light attenuation, phytoplankton, zooplankton, and productivity; while total suspended solids, turbidity, nutrients, organics, and metals would increase in the short term. Overall, MO3 would have a moderate short-term negative impact on water quality, particularly in McNary Reservoir due to the mobilization of sediment during dam breaching. Over the long term, MO3 would have a negligible to minor beneficial effect on water quality in Region D.

For further details, please refer to the Water Quality Technical Appendix D.

### *3.4.3.7 Multiple Objective Alternative 4*

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

**Water Quality**

***Water Temperature***

Under MO4, the selective withdrawal systems at Hungry Horse and Libby Dams would continue to be operational and therefore continue to maintain water temperatures at both projects in manners similar as those described in the No Action Alternative. Changes in water temperatures downstream of Libby Dam could occur due to the *December Libby Target Elevation* and *Modified Draft at Libby* measures. With these measures, water temperatures downstream of Libby Dam could be warmer in the winter and colder in the early spring as compared to the No Action Alternative.

There would be no changes to operations expected at Albeni Falls Dam for median and high water years under MO4, so the temperature conditions in Lake Pend Oreille and the Pend Oreille River are expected to remain unchanged and reflect conditions as described in the No Action Alternative for the median and high flow conditions. For the drier 40 percent of years, Lake Pend Oreille would be up to 2.6 feet lower in the summer due to higher outflows from Albeni Falls Dam. Due to this change, it is possible that higher summer flows might increase or decrease the temperature (ranging from 0.9 to 1.8 degrees Fahrenheit) in the Pend Oreille River depending on flow and weather conditions (Appendix D).

### *Total Dissolved Gas*

TDG below Hungry Horse Dam in the South Fork Flathead River could be affected by multiple operational measures. All of these measures may result in a deeper drawdown of the reservoir; however, these reductions would likely occur after the part of the year when spill and associated high TDG generally occur. TDG may be reduced in dry years subsequent to a large drawdown in the reservoir under MO4 because the reservoir would enter into the second year with much less carryover, which could, in turn, result in lower spill from the dam in the early months of the year. Despite the potential to reduce TDG in these water years, the TDG below the dam under MO4 is expected to be similar to the No Action Alternative for most conditions.

MO4 would modify Libby Dam's draft and refill operations, resulting in a small increase in spill compared to the No Action Alternative. For the 80-year period from 1928 to 2008, model results predict 6 years with spill under MO4 versus only 2 years for the No Action Alternative. Of these years when spill would occur, 43 days would have TDG exceeding 110 percent for MO4 versus only 8 days exceeding 110 percent TDG for the No Action Alternative. Regardless, Libby Dam is not expected to spill frequently under MO4, so downstream TDG saturations should remain less than 110 percent the majority of time.

Albeni Falls Dam spill is highly dependent on runoff volumes. Historically, Albeni Falls Dam spills most years. Because there are few changes in Albeni Falls Dam operations between MO4 and the No Action Alternative, spillway operations and TDG conditions under MO4 are expected to be similar to the No Action Alternative.

### *Other Physical, Chemical, and Biological Processes*

The modified operations under MO4 could result in changes in the drafting depth, water elevations, and retention times of Lake Koocanusa. Changes in reservoir elevation and retention times may result in changes to concentrations of nutrients such as phosphorus and nitrogen, metals such as selenium, and phytoplankton. This may lead to greater quantities of selenium and nitrate in Lake Koocanusa and the Kootenai River downstream of Libby Dam. The shorter residence time (amount of time that water stays in the reservoir) may also allow phosphorus to move farther down reservoir before settling out or transforming. This increase in nutrients available in the reservoir could make the lake more susceptible to increased phytoplankton blooms, including potentially toxic species, under MO4.

The decrease in pool elevation and volume during the summer months anticipated under MO4 at Hungry Horse and Libby Reservoirs may result in reduced biological productivity, which could impact phytoplankton and zooplankton populations that are important food sources for fish. In addition, the increased outflow under MO4 from both Hungry Horse and Libby Dams could reduce downstream river productivity with increasing flow from conditions in the No Action Alternative.

Water quality conditions in Lake Pend Oreille and the Pend Oreille River would be very similar under MO4 when compared to the No Action Alternative. However, for the drier 40 percent of years when the lake would be 2.6 feet lower in the summer, the shallow nearshore areas may be more susceptible to increases in macrophyte and periphyton growth and coverage. In addition, if there are increases in nearshore nutrients, it is possible that nuisance aquatic growths may further impair beneficial uses under MO4.

**Sediment Quality**

Many of the proposed actions under MO4 are related to juvenile fish passage. These actions (changes to fish ladders, screens, intakes, bypass areas) would not impact sediment movement and would not change existing sediment conditions in Region A. Proposed changes to the timing and magnitude of operational flows also are not expected to impact sediment movement or existing sediment conditions; the proposed flows are within the historical range of flows.

**REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS**

**Water Quality**

***Water Temperature***

From January through March, more empty space is held in Lake Roosevelt under MO4 for the updated winter space requirements for rain-induced flood mitigation (*Winter System FRM Space*), as well as the decreased draft rate used in planning the drawdown (*Planned Draft Rate at Grand Coulee*). Water temperatures in Lake Roosevelt and downstream of the dam are not anticipated to change from the No Action Alternative in average and wet water years; however, in drier years, comparison between MO4 and the No Action Alternative indicates that water temperatures may increase early in the year below the dam. Similar to the No Action Alternative, Lake Roosevelt would refill in July in average to wet years; however, in drier years, when Grand Coulee is managed to support the *McNary Flow Target* measure, the reservoir would not refill. Rather than being stored, warm water would be passed through the reservoir in May through July, creating conditions that are 0.8 degrees Fahrenheit warmer, on average, downstream of Grand Coulee Dam. Late summer temperatures would tend to be slightly (1 to 2 degrees Fahrenheit) warmer, except in the driest/warmest scenario, when model results show a decrease in temperature. The cause of this impact is likely a combination of changes in storage timing and outflows and over-simplifying model assumptions. In most years, there tends to be a rise in water temperature in September under MO4, which coincides with a reduction in total project outflows that are lower under MO4 as compared to the No Action Alternative. Water quality standards below Grand Coulee are expected to continue to be exceeded in August and September, as compared to the No Action Alternative. Overall water temperature effects downstream of Grand Coulee Dam are expected to be minor.

Flow pattern changes in Grand Coulee Dam outflows would be seen through Rufus Woods Lake and Chief Joseph Dam, as well as at the tailwater and downstream, under MO4. MO4 water temperatures at Chief Joseph Dam tailwater are similar to, or slightly warmer, than the No Action Alternative with the majority of temperature differences in the 1 degree Fahrenheit range. Tailwater temperatures under MO4 are predicted to exceed the Washington State standard of 63.5°F) as measured by the 7-day average of the daily maximum temperature in August and September; this would occur under the No Action Alternative as well. Water temperature effects downstream of Chief Joseph Dam are minor based on the logic presented in Section 3.4.3.2.

***Total Dissolved Gas***

There are multiple measures (*Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Winter System FRM Space*, *Lake Roosevelt Additional Water Supply*, *Grand Coulee Maintenance Operations*, *McNary Flow Target*) under MO4 that would result in changed operations at Grand Coulee Dam.

These operational measures are also included in MO1 with one exception—the addition of the *McNary Flow Target* measure. During drier years, the *McNary Flow Target* measure would require the release of up to an additional 2 MAF of water from Lake Roosevelt to help maintain fish flow objectives in the lower river; 1.0 MAF of that volume is backfilled from Libby, Hungry Horse, and Albeni Falls Dams during summer. While this would result in changes to outflows, this measure would not result in increases in TDG from the No Action Alternative at Grand Coulee Dam as the measure would be implemented in below average flow years, and in actual operations, spill would be avoided to implement this measure.

The *Winter System FRM Space* measure could result in a deeper draft and larger outflow in the month of December; however, the difference in TDG response between MO4 and the No Action Alternative would be similar in this time of year. From January through March, because the reservoir is lower for the FRM measures, there would typically be lower outflows, and in some situations, less spill (and corresponding TDG) in those following few months (mid-April to mid-June). The *Grand Coulee Maintenance Operations* measure has the potential to increase spill through the reduction in the hydraulic capacity of the powerhouse at Grand Coulee; however, the other actions under MO4 tend to minimize the effects of these measures on TDG and the higher TDG that would be associated with this measure is not reflected in modeled results. Overall, MO4 results in major reductions in TDG downstream of Grand Coulee Dam as compared to the No Action Alternative.

At Chief Joseph Dam, forebay TDG saturations are predicted to be similar under MO4 as compared to the No Action Alternative under a wide range of flow and air temperature conditions. The number of days the tailwater exceeds the 110 percent TDG criteria is predicted to be slightly lower under MO4 than the No Action Alternative for all flow and meteorological conditions; TDG effects below Chief Joseph Dam are considered negligible under MO4.

***Other Physical, Chemical, and Biological Processes***

Overall, MO4 operational measures would result in an earlier winter drawdown of Lake Roosevelt and a larger drawdown in the spring; however, the overall lake level is expected to be similar to the No Action Alternative lake elevation by July 1. River mechanics analysis indicates minor increases in the mobility of bed material in Lake Roosevelt under MO4. If contaminated slag is present in the mobilized bed material, this could create additional toxicity in fish and other aquatic organisms. However, the change in potential toxicity is unknown. Reservoir drawdowns of longer duration under MO4 increase the exposure of shorelines. Increased exposure has the potential to increase mercury methylation rates, which could lead to greater buildup of mercury quantities in aquatic organisms (i.e., bioaccumulation) (Willacker 2016).

Decreased residence time, associated with higher outflows and reduced residence times when the *McNary Flow Target* measure is implemented, within the lake could beneficially affect some areas that are intermittently impaired by algae blooms, such as the section of reservoir where the Spokane River enters into the reservoir; lower DO in this reach of reservoir was also slightly improved in low-flow years. The lower drawdown rate associated with operational measure *Planned Draft Rate at Grand Coulee* could reduce turbidity in the lake due to shoreline erosion.

Chief Joseph Dam and Rufus Woods Lake elevations and flows under MO4 are predicted to be similar to the No Action Alternative. As such, the water quality of Rufus Woods Lake under MO4 would be similar to the No Action Alternative. The harmful algae blooms described for the affected environment and the No Action Alternative would be expected to continue in the future under MO4.

**Sediment Quality**

MO4 operational and structural measures would not impact sediment movement and would not change existing sediment conditions in Region B. Operational flows under MO4 would be within the historical range of flows; therefore, sediment conditions are not expected to change.

## REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS

### Water Quality

#### *Water Temperature*

Water temperature conditions at Dworshak Dam would be very similar under MO4 as the No Action Alternative. Short-term differences could occur, but the outflow temperatures would remain less than 54°F year-round, and reservoir temperatures would not change.

Temperatures at the four lower Snake River projects would be the same under MO4 as the No Action Alternative, suggesting that water temperatures are not sensitive to the change in spill from the No Action Alternative in MO4 for the lower Snake River.

#### *Total Dissolved Gas*

TDG downstream of Dworshak Dam would be very similar under MO4 when compared to the No Action Alternative. The primary difference would be some reduction between April and

June, when water is typically released from the dam for flood risk management and refill purposes.

The *Spill to 125 percent TDG* measure sets juvenile fish passage spill to not exceed 125 percent TDG saturation, as measured at the tailrace, at all lower Snake River dams from March 1 to August 31; there is no forebay criteria. Due to the earlier start of juvenile fish passage spill and the higher tailwater TDG limits, MO4 model results show moderate to major increases in forebay and tailwater TDG saturations as compared to the No Action Alternative. It should be noted that there are instances in which TDG does not hit the 125 percent limit. This is primarily due to the assumptions used to determine spill at the onset of modeling. In real-time, the 125 percent TDG limits could likely be met more often, as long as there was enough water to spill while maintaining minimum generation at the projects.

***Other Physical, Chemical, and Biological Processes***

For the projects in Region C, MO4 is not expected to alter other physical, chemical and biological water quality parameters as compared to the No Action Alternative.

**Sediment Quality**

No changes to sediment quality and current sedimentation patterns in the Region C are expected as compared to the No Action Alternative.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

**Water Quality**

***Water Temperature***

Under MO4 and as with the No Action Alternative, the four lower Columbia River reservoirs (McNary, John Day, The Dalles, and Bonneville) would continue to show weak to no stratification during the summer months, largely due to the short residence time, wind and flow-induced turbulent diffusion, and convective mixing that occurs in the reservoirs. Maximum tailwater water temperatures and the frequency of water temperature standard exceedances would be similar for MO4 and the No Action Alternative over a range of river and weather conditions. Minor effects to water temperature are anticipated downstream of McNary Dam, while negligible effects are expected downstream of John Day, The Dalles, and Bonneville Dams.

***Total Dissolved Gas***

The *Spill to 125 percent TDG* measure sets juvenile fish passage spill to not exceed 125 percent TDG saturation, as measured at the tailrace, at all lower Columbia River dams from March 1 to August 31; there is no forebay criteria. Due to the earlier start of juvenile fish passage spill and the higher tailwater TDG limits, there would be negligible to major increases in forebay and tailwater TDG saturations as compared to the No Action Alternative, depending on the project.

It should be noted that there are instances in which TDG does not hit the 125 percent limit. This is primarily due to the assumptions used to determine spill at the onset of modeling. In real-time, the 125 percent TDG limits could likely be met more often, as long as there was enough water to spill while maintaining minimum generation at the projects.

***Other Physical, Chemical, and Biological Processes***

For the lower Columbia River projects in Region D, MO4 is not expected to alter other physicochemical and biological water quality parameters as compared to the No Action Alternative.

**Sediment Quality**

No changes to sediment quality and current sedimentation patterns in the Region D are expected as compared to the No Action Alternative.

**SUMMARY OF EFFECTS**

Although the effects of MO4 differ across the various projects in terms of water quality, they can generally be categorized as follows.

In Region A, with the exception of Lake Pend Oreille, MO4 water temperatures would largely be similar to the No Action Alternative. In the Pend Oreille River, during dry years, there would be a change in water temperatures ranging from a decrease of about 0.9 degree Fahrenheit to an increase of 1.8 degrees Fahrenheit in the summer, depending on flows and weather. The TDG below the dams under MO4 are expected to be similar to the No Action Alternative for most conditions. Minor changes to the physical, chemical, or biological processes in the reservoirs located in Region A would occur. MO4 would not impact turbidity or sediment concentrations in the region. Overall, water quality effects in Region A are expected to be negligible to minor.

In Region B, minor water temperature effects between MO4 and the No Action Alternative would be expected. Major reductions in TDG are expected below Grand Coulee Dam while negligible effects are expected downstream of Chief Joseph Dam. MO4 operational measures would result in an earlier winter drawdown of Lake Roosevelt and a larger drawdown in the spring. This could prolong sediment exposure in the top 10 to 20 feet of the reservoir and promote a higher rate of mercury cycling. Overall, however, water quality effects in Region B are expected to be negligible to minor as compared to the No Action Alternative.

In Region C, water temperatures would largely be the same as the No Action Alternative. TDG downstream of Dworshak Dam would be very similar under MO4 when compared to the No Action Alternative. Due to the earlier start of juvenile fish passage spill and the higher tailwater TDG limits, MO4 would have notable increases in forebay and tailwater TDG saturations as compared to the No Action Alternative. There would be no changes to other water quality parameters. With the exception of TDG, these effects would have a negligible impact to water quality. For TDG levels, there would be a moderate to major change as compared to the No Action Alternative.

In Region D, due to the earlier start of juvenile fish passage spill and the higher tailwater TDG limits under MO4, there would be notable increases in forebay and tailwater TDG saturations as compared to the No Action Alternative. There would be minor water temperature effects downstream of McNary Dam due to summer warming from the *McNary Flow Target* measure; effects further downstream at John Day, The Dalles, and Bonneville Dam would be negligible. TDG effects would vary by project with negligible to major changes expected as compared to the No Action Alternative.

For further details, please refer to the Water Quality Technical Appendix D.

### 3.4.4 Tribal Interests

Water quality concerns vary throughout the basin and include issues caused by operations of the 14 Federal projects (such as TDG) and issues caused by urban growth, agriculture, pollution, and industry (Section 3.4.2.1, Water Quality). Some tribes in the study area have water quality standards that have been approved by EPA. Contamination, be it through impaired water quality standards, heavy metals coming from upriver mining activities, radioactive sediments near Hanford, affects Native American people, tribes, and culture.

The water quality analysis (Section 3.4.3) described varying effects of the MOs across the different regions and projects. The analysis focused on operational effects to TDG, temperature, and other water quality conditions. MO1, MO2, and MO4 would have varying impacts on water quality, depending on location (MO3 is discussed below), primarily through TDG, temperatures, and nutrients (productivity). Of concern for tribal interests are measures at Grand Coulee. MO2 and MO3 would result in increased exposure of reservoir shoreline sediment and subsequent increased potential of mercury cycling which could lead to greater bioaccumulation, particularly between April and July due to the oxidization of metals in sediments along the exposed shorelines. This may lead to increased fish consumption advisories for Lake Roosevelt, which would further adversely affect tribes. Water quality effects may also harm tribal net pen fisheries. MO2 and MO4 may also impact dissolved oxygen levels near the Spokane Arm, and water quality concerns there are of concern to the Spokane Tribe of Indians. MOs are not expected to affect sediments near Hanford.

MO3 would result in impaired water quality in the lower Snake River reach (Region C) due to dam breaching for 2 to 10 years. As described in Section 3.4.3, there would be short-term and longer-term effects to water quality down to McNary Reservoir and below. There would be changes in temperature, TDG, and sediments and an increase in total nutrient, metal, and organic concentrations associated with finer sediment particles. While there would be significant short-term effects to water quality from dam breaching, the undammed river through this reach presents a natural flow regime which may be culturally important to tribes. Many tribes expressed a desire to have the Snake River return to more normative flow conditions. For them, dam breaching would be culturally meaningful.

Many tribes in the basin have voiced concerns over water quality in the Columbia River. Studies have shown that tribal people in the Pacific Northwest consume more fish than non-tribal residents (https://www.critfc.org/blog/reports/a-fish-consumption-survey-of-the-umatilla-nez-perce-yakama-and-warm-springs-tribes-of-the-columbia-river-basin/), and consequently, they question whether the national fish consumption rate of 12 ounces per week for adults used by the United States Food & Drug Administration and Environmental Protection Agency (2015-2020 Dietary Guidelines for Americans, https://health.gov/dietaryguidelines/2015/guidelines/) is applicable to tribal members. Furthermore, existing health advisories for fish caught in some stretches of the river reduce the recommended consumption level considerably:

> "The Washington Department of Health (DOH) has issued this fish consumption advisory for Lake Roosevelt due to mercury contamination: pregnant women, women of childbearing age, and children under six years of age should eat no more than two meals of walleye (8-ounce portion) a month" (https://wdfw.wa.gov/fishing/locations/lowland-lakes/franklin-roosevelt-lake).

In their Tribal Perspective submittal, the Confederated Tribes of the Colville Reservation captured this concern by discussing concerns among its elders:

> "Knowing smelter contamination from industrial activities in Trail, B.C. pollutes the Columbia River; she is hesitant to continue the ways taught to her. She still sweats intermittently, but fears that by heating the rocks, vaporizing the water, and burning fir boughs, toxins will be released and she or her family will inhale or ingest them., and that a human health risk might exist among tribal members from exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin) and other waterborne toxic contaminants" (See Appendix P).

Although tribal members rely on fish as part of their daily diet to a greater degree than non-tribal people, their consumption rates are still a small fraction of their heritage consumption rates.  Many of the tribes referred to this in their Tribal Perspectives.  The Coeur d'Alene Tribe provided a study of their heritage fish consumption rates which asserts "Water quality is of great importance to the Coeur d'Alene Tribe." and then provides a number of academic studies which place heritage consumption rates for tribes of the Columbia basin in general in a range with a high end of 1,000 pounds of fish per year, per member of the tribe.  Today, estimates place annual consumption at 117 pounds per year, per member (Heritage Fish Consumption Rates of the Coeur d'Alene Tribes, RIDOLFI Inc. 2016).

Another tribe provided the following: “Shoshone and Bannock peoples consumed approximately 700 pounds of salmon per person annually, prior to the development of the System. At present, only 1.2 pounds of salmon are consumed per tribal member annually.” The Confederated Salish and Kootenai Tribes of the Flathead Reservation in their Tribal Perspective discuss the importance of fish to their tribal member’s cultural diet, to protect these resources, and try to return to heritage consumption rates:

> “have developed federally-approved water quality standards for the Flathead Indian Reservation. The CSKT are continuously working to protect and improve the water quality in Reservation waters, including Flathead Lake, by various means, including: membership in the Flathead Basin Commission; negotiating with trans-boundary interests regarding coal development in the North Fork Flathead River; participating in FERC-relicensing workgroups; implementing Sėliš Ksanka Ql̓ispė Hydroelectric Project (SKQ Dam, formerly Kerr Dam) environmental mitigation requirements; and operating of a certified Tribal water quality laboratory.” (See Appendix P).

## 3.5 AQUATIC HABITAT, AQUATIC INVERTEBRATES, AND FISH

### 3.5.1 Introduction

This section provides a description of the existing Affected Environment that aquatic species inhabit in the CRS. This section also evaluates the Environmental Consequences (i.e. effects) associated with the No Action Alternative, MO1, MO2, MO3, and MO4. Each alternative evaluated in this EIS balanced multiple objectives (described in Chapter 2) and therefore, resulted in different effects which are summarized separately. The analytical tools and methods used by the co-lead agencies to evaluate the environmental consequences of the alternatives are described in Section 3.5.3.1. This section focuses on the direct and indirect effects of the alternatives while Chapter 5 discusses additional mitigation and Chapter 6 outlines the cumulative effects with other actions.

The analysis of environmental consequences performed in this chapter is specific to the measures developed by the co-lead agencies in conjunction with the cooperating agencies. The individual measures contained in the multiple objectives do not necessarily reflect full consensus of the co-lead agencies and cooperating agencies, but were analyzed to consider a wide range of possible actions and associated consequences or effects (see Chapter 2).

This EIS assesses the impacts of operating and maintaining the CRS while also implementing actions that address the effects of CRS operations and maintenance and conserve fish and wildlife. The analysis in the environmental consequences section (3.5.3) focuses on evaluating the impacts of the EIS alternatives on aquatic species. The co-lead agencies evaluate these consequences on multiple categories of species including ESA-listed and non-ESA listed, as well as anadromous and resident species. The co-lead agencies also consider the impacts of the alternatives on the broader food availability for the affected species, such as impacts to macroinvertebrate communities.

In general, the distribution and abundance of species affected by the CRS are influenced by a variety of biotic and abiotic factors that interact with aquatic species at various life stages. The species described herein use a broad range of habitats depending on life stage, and can thus be more (or less) sensitive to natural and anthropogenic stressors, only some of which are caused by CRS operations and maintenance, depending on when and where those stressors overlap with the species' presence.

For context, it should also be noted that there are a host of other regional entities, in addition to the CRS co-lead agencies, who are formally engaged in mandated and voluntary actions to address a wide range of impacts to salmon and steelhead in and around the Columbia Basin and within areas impacted by the CRS. From 2010 to 2019, NMFS's West Coast Region has completed over 400 "formal" and "formal programmatic" biological opinions (BiOps) applicable to actions that impact ESA listed salmon and steelhead in the affected environment. While this list includes activities undertaken by the co-lead agencies, many of these BiOps address impacts that are upstream, downstream, or inland from CRS management and non-operational conservation measures. This also includes related mitigation activities, including non-CRS co-lead agency activities and impacts:

- Federal and non-federal hydroelectric dam operations and assets and related fish passage, turbine mortality, predation, migration timing, water levels, habitat blockage, and all related effects
- Water quality and related impacts of water temperature, total dissolved gas, withdrawals, storage, irrigation, siltation, pollution, farming, grazing, logging, mining, standards compliance and enforcement, dredging, berth deepening, and all related effects
- Habitat conservation and land management and related impacts of floodplain management, road and bridge projects, other construction near water ways, forestry practices, agricultural practices, marine docking and transportation, and all related effects
- Hatcheries and harvest management and related impacts of competition and interbreeding, commercial and recreational fish harvest, decadal or year-to-year changes in ocean environments, drought conditions, hatchery take for propagation, disease and toxics exposure and all related effects

The region's collective ability to successfully carry out actions that benefit salmon and steelhead is dependent on many common effects, in combination with the actions included in the analysis. It is also dependent on sustained compliance with regulatory requirements and building upon successful implementation efforts to date.

### 3.5.2 Affected Environment

The Columbia River Basin is home to a variety of aquatic organisms, including rare, threatened, and endangered aquatic species. This section begins with an introduction and background section, which includes general discussions of the overall study area (Figure 3-109) and a discussion of past effects. The affected environment includes a description of aquatic habitat elements, followed by a description of anadromous fish, resident fish, and aquatic macroinvertebrates that may be affected by the MOs. Existing conditions are described by species or region, with species-specific details where relevant to the analysis, including distribution, life history patterns, population status, and habitat requirements. Section 3.5.3, Environmental Consequences describes the effects of the various MOs on aquatic habitat, fish, and macroinvertebrates, as compared to the No Action Alternative.

#### *3.5.2.1 Analysis Area and Background*

The primary area of analysis of effects to fish and aquatic habitats includes the mainstem Columbia and Snake Rivers as well as the confluences of major tributaries. Potential effects in Canadian portions the mainstem Columbia, as well as the Kootenai and Pend Oreille rivers downstream of CRS projects were not considered in this analysis. The effects in this resource were generally expected to be similar to the effects described on those tributaries in the United

States. Other rivers in the study area are described where measurable changes in the abundance of salmon, steelhead, lamprey, and other key fish species have altered components of the ecosystem.

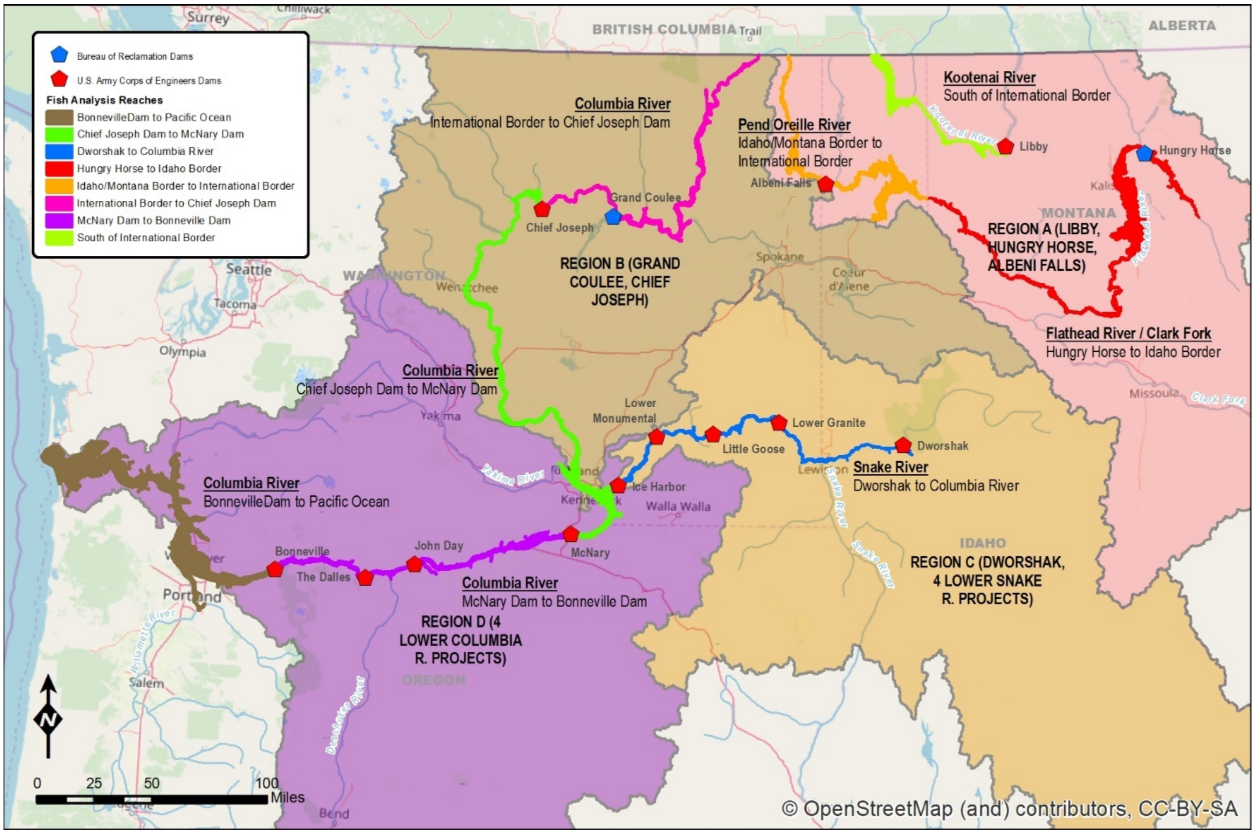

**Figure 3-109. Study Area Map**

Fish are characterized as either anadromous or resident. Resident fish are characterized as fluvial, adfluvial or non-migratory (see text box).

**What are the Common Fish Life History Forms?**

All fish use some kind of spawning and migration behaviors, often referred to as their "life history strategy." The fishes' life history determines its label of anadromous or resident, and if resident then it can be fluvial, adfluvial, or non-migratory.

**Anadromous:** As juveniles, fish migrate from freshwater to marine environments and then return to freshwater as adults to spawn. Eggs incubate in gravel and young fish emerge to rear in freshwater as they migrate downstream or prior to migration.

**Resident:** The entire life of the fish is within freshwater, in either streams, rivers, or lakes. Some species migrate to a different freshwater habitat for spawning having fluvial or adfluvial migration patterns, or can be called resident referring to no migration between spawning and rearing habitats.

**Fluvial:** These fish live entirely within flowing water and may migrate between larger rivers and smaller tributaries.

**Adfluvial**: Adults spawn and juveniles rear in freshwater streams but migrate to lakes for feeding as sub-adults, then migrate back to flowing water for spawning.

#### *3.5.2.2 Aquatic Habitat*

Features such as water quantity, quality, depth, velocity, cover, substrate, riparian and aquatic vegetation, and prey availability are all important components of aquatic environments that provide habitat for a diverse array of aquatic species. An overview of these features is described in this section, while species or location-specific features are discussed in individual species' sections. Water management operations at Columbia River System projects can affect these aquatic habitat features.

Aquatic habitat in this analysis is defined as all locations in the study area that are accessible to fish species. The existing conditions of the study area, which includes the 14 Federal dams, are influenced by surrounding areas and other projects upstream; these other projects are mentioned where relevant to the habitat under analysis.

Aquatic habitat can be divided into two categories: riverine habitat and reservoir/lake habitat. Each habitat hosts different species that have adapted to these conditions.

Analysis of the impacts of the MOs on aquatic habitat is described in the effects analyses for the specific fish species.

**AQUATIC HABITAT CATEGORIES**

**Riverine Habitats**

Rivers meander across their landscapes according to the underlying geological and physical features of the landscape, surrounding terrain, and dominant weather patterns.

A natural river ecosystem has a relatively stable pool-to-riffle ratio, which determines how and where the various plants and animals find their supporting habitats in channels and along shorelines. Riffles are key spawning locations; depth, velocity, and substrate determine spawning areas for salmon and steelhead, lamprey, and sturgeon. Pools support feeding areas for juvenile salmon and steelhead and holding areas for adult salmon and steelhead on upstream migration. Pools and riffles support different communities of invertebrates, which serve as prey items for fish and help with the important nutrient cycling process of the river ecosystem.

Along the riverine shorelines, beaches and sandbars form by deposition of suspended sand in zones of recirculating flow or eddies along the channel margin or by obstacles such as boulders and large logs in the channel that cause slower velocity water where sediment drops out of suspension. Juvenile fall-run Chinook salmon favor areas with gently sloping shorelines that are often associated with beach areas. Tiffan et al. (2006) found that along the Hanford Reach, the longest free-flowing reach of the Columbia River, subyearling fall-run Chinook salmon were most likely to occur in habitats with low lateral bank slopes with intermediate-sized gravel and cobble substrates.

Armoring, bulk-heading, dredging, filling, dock and pier construction, levee construction, riparian vegetation removal, and urbanization and industrialization have altered shorelines of importance to juvenile salmon during their freshwater migration downstream to the Columbia River estuary. Loss of shoreline aquatic vegetation and large woody material has reduced total habitat available for juvenile foraging, cover to hide from predators, and provision of insects and other detritus that flow into mainstem areas for food and cover.

In the riverine habitat immediately downstream from many of the dams, variations in flows as a result of power generation such as peaking and load factoring operations intermittently inundate and dewater the river shorelines. Downstream areas from storage projects experience more elevation changes due to peaking and load factoring operation than areas downstream of run-of-river projects. These river edges are nearly devoid of insect life and are biologically unproductive. When recolonization of aquatic life occurs during higher flows, subsequent reduction in flow can cause widespread stranding and desiccation of insects, small fish, and fish eggs, especially when it occurs rapidly. Flood pulses mimicking the natural flow regime, however, promote biological production and healthy ecosystems, whereas anthropogenic modifications of flows in temperate rivers typically reduce production (Junk, Bayley, and Sparks 1989). Intermittent high discharges can scour portions of the main channel, dislodging insects and their habitat. Frequent scour events below dams limit production in the zone protected by minimum flow requirements. The varial (drawdown) zone is an area of the upstream ends of a reservoir or river that is periodically inundated and dewatered as the pool or flow rate changes. The area typically lacks shoreline vegetation because perennial riparian vegetation or shallow aquatic vegetation establishment may be impaired and the community structure can diverge considerably from the reservoir bottom. Recruitment of large wood may be reduced. Historical habitats had dynamic flow regimes that fostered biological productivity by transporting terrestrial organic matter and nutrients to the riverine environment. Desiccation or other flow alternations outside the historical range can lead to less productive habitats. The manipulated flow regime of varial zones means they lack lasting, quality shallow-water habitat. With the change in habitat types from a productive, permanently wetted reservoir bottom to unproductive varial zone, the fish assemblage has also shifted. Desiccation of the river shorelines reduces aquatic insect populations that require wetted areas to complete their early life stages.

**Reservoir/Lake Habitats**

Each of the 14 Columbia River System projects has impounded a segment of river, thereby turning the flowing river into a more lake-like reservoir. Along the mainstem Columbia and Snake Rivers, about 486 miles of riverine habitat have been converted to lentic (still, freshwater) or semi-lentic reservoirs (Ebel et al. 1989). Dam construction has caused large-scale changes in habitat types that result in different species distribution, abundance, assemblages, suitability, productivity, and predator/prey relationships. These habitat changes have often favored non-native and/or invasive species that compete with and prey on native species.

Most reservoirs create three different habitat zones (Hjort et al. 1981). The first zone is the forebay area, which is typically lacustrine (lake-like) habitat. At the upstream end of the reservoir is a second zone that tends to be shallower and has substantial flow velocities. The third zone, between the forebay and the upstream end, is a transition area that changes from riverine at the upstream end to more lake-like in the downstream direction toward the forebay. Each zone can include several sub-types of habitat; however, most can be characterized as either backwater (including sloughs and embayments) or open-water habitats (Hjort et al. 1981; Bennett et al. 1983; LaBolle 1984).

Backwaters and embayments provide comparatively warmer temperatures, finer substrate, and submergent and emergent vegetation. The non-native resident fish species that spawn in these areas include bass, crappie, bluegill, pumpkinseed, yellow perch, northern pike, brown and black bullhead, and carp; for these species, spawning occurs from May through mid-July. Backwater areas support a greater concentration of zooplankton, which attracts the smaller fish species. This in turn attracts the larger predatory fish that prey on the smaller fish species. Open water is deeper, has less structure than the backwater areas, and has a range of water velocities. Species that spawn in open water include the non-native shad and walleye, as well as native minnows, suckers, sandroller, and white sturgeon. Non-native invasive predatory fish that spawn in the mainstem include walleye, bass, and channel catfish. The amount of juvenile salmonid predation by birds and native and non-native fish around dams depends on multiple factors. Species, proximity to suitable predator habitat, areas with delayed salmonid migration, and distance from avian colonies influence rates of predation (Petersen 1994; Venditti, Rondorf, and Kraut 2000; McHugh et al. 2011; Evans et al. 2016). In the lower Columbia River, marine mammals prey on adult salmonids and white sturgeon in the tailrace of Bonneville Dam; long-term trends of predation at Bonneville Dam and effects on populations are tracked annually (Tidwell et al. 2019). Research to measure and track the number of salmonids eaten by predators at Columbia River Basin dams and options to manage predation (e.g., predator removal or hazing to scare them away) is ongoing. General use of the project area by avian and marine mammal species described is in Section 3.6, Vegetation, Wetlands, and Wildlife.

Most of the native resident species spawn in flowing waters at the headwaters of the reservoirs or in tributary streams. Some species, however, also spawn in the reservoirs. For instance, northern pikeminnow will spawn either in flowing water or along gravel beaches in reservoirs (Wydoski and Whitney 1979). According to GEI Consultants Inc. (2004a), Lake Pend Oreille continues to provide good rearing habitat for cold water fish species; the Corps carefully manages Albeni Falls Dam operations to facilitate shoreline spawning habitat for kokanee salmon.

Project operations influence the lake-like conditions of reservoirs. The relatively shallow run-of-river reservoirs have short retention times (only a few days) while the storage reservoirs can have much longer retention times of more than 35 days. In run-of-river reservoirs, water is not stored so retention time does not change notably under different operations, and short retention time is conducive to faster travel times for outmigrating juvenile salmonids, which is beneficial for these species. In storage reservoirs such as Lake Roosevelt, however, retention time can be an important factor in providing habitat for the reservoir fish. Underwood and Shields (GEI 2004b) demonstrated that zooplankton density in Lake Roosevelt decreases as water retention time decreases below 30 days. Zooplankton is the primary food source for kokanee and for the fry life stage of many fish species. Therefore, dam operations that reduce water retention time and food availability for fish also reduce the lake's fish carrying capacity. Water retention time and reservoir elevation are the most important predictor of entrainment (unintentional passage of fish through turbines or spillways) of fish and nutrients through dams (McLellan et al. 2008).

As with riverine varial zones described above, biological resources such as plants, invertebrates, and fish cannot survive the periodic inundation and draining of the shoreline around reservoirs. These zones are impediments to migration as fish move into and out of tributaries that flow through the varial zone. This is particularly true in storage reservoirs with significant drawdowns. Increased flow from tributaries promotes juvenile emigration from streams into reservoirs, where they encounter a barren landscape with little cover and are particularly vulnerable to predation. Adults migrating into tributaries also encounter these barren reaches, which are highly dynamic and often pose physical impediments and render individuals especially vulnerable to predation. These varial zones are likely a major limiting factor to adfluvial species, such as redband trout and bull trout.

**AQUATIC HABITAT FEATURES**

**Water Quantity**

Water resources in the Columbia River System are carefully managed for multiple purposes to meet requirements for FRM, hydropower, irrigation, navigation, recreation, cultural resources, and to maintain an ecosystem that supports fish and wildlife. On average, more than 134 Maf of water flow through the Columbia and Snake River Basins annually. The lower flows each year occur from September through December, and peak flows occur in May and June with snowmelt from the higher elevations of the study area (Figure 3-110). An example hydrograph based on the 10-year average of outflows from Bonneville Dam from 2010-2019 appears below. For more detail on water flows and timing, see the descriptions in Section 3.2, *Hydrology and Hydraulics*.

Quantity and timing of flows are important for rearing and outmigrating juvenile salmon and steelhead, temperature regulation in certain river reaches, adult salmon and steelhead upstream migration, access to and preservation of spawning sites, and tributary connectivity. In addition, spawning and migratory behavior of resident species is influenced by quantity and timing of flows.

High spring runoff flows occur from April through June and are critical in moving juvenile salmon and steelhead out to the ocean. These flows also facilitate spawning behavior and migratory patterns of resident species such as white sturgeon and redband trout. These same flows allow adult salmon and steelhead to migrate upriver to natal spawning areas. During low water years, travel time for outmigrating juvenile salmon and steelhead is increased and survival reduced. Consequently, some of the water stored in upstream reservoirs is released to augment high spring flows to assist juvenile fish during outmigration. In addition, water stored for flow augmentation can be released from July through September to reduce adverse effects of high water temperatures and improve survival and migration success.

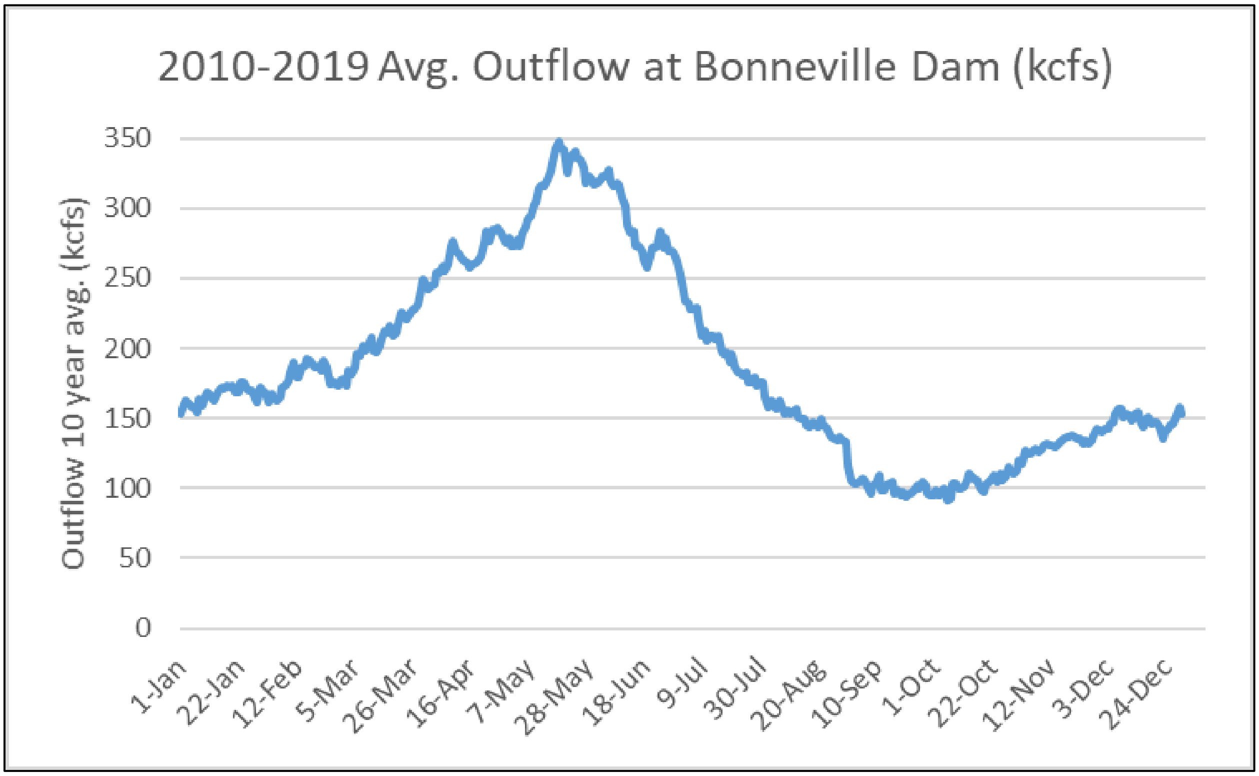

**Figure 3-110. Example Hydrograph Showing the Average Discharge throughout the Year at Bonneville Dam**

**Water Depth**

In some reaches, water depth is critical for fish to leave the mainstem rivers and access tributary habitat. Timing and quantity of discharge from dams can affect the depth of water for accessibility of some tributary habitats. One example of this is the minimum tailwater elevation at Bonneville Dam to allow chum salmon to access tributaries of the Columbia River near Ives Island.

In reservoirs and in connected floodplain aquatic habitats, the shallower backwater areas host the greatest abundance of fish in all life stages. Backwater and embayment areas provide slightly warmer habitat, finer substrate, and submergent and emergent vegetation. In reservoirs, the duration and depth of substrate inundation as the reservoir refills and drafts controls the annual production of benthic (bottom-dwelling) insects. Juvenile salmon and steelhead rear in areas of flowing water shallower than about 5 feet (1.5 meters [m]) and find bottom-dwelling aquatic insect larvae such as caddisflies, mayflies, and chironomids for food. Certain types of resident fish use shallow backwater and embayment areas of lakes and reservoirs.

Deep habitats support fewer fish compared to shallower areas. The majority of the species found in deeper waters are suckers and minnows; white sturgeon occur in deeper waters as well. Mid-depth habitats support a community higher in species diversity and abundance than deep habitat, but lower in abundance than shallow habitat (Bennett et al. 1991). In storage reservoirs, pelagic species such as kokanee occupy deeper habitats, exploiting rich zooplankton communities and production occurring within the euphotic zone (i.e., the depth in which sunlight penetrates).

**Water Velocity**

The habitat factors that influence water velocity are gradient, roughness, width, and depth of the river channel, lake, or reservoir. Roughness is determined by substrate coarseness such as sand, cobbles, or boulders, as well as any vegetation or other structures that affect flow. These habitat factors affect which species will use a given area of aquatic habitat. In the management of the 14 projects of the Columbia River System, water managers can control velocity to some extent through holding water or releasing it through the operating projects.

Water velocity and volume play a key role in the life cycle of salmon and steelhead and many other species. Water flow affects migratory movements of fish downstream and upstream. The timing of many runs of anadromous salmon and steelheads corresponds with peak flow (Collins 1892).

Decreased flow affects juvenile and adult migratory travel time, which increases their exposure to predation, elevated water temperatures, greater susceptibility to disease, and other sources of mortality and injury.

Water velocity also is a key factor in determining aquatic macroinvertebrate communities, which in turn determines whether fish can find an adequate quantity and variety of prey items. For example, the macroinvertebrates that are able to cling to rocks and graze algae can remain in faster-flowing water compared to the species that burrow into sand where water moves slower and deposits organic litter.

**Retention Time**

The retention time (RT) of a reservoir is the average time a water molecule will spend in that reservoir. RT is a theoretical value calculated as the ratio of reservoir volume to average flow (either inflow or outflow). The RT in a reservoir or lake is important because it influences several lake and reservoir behaviors including stratification (increasing with increasing retention time) and retention of nutrients (Straškraba 1999). When RT is short, the entire reservoir could become a riverine zone; when the RT is long it can be a more lacustrine (lake) zone (Straškraba 1999). Reduced retention times can result in increased entrainment of fish and food source out of the reservoir.

**Water Quality**

***Temperature***

Native fish species of the Columbia River Basin are adapted to cold flowing water, although some persist in slightly warmer temperatures in the lakes and reaches of the larger rivers. Each species and life stage can have a different range of tolerable and optimum temperatures. Most native species in the Northwest are cold water fish, and the introduced (non-native) species are warm water fish that tolerate and often thrive in the altered temperature regime that can be stressful for the native fish.

Warmer water temperatures generally occur in late summer and fall. These warmer temperatures increase the risk of native fish disease and mortality, affect their toxicological responses to pollutants, and can affect migratory movements because they can increase the body temperature of the fish. Water temperatures can be too cold, particularly in tailwater environments. These conditions may limit growth and productivity. Water temperatures can be influenced by a variety of factors including habitat, surface air temperatures, and water storage, inflows, reservoir surface area, solar radiation absorption, and diversions (Section 3.4, Water Quality).

Fish can move from an unsuitable water temperature into a cooler area to maintain control over body temperature. If available, juvenile and adult salmon will occupy water that is 13°C to 18°C, with the warmer water selected only when excess food is available. Water temperatures of approximately 23°C to 25°C can be lethal to salmon and steelhead, and salmonid eggs can die above 11°C (EPA 2001). Cold water refuges are areas in which the water temperature is colder than the predominant river temperature. These areas are important for salmon and steelhead as they migrate upstream, often in the warmest months of the year (EPA 2019). The Columbia River Cold Water Refuges Project, coordinated by the EPA, is designed to identify the cold water refuges currently available for use by migrating salmon, assess the sufficiency of the refuges for current and future populations, and identify strategies to restore, enhance, and protect high quality refuges for the future.

Dams and reservoirs can change water temperature through their effects on water velocity, water storage, water diversion, and irrigation return flows. The operation of dam and reservoir projects, withdrawal of surface waters for irrigation, and pumping of groundwater for irrigation alter the flow regime, most notably by dampening peak flows and impounding water and, thus, can influence water temperatures in the Columbia River System project areas. In some cases, water becomes warmer, and in other cases, cold water can be released from a project to reduce water temperatures downstream in the system such as from Dworshak Dam.

Surface waters in reservoirs can be warmed by the sun and air temperatures. However, water deeper in reservoirs, remains cold. Choices in operations, limited by the dam's configuration, can result in warm or cold water being released. Specifically, at Dworshak, Libby, and Hungry Horse Dams, selective withdraw depth gates area used to influence downstream water temperatures. These cold water releases are beneficial since historical temperatures in the lower Snake River basin prior to the construction of the lower Snake River dams and the Hells Canyon Complex show that temperatures in the free-flowing lower Snake River often exceeded 20°C in July and August and occasionally exceeded 25°C.[1] The warmer water temperatures occurring in late summer and fall, from a variety of factors, increase the risk of native fish disease and mortality, affect their toxicological responses to pollutants, and can affect migratory movements. Warmer water temperatures increase the foraging rate of predatory fish and help support habitat beneficial to invasive predatory fish. In fact, water temperature is probably the most important physical variable affecting the consumption rate and growth of predatory fishes (Brett 1979). For example, laboratory experiments demonstrated maximum consumption of salmon and steelhead prey increased from 0.5 smolts per day at 8.3°C to seven smolts per day at 21.7°C (Vigg and Burley 1990).

#### *Dissolved Oxygen*

Dissolved oxygen (DO) is a critical water quality component for all aquatic life. The daily cycling of photosynthesis and respiration is chiefly responsible for fluctuations in DO concentrations. Most aquatic animals need a minimum of five parts per million (ppm) of DO in water, although some species like carp, which are non-native in the system, can tolerate lower levels. The deep areas of reservoirs with high water retention times and limited vertical mixing can become oxygen depleted, which is harmful to fish and macroinvertebrates. During late summer of some years, high water temperatures (20°C to 22°C) and low DO levels (less than 6 ppm) have potential to cause direct mortality or deteriorate living conditions for native species in the Columbia River Basin.

#### *Total Dissolved Gas*

Plunging water over waterfalls, cascades, or dam spillways can cause downstream waters to become supersaturated with dissolved atmospheric gases referred to as supersaturated total dissolved gas (TDG), resulting from the entrainment of air bubbles into plunging water. The primary gases making up TDG pressure in water are oxygen, nitrogen, argon, and carbon dioxide. High TDG levels in water may persist for many miles downstream from their source. Elevated TDG can cause gas bubble trauma (GBT) in aquatic organisms, resulting in injury or death. GBT is an acute condition involving the growth of bubbles in the vascular system of the fish. Extreme cases of GBT are lethal. Dam operators try to control TDG by reducing spill to achieve less gas saturation in water. However, the severity of TDG supersaturation decreases by approximately 10 percent for every meter of water depth due to pressure. Migrating anadromous fish are typically quite mobile and may sound where adequate water depth is available decreasing both the severity and duration of TDG exposure below dams.

[1] Peery, C.A. and T.C. Bjornn. 2002. Water Temperatures and Passage of Adult Salmon and Steelhead in the Lower Snake River. Technical Report 02-1. U.S. Geological Survey, Idaho Cooperative Fish and Wildlife Research Unit, University of Idaho, Moscow, Idaho.

At the Lower Snake and Columbia River dams, spill is used to pass juvenile salmon downstream, limited the spill volume that produces 120 percent TDG saturation in the tailrace. Thus, TDG levels during April through June are 115 percent-120 percent throughout this reach as permitted by Oregon and Washington waivers to the Clean Water Act. Spill levels are lower in July and August at some dams, and the extent of high TDG waters is therefore reduced as well.

During high river discharges, uncontrolled spill can cause spill in excess of 120 percent TDG. Dam operators target certain operations intended to reduce adverse impacts, and to meet Clean Water Act limits of TDG by reducing spill or using certain spill patterns to achieve less gas saturation in water. The co-lead agencies have also constructed structural components of the dams in order to reduce adverse impacts of TDG, e.g. spillway flow deflectors.

***Pollutants***

The major pollutants in the Columbia River Basin are released from the adjacent landscape through urbanization and agricultural use of pesticides, fertilizers, and herbicides, as well as legacy contaminants from mining and industrial practices. On water activities such as navigation and recreation can also release contaminants. Oils and grease necessary for turbines and other machinery at the dam can leak into the river. The Corps and Reclamation applied for National Pollutant Discharge Elimination System permits for discharges of pollutants, including oil or grease, from appropriate point sources. These releases have resulted in increased pollutant loads moving through the Columbia River Basin, as well as lingering in settled sediments or by accumulation within resident plant and animal communities. Pollutants can disperse downstream through the Columbia River dams; some pollutants settle out when water slows down at a reservoir and others travel all the way to the estuary. Passing by a greater number of dams increases the chance of pollutants settling out and becoming part of the sediment.

***Turbidity***

Turbidity is an indicator of the amount of suspended particles in water. The particles are usually fine sediments of sand, silt, or clay but can be organic compounds such as plankton. Fish require specific levels of sediment and turbidity to hide from predators, but they also require clear waters to find their prey and have optimal gill function. The various native species in the Columbia River System have different ranges of tolerance for turbidity.

Flow regulation and the existence of reservoirs reduce turbidity in the rivers where Columbia River System dams are located. Turbid stormwater is held in reservoirs and released at a slower rate into clear water, compared to unimpounded rivers. This prolongs the duration of downstream turbidity, while reducing the intensity of downstream turbidity peaks. Reduced turbidity allows visual predators, such as smallmouth bass, to more effectively prey on native fish, such as juvenile salmon and steelhead.

Natural levels of turbidity are an important factor related to sturgeon migration, spawning, and survival. The reduced turbidity levels in reservoirs were linked to increased predation of white sturgeon larvae in laboratory studies (Gadomski and Parsley 2005).

**Substrate**

The capacity of any aquatic habitat to support fish and invertebrate populations depends largely on the substrate characteristics as well as depth and velocity of water, which in turn influence the size of substrate at the reach scale. The primary transport mechanism for water column sediment is surface water flow. Higher flows transport larger amounts of sediment with a wider range of particle sizes and weights while lower flows transport lighter, smaller particle fractions. Sediment particles settle in areas where flows and velocity decrease, such as backwater areas and impounded sections of the Columbia River System. Sediments fall out of suspension at a rate proportionate to their size and weight. This is why substrate in slower pool and glide habitats typically contains smaller materials than in faster riffle and run habitats, which often have enough power to keep smaller sediments in suspension.

Each fish species has adapted to spawn and feed in specific substrate types in combination with water velocity. Spawning substrate size preference varies by species and depends mostly on size of fish–larger fish can use larger substrates compared to smaller fish. For example, fall Chinook salmon in the Columbia and Snake Rivers use gravel beds with sediment size ranging from 1 inch (2.5 centimeters [cm]) up to 12 inches (30 cm) (Geist and Dauble 1998), whereas cutthroat trout select substrate sizes of 0.2 to 4 inches (0.6 to 10.2 cm) (Bjornn and Reiser 1991).

Sedimentation processes have been altered in the Columbia River Basin because of the construction of the Columbia River System and other projects. Many of the projects, particularly the storage projects, have interrupted the natural sorting regime of sediment. The mobilized bedload can only travel downstream to the next point at which the reduction in velocity means the river can no longer carry the larger grain sizes. USGS (1984) described downstream effects of dams showing that sediment concentrations and suspended loads decreased substantially for hundreds of miles downstream. Additionally, riverbed degradation varied from slight to 24 feet (7.5 m) deep with a coarsening of bed material and lengthened the degraded area over time extending to at least 30 years beyond dam construction and as much as 75 miles (120 kilometers [km]) beyond the dam site. One example of an issue created by changed sedimentation in the study area is that fine sediments that have accumulated in the lower 22 miles of the Flathead River have shifted the insect biota from a stonefly and mayfly assemblage to a midge-dominated community, which affects food availability for fish.

**Aquatic Vegetation**

Aquatic vegetation in rivers and reservoirs can be important habitat features for both fish and wildlife. Examples of fish habitat provided by aquatic vegetation include aquatic grasses in shallow reservoir areas providing spawning habitat to species that attach their eggs to vegetation, or predatory fish using cover to lie and wait for prey.

Much of the aquatic vegetation in the Columbia River, also known as macrophytes, that is in over-abundance is not native, and in many cases, it is detrimental to native fish communities through increases in water temperatures, cover for non-native predators, effects on flows, and tribal fisheries. Invasive aquatic plants are a problem in the basin and are on a trajectory for worsening unless aggressive management plans are implemented.

Aquatic vegetation as part of the affected environment is discussed further in Section 3.6, Vegetation, Wetland, and Wildlife.

**AQUATIC HABITAT CONNECTIVITY**

Connectivity, or the ability for aquatic species to access other aquatic habits, is an important part of species survival. Rivers play a vital role in connecting various terrestrial and aquatic habitats, and their value to all the plant and animal components of the ecosystem extends well beyond their surface area. Conversely, isolation of habitats has caused and can further risk extirpation of all the individuals in the confined space, which reduces overall abundance and biodiversity. For fish species, connectivity to different types of aquatic habitats is important for them to complete their chronological life stages, particularly for the anadromous species, which benefit from accessing the entire river system from the spawning area to the ocean.

The key aspect of longitudinal connectivity in aquatic habitat is the ability of fish to reach each type of habitat critical to its particular life stages. This primarily applies to the anadromous fish that travel long distances from the ocean up the large rivers to small tributaries, but also applies to some resident species that move between tributaries and reservoir habitats that can become disconnected at lower pool elevations. Longitudinal connectivity is important to prevent species fragmentation and to provide access to spawning, rearing, and foraging habitat for migratory fish (Fullerton et al. 2010). Loss of connectivity in the study area has led to the extirpation of multiple salmon populations and the continued fragmentation of resident fish populations. Conditions in the headwaters of rivers can have a direct effect on downstream habitats and organisms (Fullerton et al. 2010). In addition, longitudinal connectivity allows for transportation of sediment and nutrients in the form of woody debris, food items, and other organic matter.

Construction and operation of Federal and non-Federal dams in the Columbia River Basin have impacted longitudinal connectivity by blocking or otherwise affecting migratory fish corridors, changing stream flow patterns, and altering natural water temperature regimes that in many areas can cause delay of migration or even form thermal barriers.

Lateral floodplain connectivity in the context of aquatic habitat refers first to the ability of the river to move water into the adjacent landscape, and second, the ability of aquatic species to access aquatic habitats such as ponds, wetlands, and side channels. This connection between the river and its adjacent floodplain areas is important to many fish species to find appropriate habitat for spawning, rearing, and overwintering life stages. Many of the Columbia River System projects have eliminated floodplain habitat by inundating side channels and other important diverse types of habitats, or by altering flow regimes so that those floodplain habitats are no longer accessible by aquatic organisms.

#### *3.5.2.3 Anadromous Fish*

The affected environment for anadromous fish (Section 3.5.1) is organized by species in order to facilitate descriptions common to the species across specific runs throughout the Columbia River Basin. The environmental consequences analysis for anadromous fish (Section 3.5.2) is organized differently (Upper Columbia River, Middle Columbia River, Snake River, and Lower Columbia River) because the effects on those species are similar in these geographic areas.

The Columbia River Basin hosts many anadromous fish species. Anadromous fish use freshwater habitat for spawning and early juvenile life stages before migrating to marine waters to grow and mature for part of their lifecycle. Among the salmon and steelhead species, Chinook salmon (*Oncorhynchus tshawytscha*), steelhead (*O. mykiss*), sockeye salmon (*O. nerka*), and coho salmon (*O. kisutch*) are widespread in the Columbia River Basin. Chum salmon (*O. keta*) has a more limited distribution in estuary tributary streams.

Other anadromous fish include Pacific lamprey (*Enstophenus tridentatus*), eulachon (*Thaleichthys pacificus*), green sturgeon (*Acipenser medirostris*), and American shad (*Alosa sapidissima*). In addition, white sturgeon (*Acipenser transmontanus*) have a unique physiology that allows them to move regularly between fresh and saltwater. They are discussed in this document as resident fish, but the lower river populations are also known to move into the near-ocean environment to feed. Pacific lamprey have a widespread distribution in the region, migrating as far as the Clearwater and Salmon River tributaries of Idaho and the Methow subbasin in the upper Columbia River. Green sturgeon, by contrast, have a relatively limited distribution in the Columbia River Basin, only migrating upstream to about the city of Longview, Washington, well below Bonneville Dam. American shad are the only non-native anadromous species in the Columbia River Basin.

Migratory salmonids are important vectors of energy and nutrients between marine and freshwater ecosystems. For example, anadromous fish carry nutrients across habitat boundaries, and they influence community and food web structure in aquatic as well as terrestrial ecosystems (Gende et al. 2002). Spawning salmon contribute an estimated 5 to 95 percent of the nitrogen and phosphorus in salmon-bearing streams (Gresh et al. 2000). Anadromous fish deliver resources that affect food web productivity and influence a diverse array of flora and fauna across vast landscapes in the Columbia River Basin (Naiman et al. 2002).

Anadromous salmon and steelhead returns can vary widely from year-to-year and as shown in Figure 3-111, as recently as 2014, salmon and steelhead were returning to Bonneville Dam on their way to upstream tributaries in numbers not been seen in many decades. As the ISAB noted in 2016 "More salmon returned from the Pacific Ocean and were counted crossing Bonneville Dam, 146 miles inland, on their way to spawn—at hatcheries or in the wild—in 2014 than in any year since 1938, when fish counting began there. The 2014 run was about 2.5 million fish, continuing the trend of big returns in the 21st Century compared to the 1990's" (ISAB, 2015-1). During that same period, NMFS noted in their 2016 5- year status review of Pacific salmon and steelhead that wild Snake River spring Chinook salmon abundance had increased over the levels reported in their prior review for most populations, although the increases were not substantial enough to change viability ratings. NMFS attributed the relatively high ocean survival in recent years as a major factor in the abundance patterns leading up to their 2016 review (NMFS, 2016). Although the number of adult salmon and steelhead has declined since 2014, even with consistent operations of the CRS, and NMFS's 2020 status review will encompass years with lower returns and declining ocean conditions, these returns show that salmon and steelhead can pass upstream and downstream through the system in its current configuration when conditions are suitable.

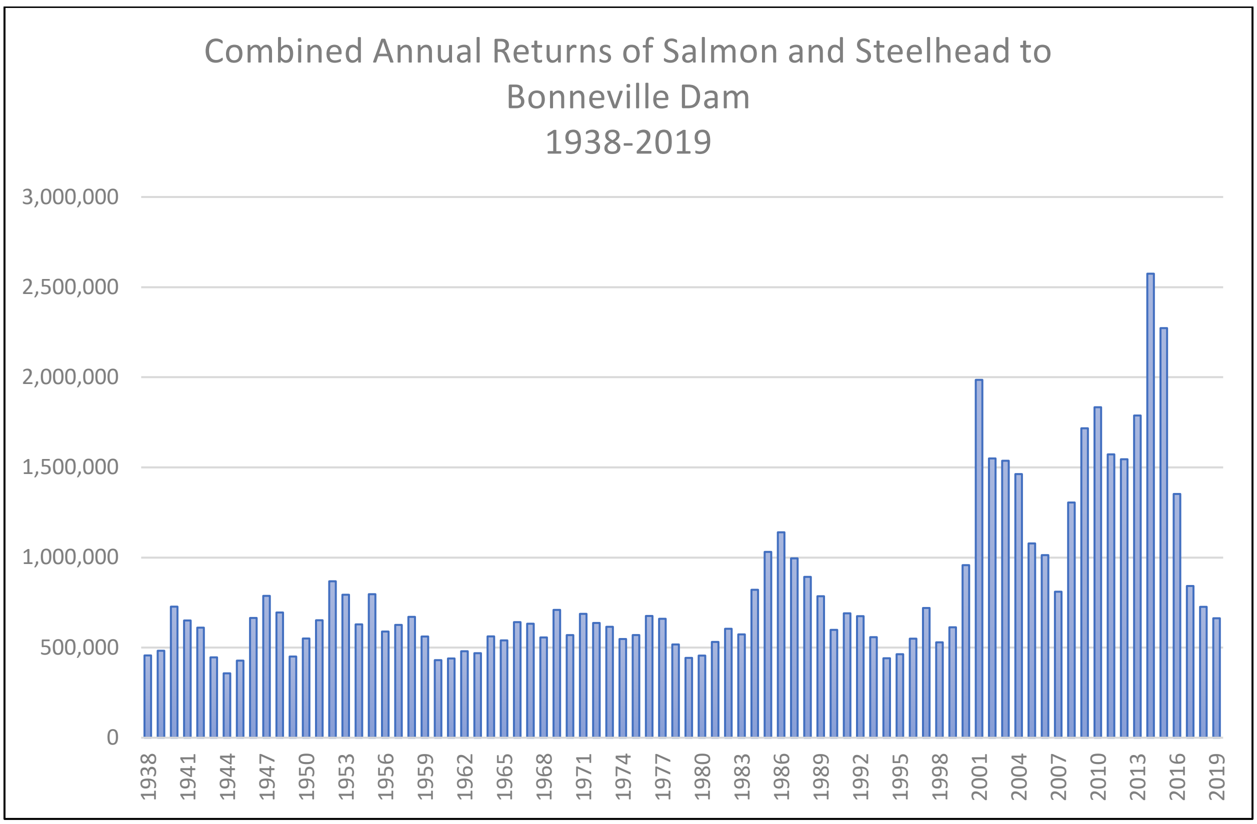

**Figure 3-111. Combined Annual Salmon and Steelhead Returns (all species) to Bonneville Dam from 1938-2019.**

These returns are a combination of hatchery and natural origin fish. (Data Source: University of Washington-Data Access Real Time (DART) tool)

On February 4, 2020, the co-lead agencies viewed a presentation prepared by NMFS regarding returns for the 2019 fish passage season and the Adaptive Management Implementation Plan.[2] Although not all returns occurred prior to the presentation, NMFS utilized current return numbers to project return numbers if current return rates continued in 2020 and 2021. These projections signaled that returns are low, especially for Snake River steelhead. The co-lead agencies are currently evaluating the information provided by NMFS and will have a more detailed discussion of this information in the final EIS, including any updates that NMFS may provide once all returns have occurred, if appropriate.

To aid the downstream passage of juvenile salmon and steelhead, the co-lead agencies have worked to improve passage and survival past the dams and through the reservoirs of the CRS. Figure 3-112, shows recent estimates of survival at the eight lower CRS projects with fish passage. The dam survival estimates do not include systemwide or latent effects (see section 3.5.3.1). These estimates were developed show progress towards meeting the individual dam survival goals developed during the 2008 Biological Opinion of 96 percent survival past each dam for yearling Chinook and steelhead, and 93 percent for Snake River sub-yearling fall Chinook. In their 2017 analysis of system improvements used for recovery planning analysis, NMFS concluded that:

> "In summary, recent average annual reach survival estimates for migrating smolts have improved substantially compared to the 1980-2001 Base Period for Snake River steelhead, yearling spring/summer Chinook salmon, and sockeye salmon (by roughly 50-75 percent) and compared to the 1998-2005 earlier period for subyearling hatchery fall Chinook salmon (about 35 percent). As noted in the 2010 Supplemental Biological Opinion (NMFS 2010; see also Section 2.2.2.2), on a per-kilometer basis, these survival rates are approaching those estimated for several free flowing river systems. Controlling for other factors affecting adult returns such as poor ocean conditions, these increased average survival rates for inriver migrating smolts have resulted in higher adult returns in recent years compared to the Base Period" (NMFS, 2017).

Adult upstream passage through the CRS projects on the lower Columbia and lower Snake Rivers is generally safe and effective. As NMFS noted in 2017,

> "Adult salmon and steelhead can pass each of the eight mainstem dams in the lower Snake and Columbia rivers volitionally at fish ladders (also called "fishways"). In general, we consider these adult passage facilities to be highly effective. For example, the current estimate of average adult Snake River spring/summer Chinook salmon survival (conversion rate estimates using known-origin adult fish after accounting for "natural straying" and mainstem harvest) between Bonneville and Lower Granite dams (2012-

[2] The Adaptive Management Implementation Plan (AMIP) was a component of the 2010 and 2014 NMFS Supplemental BiOps and 2019 NMFS CRS BiOp and included triggers for: (1) unexpected declines in adult abundance and (2) environmental disasters or environmental degradation (either biological or environmental) in combination with preliminary abundance indicators. If certain triggers are met, the co-lead agencies would work with NMFS and other regional salmon managers to coordinate on a regionwide diagnostic effort to take an appropriate response.

2016) is approximately 87.3 percent, or 73.7 percent when harvest and straying are included ….” (NMFS, 2017)

Figure 3-113 displays the trends described by NMFS for Snake River stocks and reflects the combination of passage, straying, and harvest. Once adult salmon and steelhead pass the furthest upstream dam in their migration, there may continue to be losses influenced by a combination of many factors including natural mortality, water quality, straying, and harvest.

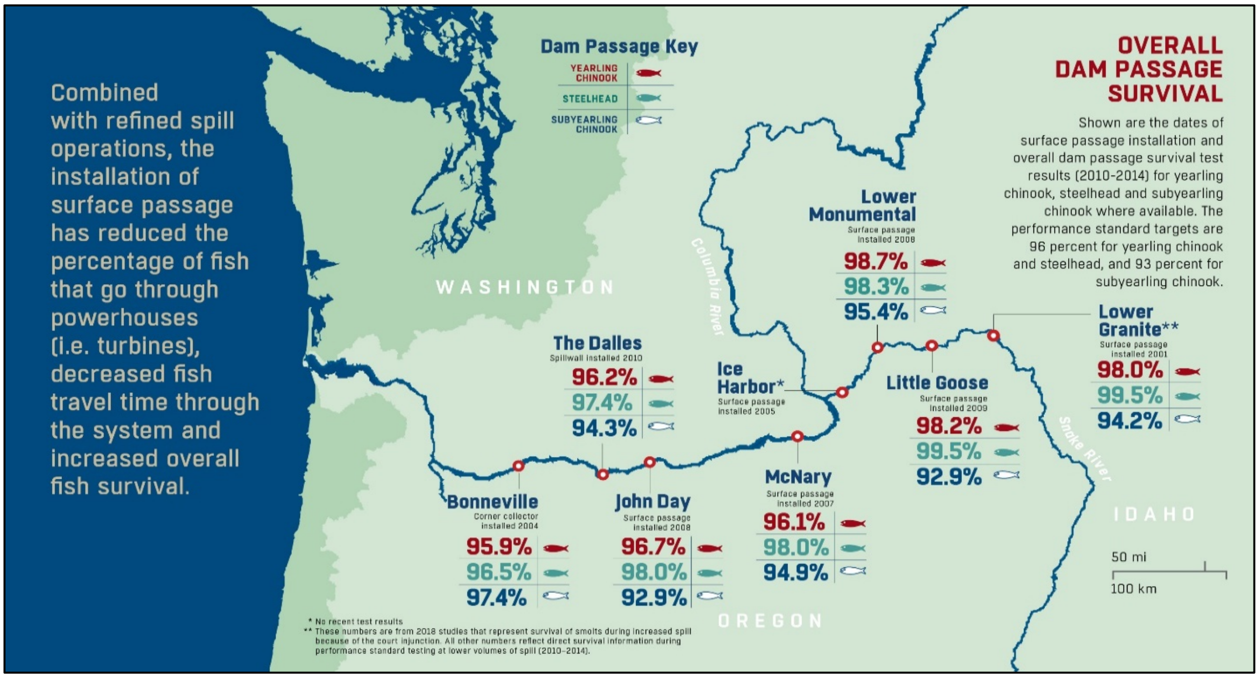

**Figure 3-112. Recent Estimates of Dam Survival at Columbia River System Projects**

Note: These dam-specific survival estimates do not include systemwide or latent effects.

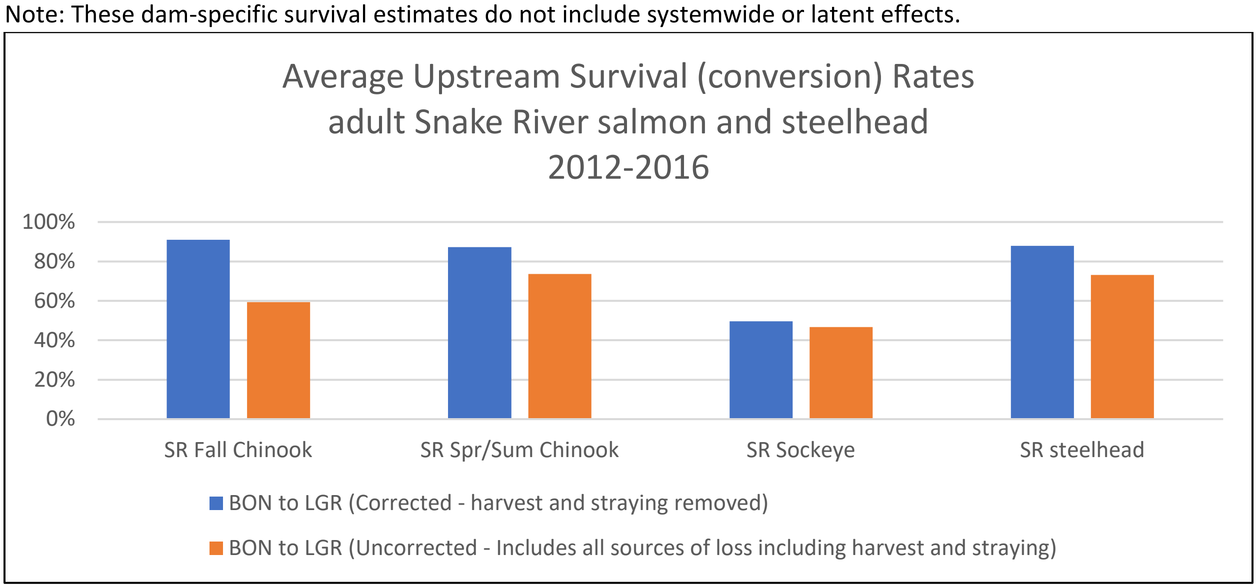

**Figure 3-113. 2015–2019 Snake River Spring/Summer Chinook Salmon Upstream Survival Rates**

Figure is based on data from NMFS (2017).

## ENDANGERED SPECIES ACT–LISTED ANADROMOUS FISH

An inventory of the ESA-listed anadromous species and their designated critical habitat in the study area appears in Table 3-57. Details on distribution, population status, and threats to each of these species appear in the *Federal Register* notices that National Marine Fisheries Service (NMFS) and the U.S. Fish and Wildlife Service (USFWS) provide for all listing actions; these are cited in the table. Species status and relevant CRSO study area information appears in their respective subsections later in this section.

**What are Evolutionarily Significant Units and Distinct Population Segments?**

ESA-listed fish species may be identified as an evolutionarily significant unit (ESU) or a distinct population segment (DPS). Scientists developed the concepts of ESU and DPS to define a listable population unit according to ESA policy for Pacific salmon (56 *Federal Register* [FR] 58612).

An ESU or DPS is a vertebrate population or group of populations that meet certain criteria of being discrete or isolated from other populations of the species and significant to preservation of the genetic diversity of the species (61 FR 4722). These designations can apply to populations within the species if these conditions occur: (1) they are substantially isolated from other populations of the same species due to physical, physiological, ecological, or behavioral separation; and (2) the population or group represents an important component required to maintain conservation of genetic diversity of the biological species per the ESA regulations (61 FR 4722). Typically, DPS is used for steelhead and inland species, and ESU applies to salmon.

**Table 3-57. Status and Critical Habitat of Anadromous Columbia River Basin Endangered Species Act–Listed Species**

| Species and ESU or DPS | | ESA Listing Status | Critical Habitat Designation |
|---|---|---|---|
| Chinook salmon | Upper Columbia River Spring-run ESU (*Oncorhynchus tshawytscha*) | Endangered 1999 | 2005 |
| | Snake River Spring/Summer-run ESU (*O. tshawytscha*)[1/, 2/] | Threatened 1992 | 1993 |
| | Snake River Fall-run ESU (*O. tshawytscha*)[1/] | Threatened 1992 | 1993 |
| | Lower Columbia River ESU (*O. tshawytscha*) | Threatened 1999 | 2005 |
| | Upper Willamette River ESU (*O. tshawytscha*) | Threatened 1999 | 2005 |
| Steelhead | Upper Columbia River DPS (*O. mykiss*) | Endangered 1997; re-classified to threatened 2006 | 2005 |
| | Snake River Basin DPS (*O. mykiss*)[2/] | Threatened 1997 | 2005 |
| | Middle Columbia River DPS (*O. mykiss*) | Threatened 1999 | 2005 |
| | Upper Willamette River DPS (*O. mykiss*) | Threatened 1999 | 2005 |
| | Lower Columbia River DPS (*O. mykiss*) | Threatened 1998 | 2005 |
| Coho salmon | Lower Columbia River ESU (*O. kisutch*)[3/] | Threatened 1999 | 2016 |

| **Species and ESU or DPS** | | **ESA Listing Status** | **Critical Habitat Designation** |
|---|---|---|---|
| Chum salmon | Columbia River ESU (*O. keta*) | Threatened 1999 | 2005 |
| Sockeye salmon | Snake River Basin DPS (*O. nerka*)[4/] | Endangered 1991 | 1993 |
| Eulachon | Southern DPS (*Thaleichthys pacificus*) | Threatened 2010 | 2011 |
| Green Sturgeon | Southern DPS (*Acipenser medirostris*) | Threatened 2006 | 2009 |

1/ State-listed threatened: Oregon (Oregon Administrative Rule [OAR] 635-100-0105).
2/ State-listed threatened: Idaho (Idaho Administrative Procedures Act [IDAPA] 13.01.06).
3/ State-listed endangered: Oregon (OAR 635-100-0105).
4/ State-listed endangered: Idaho (IDAPA 13.01.06).
5/ State-listed species of concern: Montana (Montana Fish, Wildlife and Parks [MFWP] 2018).

### Salmon and Steelhead

Considerable scientific literature is available on ESA-listed salmon and steelhead species in the Columbia River Basin, including the life history of these species, how fish migrate through Columbia River System projects to and from the ocean, migratory timing, abundance, and in some cases, survival rates passing the dams. Additional information on existing conditions for fish regarding Columbia River System operations and configurations is provided in NMFS biological opinions (NMFS 2008a, 2010a, 2014a, 2019).

Multiple factors have contributed to the historical decline and current status of salmon and steelhead. The construction and operations of the Columbia River System are among the many factors that have adversely affected these species. The adverse impact of past Columbia River System operations has been reduced over time, and multiple mitigation actions have improved habitat, hatchery operations, and predator management, thus increasing survival rates of individuals in these ESUs, reducing extinction risk, and thereby contributing to improvements in the likelihood of recovery.

As adults migrate upstream and juveniles outmigrate, they negotiate up to eight CRS project dams, as well as other non-Federal facilities. Factors such as migration delays, fallback, encounters with powerhouse facilities, TDG, and water temperatures can all affect the survival of anadromous fish.

Metrics used to track these factors include the following:

- Juvenile travel time
- Juvenile in-river survival
- Dam passage survival
- Powerhouse encounters
- Water particle travel time
- Mortality from GBT

For some species, information is available to track population level metrics such as adult abundance (returning adults to a given population), and smolt-to-adult return ratios.

As a group, salmon and steelhead are diverse in their biology, exhibiting a range of life history and reproductive strategies. Terms that are used in this EIS to describe each species include descriptors of the migratory patterns of salmon and steelhead and the reproductive types. Reproductively, salmon and steelhead tend to reproduce once before dying (semelparous), but some steelhead and other fish can reproduce multiple times (iteroparous).

Anadromous fish hatch from eggs in freshwater, then migrate to the ocean while undergoing the physiological process of smoltification to grow and mature, and then return to freshwater as adults to spawn. Non-anadromous fish remain in freshwater throughout their life cycle. Pacific salmon and steelhead are largely anadromous, although there are non-anadromous forms (e.g., non-anadromous sockeye are called kokanee, and non-anadromous steelhead are called rainbow or redband trout).

The terms ESU and DPS comprise one or more populations as a “species” under the ESA. A population of fish is a group of the same biological species that spawns in a particular lake or stream (or portion thereof) at a particular season and which, to a substantial degree, does not interbreed with fish from any other group spawning in a different place or in the same place at a different season (McElhany et al. 2000). The ESA terms ESU and DPS comprise one or more populations, as the key feature of an ESU or DPS is reproductive isolation from other groups in that same species.

Juvenile salmon and steelhead originating above Bonneville Dam migrate downstream through as many as eight Columbia River System projects, and the same is true for adult salmon and steelhead returning to spawning grounds in the opposite direction. Migration habitat features important to salmon and steelhead as they migrate through the Columbia River and lower Snake River reaches include water quality, water temperature, water velocity, passage survival, adult fallback (i.e., deviation from upstream migration to move back downstream through dams already ascended), and factors that may influence delayed mortality.

#### *Chinook Salmon*

Chinook salmon are the largest of the Pacific salmon and are known by many names, most commonly king salmon, or Chinook salmon. Chinook salmon have an anadromous life history (although non-anadromous males and landlocked populations do occur) and are semelparous. Age at maturity is highly variable among populations, but most Chinook salmon on the West Coast spawn at 3, 4, or 5 years of age. Chinook salmon are classified into two life history types: stream-type and ocean-type. These life history types have several ecological differences, but the most basic difference is how long the juveniles spend in the freshwater habitat prior to migrating out to the ocean; stream-type juveniles outmigrate as yearlings, whereas ocean-type juveniles outmigrate much younger and may spend substantial time in the estuarine environment below Bonneville Dam before entering the ocean environment. In the Columbia River Basin, Chinook salmon occurring west of the Cascade Crest tend to be primarily ocean-type (Myers et al. 1998). Chinook salmon occurring east of the Cascade Crest include both stream-type and ocean-type races, with the stream-type occurring in the Deschutes, John Day, Yakima, Wenatchee, Entiat, and Methow Rivers (Myers et al. 1998).

Chinook salmon stocks are often described as seasonal "runs." In the Columbia River Basin, there are spring-run, summer-run, and fall-run Chinook salmon stocks. The run refers to the time of year that the adults return to freshwater to start their spawning migration.

Six Chinook salmon ESUs are within the scope of this EIS (Myers et al. 1998):

- Upper Columbia River spring-run (ESA-listed endangered, further discussed in this section)
- Snake River spring/summer-run (ESA-listed threatened, further discussed in this section)
- Middle Columbia River spring-run (not ESA-listed)
- Upper Columbia River summer/fall-run (not ESA-listed)
- Snake River fall-run–ESA-listed (ESA-listed threatened, further discussed in this section)
- Lower Columbia River–ESA-listed (ESA-listed threatened, further discussed in this section)

**Life Histories: What are the Different Migration Timings of Chinook Salmon?**

**Stream- and ocean-types:** Chinook salmon can follow either stream- or ocean-type freshwater life history strategy. Stream-type Chinook salmon reside in freshwater for a year or more before migrating to the ocean as larger juveniles. Ocean-type Chinook salmon migrate to the ocean within their first year after emerging from the gravel.

**Run timing:** Salmon runs are named for the season when the adult fish return to their home estuary.

Spring-run Chinook salmon use the stream-type strategy as juveniles, then spend 1 to 4 years maturing in the ocean before returning to freshwater as immature fish (also called early or bright fish) from March through May. They migrate upriver, mature in suitable refuges for several months (March to June), and spawn in late summer and early fall (August to September).

Fall-run Chinook salmon use the ocean-type strategy as juveniles, then spend 1 to 5 years maturing in the ocean before returning to freshwater. They enter freshwater at an advanced stage of maturity, move rapidly to their spawning areas, and spawn within a few days or weeks of freshwater entry (late September to November).

**Tules and upriver brights:** Tules are sexually mature fall-run Chinook salmon and spawn in lower Columbia River tributaries. Upriver brights are fall-run Chinook salmon upstream of The Dalles Dam.

<u>Upper Columbia River Spring-Run Chinook Salmon</u>

Upper Columbia River spring-run Chinook salmon extant populations include all naturally spawned populations of Chinook salmon in Columbia River tributaries downstream of Chief Joseph Dam and upstream of Rock Island Dam, excluding the Okanogan River. This includes populations spawning in the Wenatchee, Methow, and Entiat Rivers, and the progeny of six artificial propagation programs. These fish spawn above the confluence of the Snake River and pass through four Columbia River System projects, including Bonneville, The Dalles, John Day, and McNary Dams. They also pass up to five non-federal Public Utility District (PUD) owned mainstem dams (Rocky Reach Dam and Rock Island Dam are owned and operated by Chelan County PUD while Wanapum Dam and Priest Rapids Dam are owned and operated by Grant County PUD), and Wells Dam is operated by Douglas County PUD). Annual upper Columbia

River spring-run Chinook salmon returns at Rock Island Dam averaged 3,714 fish between 2010 and 2016 and ranged from 2,167 to 6,090 fish (Oregon Department of Fish and Wildlife [ODFW] and Washington Department of Fish and Wildlife [WDFW] 2017).

Upper Columbia River spring-run Chinook salmon have unique run timing, both as juveniles and adults. Juveniles follow a stream-type freshwater cycle, meaning that they outmigrate after 1 year of rearing in freshwater during mid-spring through early summer (NMFS 2018). Returning adults enter freshwater beginning in early spring, with the peak run occurring in mid-May, and the fish reach upper Columbia River tributaries from April through July. Some males return to natal streams after one winter at sea; however, the 4- and 5-year-old adults represent the majority of the run.

This ESU's adult return run timing in early spring makes them subject to relatively higher predation from seals and sea lions (pinnipeds) compared to other salmon species because most of these pinnipeds arrive in the area downstream of Bonneville Dam in March and April and leave by early summer.

The adults then hold in tributaries until spawning in the late summer, peaking in mid-late August (NMFS 2016). After spawning, the adults' health declines rapidly and they die within a few days (Figure 3-114).

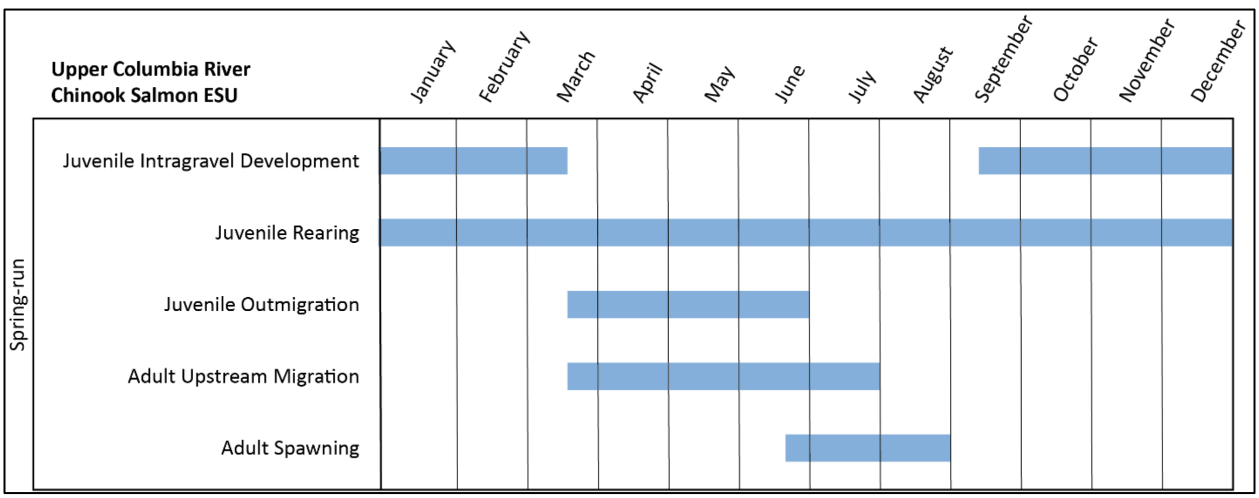

**Figure 3-114. Freshwater Life Phases for Upper Columbia River Spring-Run Chinook Salmon Evolutionarily Significant Unit**

Source: NMFS (2007, 2018)

<u>Lower Columbia River Chinook Salmon</u>

The lower Columbia River Chinook salmon ESU includes all naturally spawned populations from the mouth of the Columbia River upstream to and including the White Salmon River in Washington and the Hood River in Oregon. This ESU also includes the Willamette River upstream to Willamette Falls (exclusive of spring-run Chinook salmon in the Clackamas River), and 15 artificial propagation programs. Bonneville Dam is the only mainstem system facility within the lower Columbia River Chinook salmon ESU range (NMFS 2013). Lower Columbia River Chinook salmon might migrate through other non-Columbia River System dams depending on their spawning locations, rearing, and migratory movements (NMFS 2016).

This ESU follows an ocean-type life history with three distinct patterns based on their return to freshwater: spring-run Chinook salmon, fall-run Chinook salmon, and late fall-run Chinook salmon (NMFS 2013). These three components of the Lower Columbia River Chinook Salmon ESU all have similar ocean distributions but are exposed to different in-river effects because of migration timing (NMFS 2016).

Lower Columbia River spring-run and late-fall-run juvenile Chinook salmon exhibit a stream-type maturation that depart in the fall and early winter when they overwinter in larger rivers before outmigrating the following spring as yearlings. In contrast, lower Columbia River fall-run Chinook salmon exhibit an ocean-type maturation life history; juveniles emigrate as subyearlings in late summer or autumn and rely heavily on the Columbia River estuary before continuing to the ocean (NMFS 2013). Spring-run Chinook salmon enter freshwater from January through May before spawning from September to October. Fall-run Chinook salmon enter freshwater from August to October and spawn nearly immediately from October through December. Late-fall-run adults enter freshwater from August to November and spawn from November through January (NMFS 2013; Figure 3-115).

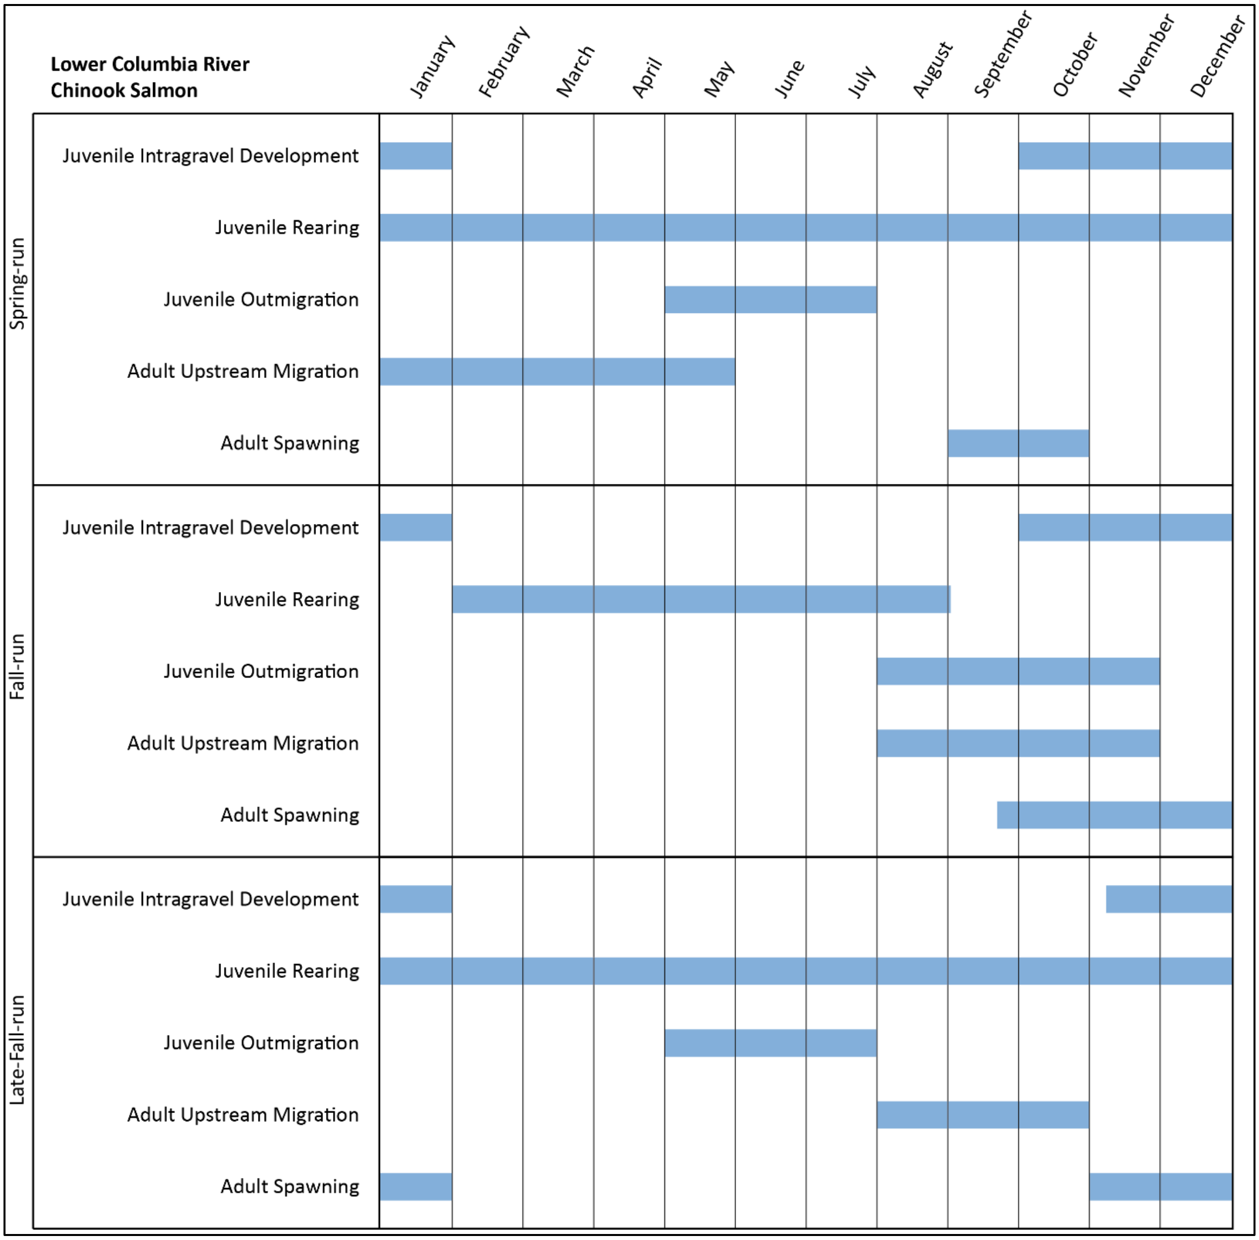

**Figure 3-115. Freshwater Life Phases of Lower Columbia River Chinook Salmon Evolutionarily Significant Unit**

Source: NMFS (2013)

<u>Snake River Spring/Summer Chinook Salmon</u>

The Snake River spring/summer Chinook salmon ESU includes all naturally spawned populations of spring/summer Chinook salmon in the mainstem Snake River and the Tucannon River, Grande Ronde River, Imnaha River, and Salmon River subbasins (NMFS 2016e), and the progeny of 15 artificial production programs.

Two distinct forms are recognized for Snake River Chinook salmon: the spring-run and the summer-run; these are distinguished when adult Chinook salmon move through the estuary and ascend Bonneville Dam in their spawning migration (Figure 3-116). Both spring-run and summer-run Chinook salmon display a stream-maturing life history meaning adults enter freshwater sexually immature and require a few months in rivers and tributaries to mature prior to spawning (NMFS 2017a). Spring-run Chinook salmon enter freshwater primarily from March through May and migrate to spawning reaches, then spawn in mid- to late August with some spawning extending into early September. Summer-run Chinook salmon enter freshwater primarily from June to July and wait to migrate to spawning areas until late summer. Some adults from both runs might hold in deep pools before completing their spawning migration.

Snake River Chinook salmon juveniles (both spring-run and summer-run) migrate to the ocean from mid-April through early June, with peak migration in mid-May (NMFS 2017a). Spring- and summer-run Chinook salmon juveniles have limited variability for rearing in their natal streams, but higher variability for the marine life stage, typically between 1 to 3 years.

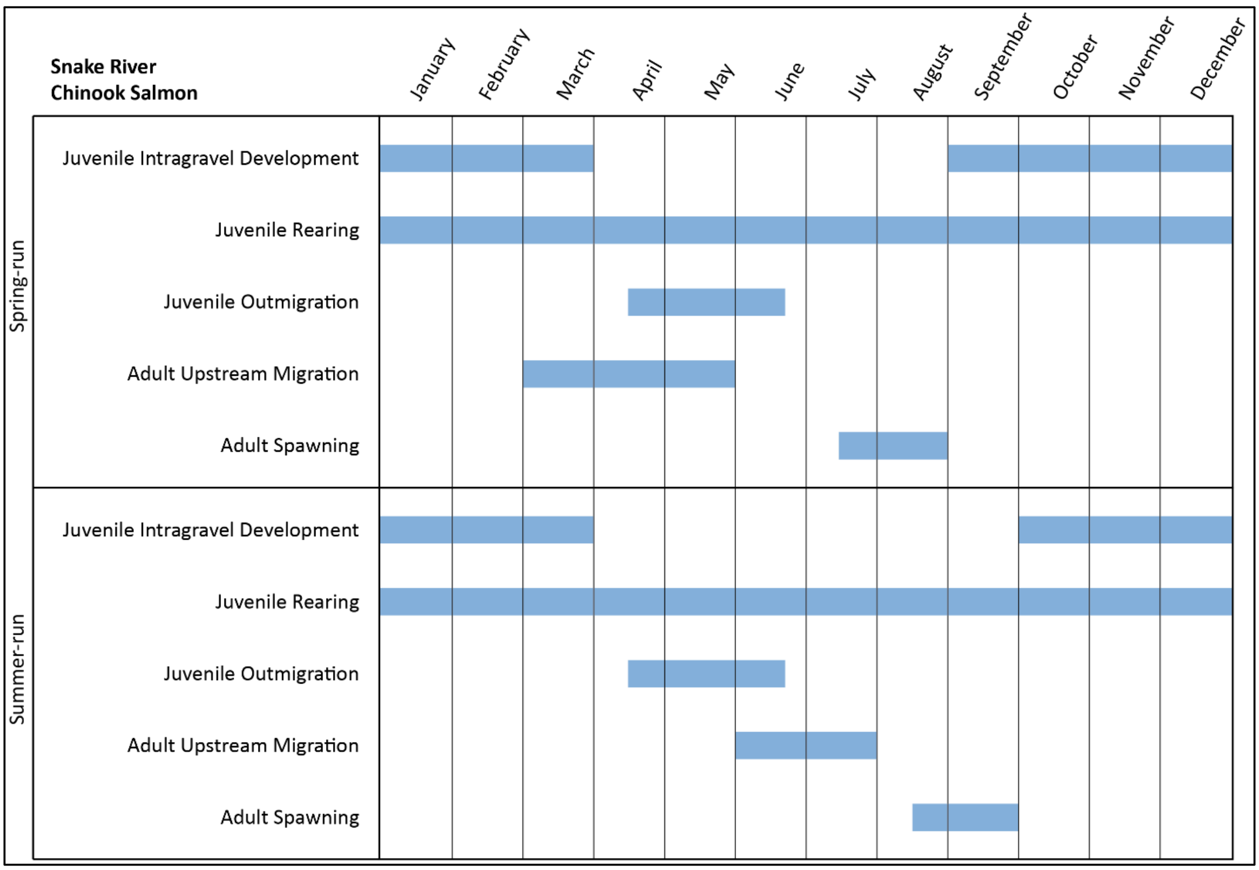

**Figure 3-116. Freshwater Life Phases of Snake River Spring/Summer-Run Chinook Salmon Evolutionarily Significant Unit**

Source: NMFS (2017)

<u>Snake River Fall Chinook Salmon</u>

The Snake River fall-run Chinook salmon spawns in the mainstem of the Snake River, Clearwater River, and major tributaries.

Snake River fall-run Chinook salmon follow an ocean-type life history; however, some fish in this ESU delay seaward migration and enter the ocean as yearlings and are referred to as having a reservoir-type life history (Connor et al. 2005). The majority of Snake River fall-run Chinook salmon juveniles of wild and hatchery origin migrate to the ocean before mid-summer as subyearlings, and some wild-origin fall Chinook salmon outmigrate in late summer including September (Figure 3-117). An exception are the Snake River fall-run Chinook salmon that migrate as yearlings and primarily originate from the Clearwater River basin (NMFS 2017). Water temperature influences the rate of development and life history of Snake River fall-run Chinook salmon, particularly for juveniles. Adult Snake River fall-run Chinook salmon enter the Columbia River from early August to September and reach the Snake River between mid-August and mid-October. Adults then spawn in the Snake River and tributaries through early December.

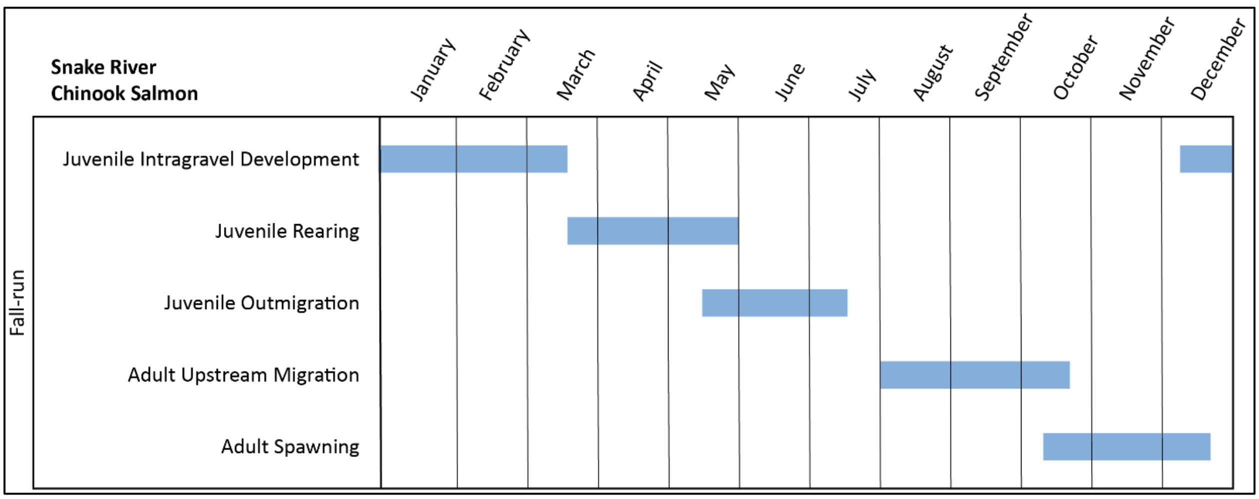

**Figure 3-117. Freshwater Life Phases of Snake River Fall-Run Chinook Salmon**

Source: NMFS (2017)

### *Sockeye Salmon*

Sockeye salmon are also called blueback and red salmon. The Columbia River Basin is the southern extent of the species on the West Coast (Gustafson et al. 1997). Sockeye salmon have anadromous and non-anadromous life history types; non-anadromous sockeye salmon, known as kokanee, are addressed in the Resident Fish sections of this EIS. There are three anadromous forms of sockeye salmon: lake-type, river-type, and sea-type (Gustafson et al. 1997). Sockeye salmon in the Columbia River Basin are lake-type and spawn in either inlet or outlet streams of lakes or in lakes themselves. Juveniles rear in the lake for 1 to 3 years before smolting and migrating to the marine environment for 1 to 4 years; adults generally return to their natal lake system to spawn. Effects to kokanee populations will be discussed in the resident sections where they occur.

Three Sockeye Salmon ESUs are within the scope of this EIS:

- Snake River (ESA-listed, further discussed in this section)

- Okanagan River (not ESA-listed)
- Lake Wenatchee (not ESA-listed)

<u>Snake River Sockeye Salmon</u>

Snake River sockeye salmon are ESA-listed as endangered. This ESU includes naturally spawned anadromous and residual sockeye salmon originating from the Snake River Basin, primarily from Redfish Lake, and also sockeye salmon from an artificial propagation program, Redfish Lake Captive Broodstock Program. Snake River sockeye salmon migrate through eight Columbia River System projects on their migratory route to and from the Pacific Ocean (NMFS 2009).

Adult Snake River sockeye salmon enter the Columbia River primarily from June through July when they migrate directly to suitable lake habitat to spawn. Adult sockeye salmon will spawn from September through October in the lakeshore gravels (ODFW and WDFW 2017). Anadromous juveniles will rear in their natal lakes for one to three years before outmigrating. Anadromous Snake River sockeye salmon juveniles migrate to the ocean from April through early July, with peak migration typically occurring in mid-April to early May (Figure 3-118) (NMFS 2015).

Resident sockeye salmon remain in freshwater to mature and reproduce (often referred to as kokanee).

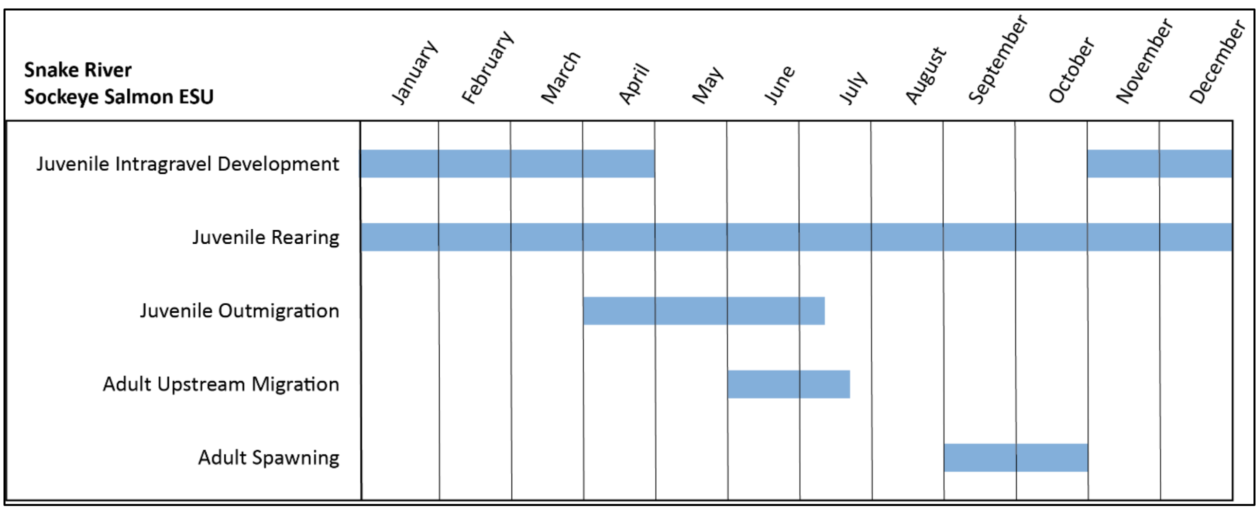

**Figure 3-118. Freshwater Life Phases of Snake River Sockeye Salmon Evolutionarily Significant Unit**

Source: NMFS (2015)

***Coho Salmon***

Coho salmon are also commonly known as silver salmon. Coho are anadromous, with a fixed life history, and semelparous. Coho salmon south of Alaska are three years old at maturity, spending half of that time in the freshwater environment prior to smolting (Weitkamp et al.

1995). Historically, coho salmon distribution extended to the upper Columbia River and the Snake River Basin (Weitkamp et al. 1995).

Lower Columbia River coho salmon are the only ESA-listed population of coho salmon in the Columbia River Basin; coho salmon found upstream of The Dalles Dam are not ESA-listed. Although coho salmon in the upper Columbia River, Snake River and their tributaries were extirpated, reintroduction programs conducted in the Clearwater, Wenatchee, Methow, and Yakima River Basins are resulting in coho salmon returning to those rivers.

<u>Lower Columbia River Coho Salmon</u>

Bonneville Dam is the only mainstem system facility within the lower Columbia River coho salmon ESU range (NMFS 2013). These fish extend up the Columbia River as far as the Hood River basin and may encounter other dams in tributaries to the Columbia River depending on their spawning locations, rearing, and migratory movements within the basin (NMFS 2016a).

Two categories are used regarding lower Columbia River coho salmon based on their return to freshwater: early-return (Type S) and late-return (Type N). While there is some overlap between these populations, Type S coho salmon generally move south of the Columbia River mouth once smolts outmigrate, and Type N coho salmon smolts and adults generally move north of the Columbia River mouth (NMFS 2013).

Type S and Type N coho salmon juveniles rear in freshwater for one to four years in pool habitat and quiet backwaters, side channels, and small creeks. Juveniles typically outmigrate as smolts from April to June, typically during their second year (Figure 3-119) (NMFS 2013). Lower Columbia River coho salmon exhibit a stream-type maturation, indicating they arrive in the Columbia River and require several months within freshwater to reach sexual maturity before spawning. Type S coho salmon adults enter freshwater in mid-August before spawning from mid-October to early November. Type N coho salmon adults enter freshwater from late September to December and spawn nearly immediately from November through January (NMFS 2013).

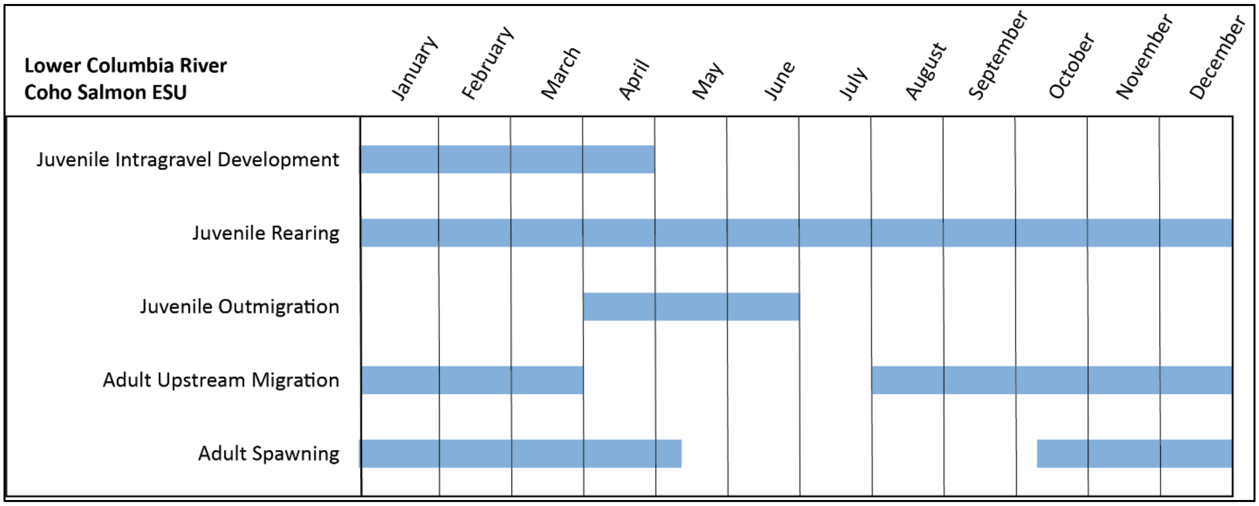

**Figure 3-119. Freshwater Life Phases of Lower Columbia River Coho Salmon Evolutionarily Significant Unit**

Source: NMFS (2013)

***Chum Salmon***

<u>Columbia River Chum Salmon</u>

Although distributed in locations above the dam historically, Bonneville Dam is the only mainstem hydropower facility within the mainstem Columbia River that chum salmon may be expected to pass (NMFS 2013). Though chum salmon are strong swimmers, they rarely pass river blockages and waterfalls, and spawn almost exclusively downstream of Bonneville Dam (NMFS 2016a).

Columbia River chum salmon spawn and incubate redds in the mainstem itself, and spawning is restricted primarily to tributary and mainstem areas downstream of Bonneville Dam. The species requires clean gravel for spawning and their spawning sites are typically associated with areas of upwelling water. Near Ives Island (downstream of Bonneville Dam), chum spawn in shallow areas where it appears river water is warmed by its transit through the gravel (Geist et al. 2002). Chum salmon also spawn in the tailrace of Bonneville Dam.

Columbia River chum salmon juveniles rear in freshwater very briefly after emerging from gravel. Juveniles typically outmigrate to the Columbia River estuary as subyearlings from March to June, where they spend several weeks to months before continuing to the ocean (NMFS 2013) (Figure 3-120). Columbia River chum salmon are primarily fall-run fish with very few exhibiting a summer-run life history. Adults arrive in freshwater from October through November after 2 to 6 years and spawn from November through December (NMFS 2013). During chum salmon spawning and egg incubation, the water surface elevation of the Bonneville tailrace is controlled to protect chum salmon redds (NMFS 2016b).

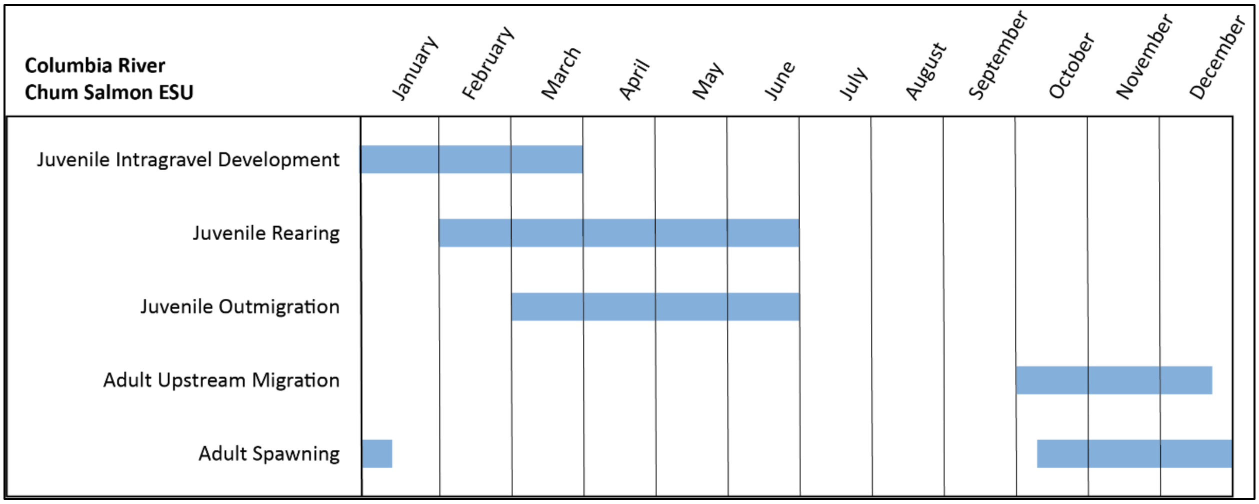

**Figure 3-120. Freshwater Life Phases of Columbia River Chum Salmon Evolutionarily Significant Unit**

Source: NMFS (2013)

### *Steelhead*

The name *steelhead* is used in this EIS to refer to anadromous populations of the biological species *Oncorhynchus mykiss*. Steelhead are anadromous, although individual fish may residualize and remain non-anadromous and have the capacity for iteroparity. Iteroparous steelhead are predominately female (Busby et al. 1996); males tend to be semelparous. Juvenile steelhead can spend between one and seven years in freshwater prior to smolting, and then spend up to three years in the ocean before their first spawning migration (Busby et al. 1996). Most steelhead in the Columbia River Basin spend two years in freshwater and two years in the ocean; some populations east of the Cascade Crest have only one ocean year (Busby et al. 1996). Steelhead have two reproductive ecotypes: ocean-maturing and stream-maturing (Busby et al. 1996). On the West Coast, these correspond to winter steelhead and summer steelhead, respectively. Ocean-maturing winter steelhead enter freshwater in a sexually mature condition and spawn shortly thereafter; stream-maturing summer steelhead enter freshwater in a sexually immature condition and can spend several months in freshwater prior to spawning (Busby et al. 1996). Both of these ecotypes occur in the Columbia River Basin.

Steelhead, and their non-anadromous kin, have two major genetic groupings that are different enough to be considered subspecies by some authors: coastal steelhead and rainbow trout (*O. m. irideus*), and inland steelhead and redband trout (*O. m. gairdneri*). Both subspecies occur in the Columbia River Basin. The coastal grouping occurs as far upstream as the Hood River in Oregon and the Wind River in Washington. The inland grouping occurs upstream of those rivers. Coastal steelhead can be winter or summer steelhead; inland steelhead are almost exclusively summer steelhead (i.e., stream-maturing) (Busby et al. 1996).

After spawning, some adult steelhead (up to 50 percent) do not die and, instead, attempt to return to the ocean, which requires these fish to migrate downstream through the dams as adults. These fish are referred to as kelts and migrate downstream in April and May during the spring freshet, similar to salmon smolts. Adult fish passage through the dams is difficult and dependent on flow, so passage survival is low during low-flow years.

Four steelhead DPSs are within the scope of this EIS:

- Upper Columbia River (ESA-listed threatened, further discussed in this section)
- Middle Columbia River (ESA-listed threatened, further discussed in this section)
- Lower Columbia River (ESA-listed threatened, further discussed in this section)
- Snake River Basin (ESA-listed threatened, further discussed in this section)

**What Are the Terms Used to Describe Steelhead?**

Steelhead are one of three salmonid species in the Columbia River Basin (besides coastal cutthroat trout and bull trout) that may spawn multiple times.

**Overwintering:** Winter runs of steelhead migrate upstream between November and April, and spawn quickly after arrival at spawning grounds. Summer run steelhead migrate from early summer to late fall to use "overwintering" habitat in reservoirs or low in tributaries before spawning in higher elevation habitat months later in early spring.

**Overshoots:** Some migrating adult steelhead may swim past their natal home stream as noted in passive integrated transponder (PIT) tag detections at dams upstream from the known source stream; these steelhead are referred to as "overshoots."

**Kelts:** After spawning, as many as 50 percent of steelhead can live to spawn again. They migrate downstream to marine waters to feed as post-spawn adults. These downstream migrating adult steelhead are called "kelts."

**What is Unique about Steelhead Life History?**

The life history pattern of steelhead in the upper Columbia River Basin is complex. Adults return to the Columbia River in the late summer and early fall. Unlike fall Chinook, most steelhead do not move upstream quickly to tributary spawning streams. A portion of the returning run overwinters in the mainstem reservoirs, passing over the upper Columbia River dams in April and May of the following year. Spawning occurs in late spring of the calendar year following entry into the river. Currently, the majority of adult steelhead passing Lower Granite Dam are hatchery origin fish. The effectiveness of hatchery fish spawning in the wild compared to naturally produced spawners is unknown at this time and may be a major factor in reducing steelhead productivity.

Juvenile steelhead typically spend one to three years rearing in freshwater before migrating to the ocean but can spend as many as seven years in freshwater before migrating. Most adult steelhead return to the upper Columbia River after one or two years at sea. Steelhead in the upper Columbia River have a relatively high fecundity, averaging between 5,300 and 6,000 eggs.

Steelhead can lose the ability to smolt in tributaries and never migrate to sea, thereby becoming resident rainbow trout. Conversely, progeny of resident rainbow trout can migrate to the sea and thereby become steelhead. Despite the apparent reproductive exchange between resident and anadromous *O. mykiss*, the two life forms remain separated physically, physiologically, ecologically, and behaviorally (70 FR 67130). Given this separation, NMFS (70 FR 67130) has proposed that the anadromous steelhead populations are discrete from the resident rainbow trout populations.

### Upper Columbia River Steelhead

Upper Columbia River steelhead may migrate through as many as nine dams including four Columbia River System projects within the Columbia River (Bonneville, The Dalles, John Day, and McNary Dams) on their migratory route to and from the Pacific Ocean, dependent on where the species has spawned (NMFS 2009). Overshoot steelhead may pass through Ice Harbor and Lower Monumental Dams in the Snake River, needing to then pass downstream out of the Snake River to continue their migration up the Columbia River. Chief Joseph Dam has no upstream fish passage and represents the end of the anadromous zone.

Upper Columbia River steelhead juveniles migrate to the ocean from mid-April through early June, with peak migration typically occurring in mid-May (Daly et al. 2014). Juveniles rear in the Columbia River for one to three years before outmigrating (Figure 3-121). Adult upper Columbia River steelhead enter freshwater from late summer to early fall and overwinter in larger rivers, such as the Columbia River, before migrating to tributaries to spawn. Adult steelhead then spawn from the following April through mid-June (NMFS 2007).

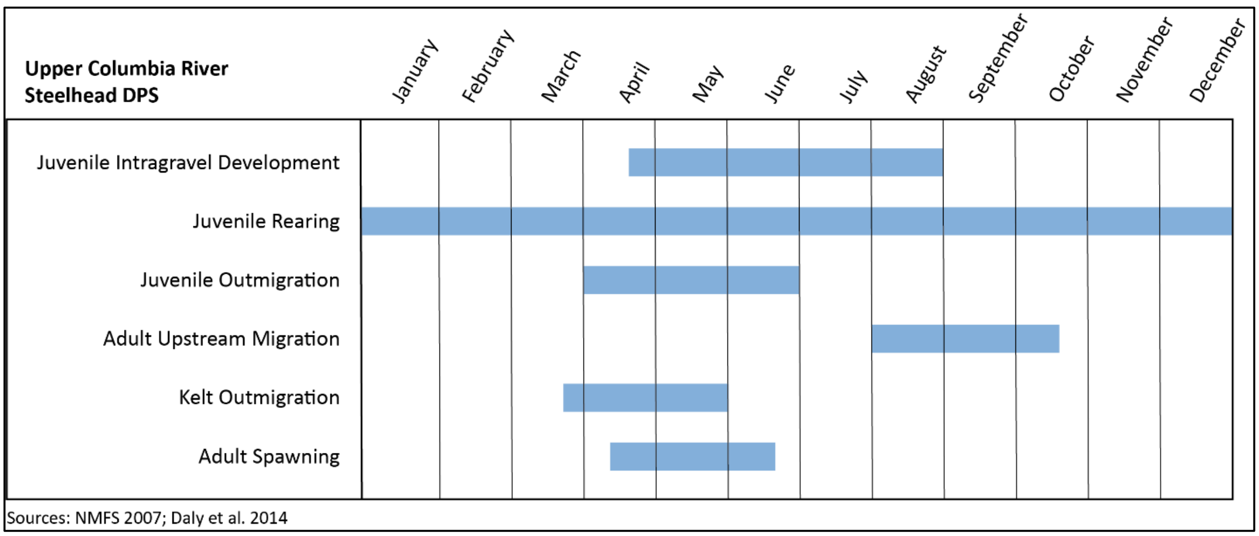

**Figure 3-121. Freshwater Life Phases of Upper Columbia River Steelhead Distinct Population Segment**

Source: NMFS (2007); Daly et al. (2014)

<u>Middle Columbia River Steelhead Distinct Population Segment</u>

Middle Columbia River steelhead may migrate through four projects within the Columbia River (Bonneville, The Dalles, John Day, and McNary Dams) on their migratory route to and from the Pacific Ocean. These fish may pass additional dams outside the project area depending on the population (NMFS 2009).

Two distinct forms are recognized for the Middle Columbia River Steelhead DPS: the stream-maturing type (summer-run steelhead) that require several months in freshwater prior to spawning and the ocean-maturing type (winter-run steelhead) that enter freshwater and spawn shortly after winter entry (Figure 3-122). Most middle Columbia River steelhead are summer-run steelhead (ODFW and WDFW 2017).

Columbia River steelhead juveniles (both summer-run and winter-run) migrate to the ocean from mid-April through early June with peak migration typically occurring in mid-May (Daly et al. 2014). Juvenile winter steelhead outmigrate March through June (ODFW and WDFW 2017). Summer steelhead enter freshwater from April through October and overwinter in larger rivers, such as the Columbia River. Winter steelhead enter freshwater from November to April and migrate to spawning areas immediately. Both summer and winter steelhead spawn from March through June (ODFW and WDFW 2017).

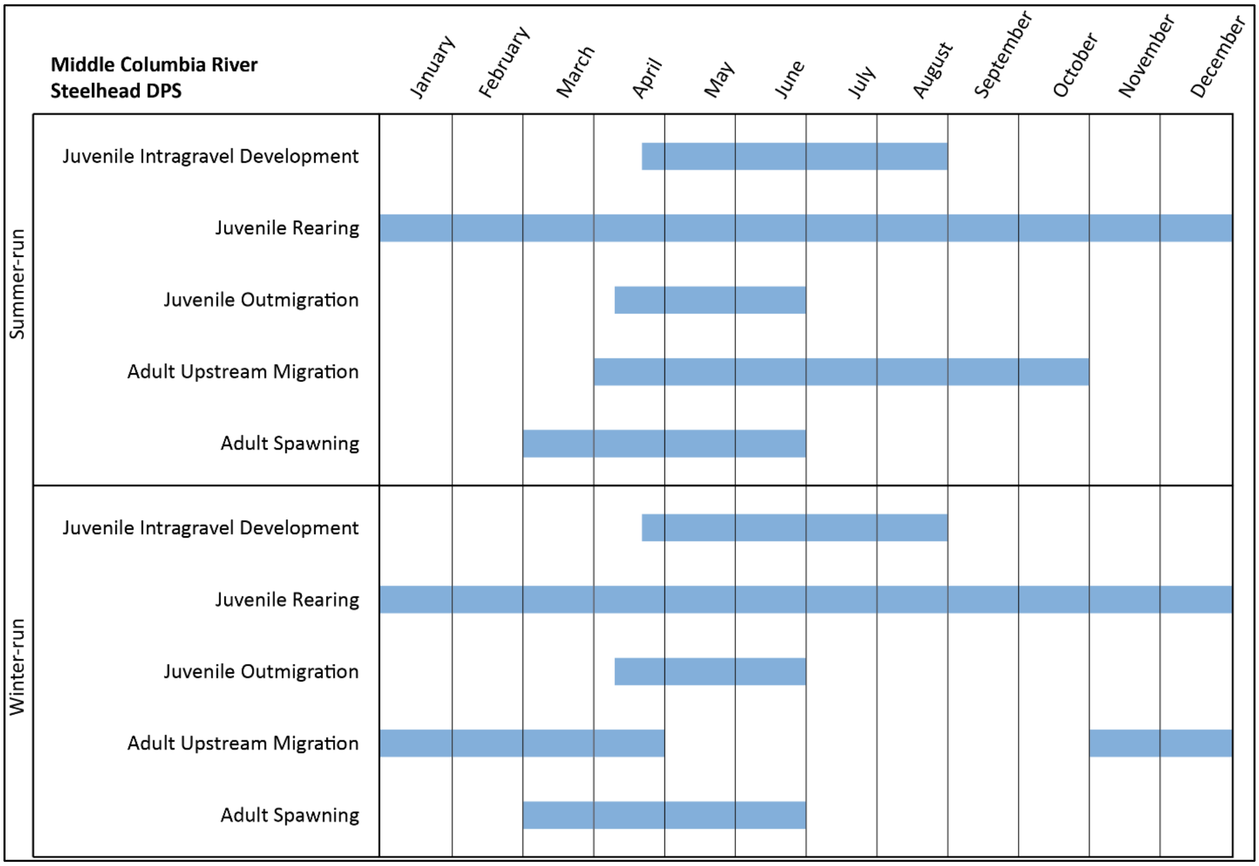

**Figure 3-122. Freshwater Life Phases of Middle Columbia River Steelhead Distinct Population Segment**

Source: ODFW (2010); Daly et al. (2014); DOE (2015); Keefer et al. (2015); ODFW and WDFW (2017)

Lower Columbia River Steelhead Distinct Population Segment

Two distinct forms are recognized for the Lower Columbia River Steelhead population: the summer-run steelhead that require several months in freshwater prior to spawning, and winter-run steelhead that enter freshwater and spawn shortly after winter entry (Figure 3-123). The majority of lower Columbia River steelhead are summer-run steelhead (NMFS 2016). Only Bonneville dam is encountered by this population of steelhead.

Lower Columbia River steelhead summer-run and winter-run juveniles rear for 1 to 4 years before outmigrating as smolts from March to June (NMFS 2013) (Figure 3-124). Adult summer-run steelhead enter freshwater from May to October and require several months to mature prior to spawning from late February to early April. Winter-run steelhead enter freshwater from

December to May already sexually mature and spawn in the spring between April and May (NMFS 2013).

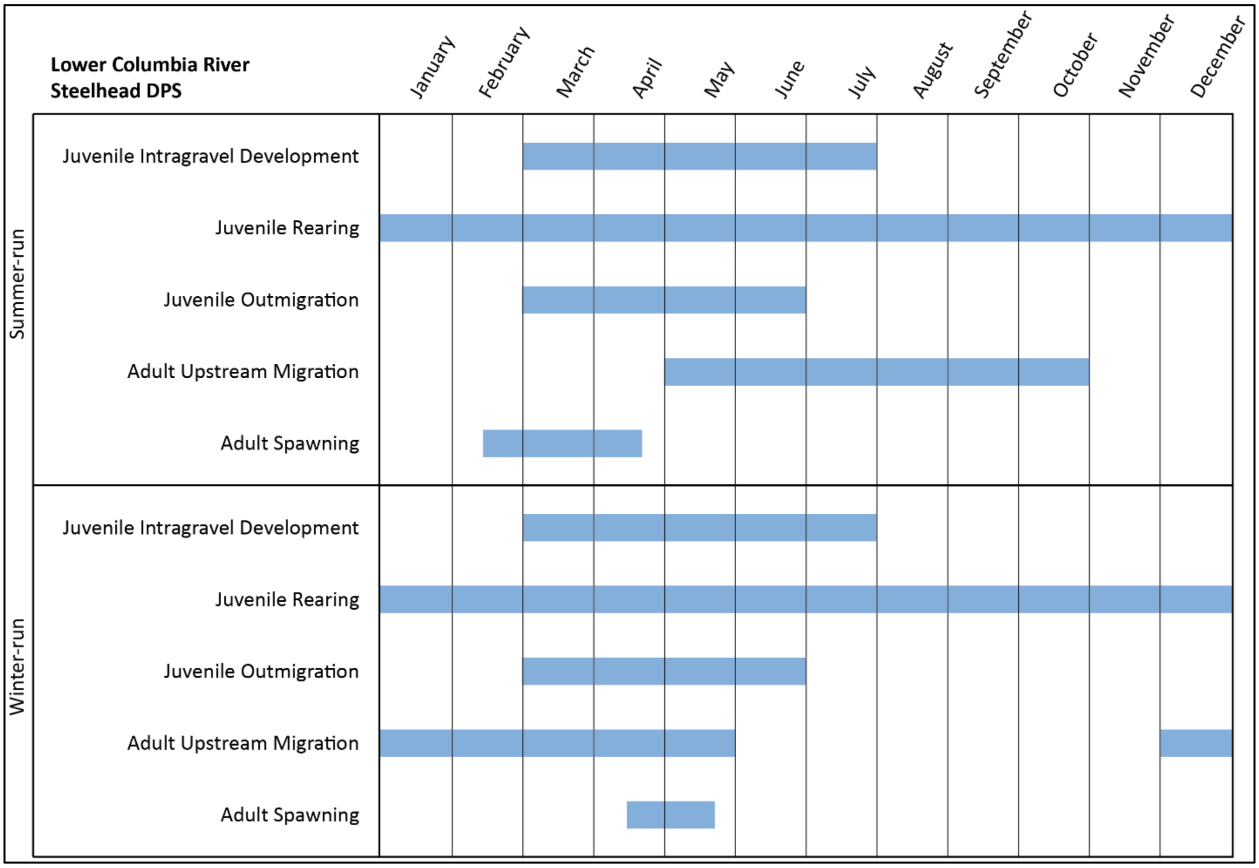

**Figure 3-123. Freshwater Life Phases of Lower Columbia River Steelhead Distinct Population Segment**

Source: NMFS (2013)

<u>Snake River Steelhead</u>

Snake River steelhead may migrate through as many as eight Columbia River System projects within the Columbia and Snake Rivers on their migratory route to and from the Pacific Ocean dependent on where the species has spawned (NMFS 2009). Columbia River System projects that Snake River Basin steelhead migrate through include the four lower Columbia River dams and four lower Snake River dams.

Snake River Basin steelhead juveniles migrate to the ocean from April to June with peak migration typically occurring in mid-May (Figure 3-124) (NMFS 2017). Steelhead have high variability in the duration juveniles rear in their natal streams; typically, juveniles will smolt between 2 and 3 years. Snake River Basin steelhead are primarily considered summer-run as adults enter freshwater from June through August and continue migrating during September before overwintering in the mainstem rivers and tributaries throughout their range. The adults then migrate to tributaries to spawn between March and early June.

### Other Endangered Species Act–Listed Anadromous Fish

Other ESA-listed anadromous fish beyond salmon and steelhead species are also located within the study area.

#### *Eulachon*

Eulachon (*Thaleichthys pacificus*), also known as Pacific smelt, are an anadromous smelt, endemic to the northeastern Pacific Ocean. They spawn in rivers from northern California to southwestern Alaska (NMFS 2017). Eulachon are rich in calories and are important to marine and freshwater food webs, commercial and recreational fishers, and indigenous people (WDFW and ODFW 2001). Eulachon are prey for marine mammals, salmon, sturgeon, and birds. In marine waters, eulachon are important in the food chain as prey of salmon and steelhead (Gustafson et al. 2010). Based on genetic information and spawning site fidelity, NMFS has determined that eulachon along the West Coast contains two DPSs. Only the Southern DPS of eulachon occur in the action area.

<u>Southern Eulachon Distinct Population Segment</u>

The southern eulachon DPS includes fish that spawn in rivers south of the Nass River in British Columbia to, and including the Mad River in California (Gustafson et al. 2010). Tributaries of the Columbia River that have supported eulachon runs in the past include the Grays, Elochoman, Cowlitz, Kalama, and Lewis Rivers in Washington and the Sandy River in Oregon (Gustafson et al. 2010). In the Columbia River, eulachon spawning runs occur annually on the mainstem lower Columbia and Cowlitz Rivers; these areas are downstream from Bonneville Dam, and the historical range included areas just upstream from the dam (Fish Commission of Oregon 1953).

Critical habitat for this DPS was defined on October 20, 2011, and includes the physical and biological features essential for conservation of eulachon in freshwater and estuarine areas downstream of Bonneville Dam (76 FR 65324). As described in its critical habitat designation, important eulachon habitat features can be summarized as (1) freshwater spawning and incubation sites with supportive water flow, quality, and temperature conditions; (2) unobstructed freshwater and estuarine migration corridors; and (3) nearshore and offshore marine foraging habitat with supportive water quality and available prey (76 FR 65324). The largest spawning run of eulachon uses the lower Columbia River mainstem and tributaries.

The timing and usage of spawning habitats has considerable year-to-year variation and is dependent on site-specific environmental factors in the lower Columbia River. Eulachon migration beyond the Lewis River (RM 87) is limited to years of very high abundance and passage to Bonneville Dam (RM 146) is rare (WDFW 2009). Historical investigations from the 1950s indicate adult eulachon occasionally migrated to Bonneville Dam, with some fish successfully passing the dam through the navigation locks to spawn as far upstream as Hood River (Fish Commission of Oregon 1953; Smith and Saalfeld 1955).

Eulachon eggs are released and fertilized in the water column in a broadcast spawning strategy (Cowlitz Indian Tribe 2014). Fertile eggs in the water column slowly sink as they drift downstream and eventually adhere to river substrates, typically in areas of pea-sized gravel and coarse sand (WDFW and ODFW 2001). Fertilized eggs typically require 30 to 40 days for larval development before hatching. After this incubation period, the eggs hatch and the larvae drift immediately out to the estuary, usually within hours to days (Cowlitz Indian Tribe 2014). Because the larvae are rapidly flushed out to the ocean by river currents with minimal time in freshwater, it is believed eulachon imprint and home to their native estuary, then select specific rivers and spawning areas based on environmental conditions at the time of their return (Hay and McCarter 2000). Adult eulachon typically enter the lower Columbia River from December to March (ODFW and WDFW 2001; NMFS 2008). A small run of eulachon can occur as early as mid-November (Cowlitz Indian Tribe 2014). Multiple runs of eulachon may migrate through the river each year. Peak abundance typically occurs in February and March (NMFS 2008). Spawning occurs in the lower sections of rivers at temperatures ranging from 4°C to 10°C. Water temperatures colder than 4°C can slow or stop migration (ODFW and WDFW 2001). When river temperatures vary above or below normal, eulachon may fail to spawn, delay spawning, or modify their migratory behavior (NMFS 2017).

#### *Green Sturgeon*

The green sturgeon (*Acipenser medirostris*) is a marine-oriented and slow-growing anadromous fish (average length of 50 to 55 inches, or 130 cm) that ranges from Alaska to Mexico. Outside of their natal system, adult and subadult green sturgeon migrate to the lower Columbia River estuary for feeding and optimization of growth (NMFS 2009). Within the lower Columbia River Basin, green sturgeon are common and were observed as far as 140 miles (225 km) upstream in the Columbia River prior to the construction of Bonneville Dam (Wydoski and Whitney 1979). Today, they do not move upriver beyond about RM 27 (WDFW 2007). In estuaries, they feed on shrimp, amphipods, isopods, clams, worms, and an assortment of crabs and fish (Moyle et al. 1995; Dumbauld, Holden, and Langness 2008).

Based on genetic information and spawning site fidelity, NMFS has determined green sturgeon along the West Coast contain two DPSs: (1) a northern DPS consisting of populations in coastal watersheds northward and including the Eel River; and (2) a southern DPS consisting of coastal Central Valley populations south of the Eel River, which is its only known spawning population in the Sacramento River (68 FR 4433; NMFS 2002). The northern DPS is not listed. Both the southern and northern DPSs occur in the Columbia River with recent surveys showing more southern DPS than northern DPS green sturgeon (NMFS 2015).

Southern Green Sturgeon Distinct Population Segment

The southern DPS green sturgeon appear in high concentrations in coastal bays and estuaries along the west coast of North America during the summer and autumn, particularly in Willapa Bay, Grays Harbor, and the Columbia River estuary. Recent data indicates the majority of these fish are either immature or in the early stages of maturation (WDFW and ODFW 2012).

Designated green sturgeon critical habitat includes the Columbia River estuary from the mouth to RM 46 (74 FR 52300).

Juvenile green sturgeon are not known to use the lower Columbia River estuary (NMFS 2018). However, in 2011, WDFW and ODFW (2012) found an age-0 (i.e., less than 1 year old) green sturgeon in the Columbia River downstream of Bonneville Dam. This was the first time an age-0 green sturgeon had been observed in the Columbia River. The specimen was retained and preserved, and genetic analysis confirmed that the animal is a green sturgeon (NMFS 2015).

Adult green sturgeon congregate in deep water areas of the estuary during the summer and fall based on tagging and recapture studies and subsequent analyses (ODFW and WDFW 2014). Peak numbers of green sturgeon occur from July through September (WDFW 2007); during this period, the Columbia River estuary is believed to have the largest concentration of southern DPS green sturgeon compared to other estuaries along the West Coast (NMFS 2009). Commercial gillnet harvest records from 1981 to 2003 provide evidence that green sturgeon primarily use the lower portions of the Columbia River estuary, with infrequent movement upstream of RM 27 (WDFW 2007).

**NON-ENDANGERED SPECIES ACT–LISTED ANADROMOUS FISH**

An inventory of the non-ESA-listed anadromous species in the study area appears in Table 3-58.

**Table 3-58. Non-Endangered Species Act-Listed Anadromous Columbia River Basin Species**

| Species and ESU or DPS |
|---|
| Upper Columbia River Summer/Fall Chinook ESU (*Oncorhynchus tshawytscha*) |
| Middle Columbia Spring Chinook ESU (*O. tshawytscha*) |
| Southwest Washington Steelhead DPS (*O. mykiss*) |
| Upper Columbia River Sockeye ESU (*O. nerka*) |
| Upper Columbia River Coho ESU (*O. kisutch*) |
| Snake River Coho ESU (*O. kisutch*) |
| Pacific lamprey (*Entosphenus tridentatus*) |

### Salmon and Steelhead

#### *Chinook Salmon*

Upper Columbia River Summer/Fall-Run Chinook Salmon

This ESU is not ESA-listed and was considered not warranted for listing (Myers et al. 1998). Hatchery production is associated with this ESU. The EIS focus for this species is where the species occurs and migrates through the mainstem of the Columbia and Snake Rivers.

Upper Columbia River summer/fall-run Chinook salmon may migrate through four Columbia River System projects based on their spawning area location and travel route to the ocean. These projects include the four lower Columbia dams. The species migrates through several other dams in the Columbia River and its tributaries, and the species spawns within the mainstem of the Columbia River and tributaries including the Wenatchee, Entiat, Chelan, Methow, Okanogan, and Similkameen Rivers.

Summer-run and fall-run Columbia River Chinook salmon have an ocean-type or subyearling life history, where young fish emerge from redds from late winter through early spring, rear and grow rapidly, and then migrate seaward before mid-summer (Figure 3-125). In addition, many upper Columbia River hatchery origin summer Chinook display a yearling life history, where they grow more slowly and holdover one year and migrate to the ocean the following year. Summer Chinook salmon enter the Columbia River from late spring (May) through late summer (August), whereas fall Chinook salmon enter the Columbia River from late summer (early August) through early November.

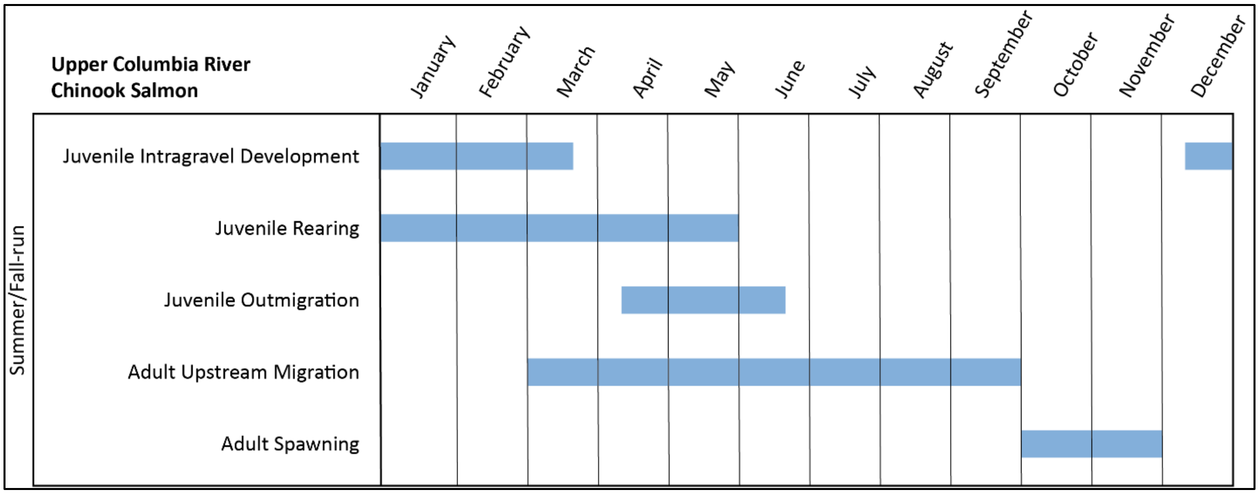

**Figure 3-125. Freshwater Life Phases of Columbia River Summer/Fall-Run Chinook Salmon**

Source: WDFW (2006)

<u>Middle Columbia River Spring-Run Chinook Salmon</u>

This ESU is not ESA-listed and was considered not warranted in 1998 (63 FR 11482). The EIS focus for this species is where the species occurs and migrates through the mainstem of the Columbia River.

Middle Columbia River spring-run Chinook salmon may migrate through four projects within the lower Columbia River on their migratory route to and from the Pacific Ocean dependent on where the species has spawned.

Middle Columbia River spring-run Chinook salmon juveniles have a similar life history as upper Columbia River spring-run Chinook salmon. The fish migrate to the ocean in the spring of their second year of life. Juvenile spring-run Chinook salmon outmigrate after one year of rearing, mid-spring through early summer (Figure 3-126). Similar to upper Columbia River spring-run Chinook salmon, middle Columbia River spring-run Chinook salmon adults enter freshwater from early spring, with the peak run occurring in mid-May, and reach the upper Columbia River tributaries from April through July. Some males return to natal streams after one winter at sea; however, the 4- and 5-year-old adults are the majority of the run. The adults then hold in the tributaries until spawning in the late summer, peaking in mid-late August. Adults die within about 1 week after spawning.

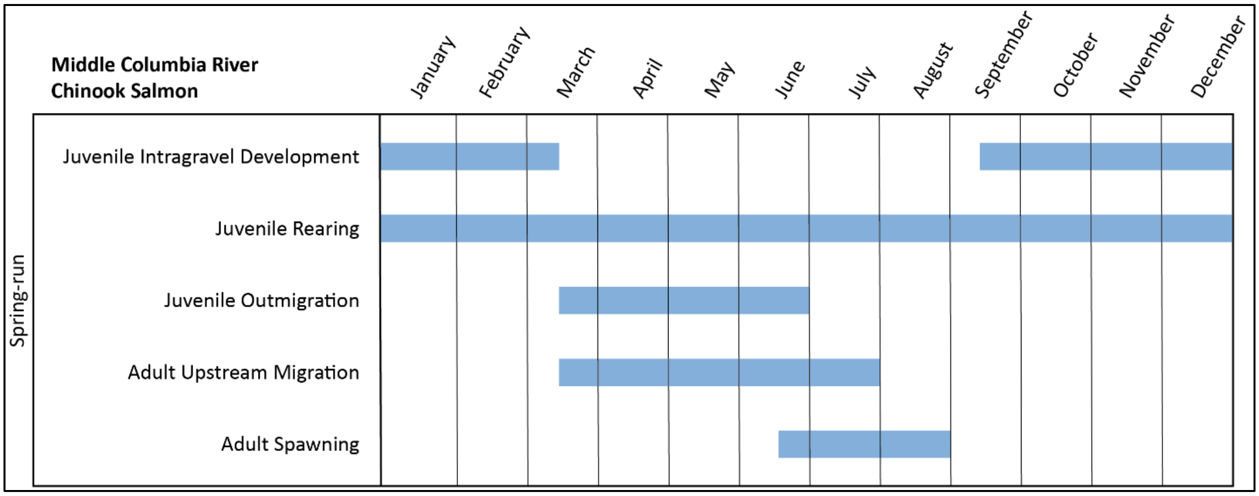

**Figure 3-126. Freshwater Life Phases of Middle Columbia River Spring-Run Chinook Salmon Evolutionarily Significant Unit**

Source: NMFS (2007, 2018)

### *Sockeye Salmon*

Upper Columbia River Sockeye Salmon

Upper Columbia River sockeye salmon are not ESA-listed. Currently, Lake Wenatchee, in the Wenatchee Basin, and Lake Osoyoos, in the Okanogan Basin, are the two main sockeye salmon–producing lakes in the Columbia River Basin; officially they constitute separate ESUs: the Lake Wenatchee Sockeye Salmon ESU and the Okanogan River Sockeye Salmon ESU. Upper Columbia River sockeye salmon migrate through as many as nine dams on their migratory route to and from the Pacific Ocean; four CRS projects and up to five PUD owned mainstem dams (Wells Dam is owned and operated by Douglas County PUD; Rocky Reach Dam and Rock Island Dam which are owned and operated by Chelan County PUD; and Wanapum Dam and Priest Rapids Dam which are owned and operated by Grant County PUD).

Anadromous juveniles will rear in their natal lakes for one to three years before outmigrating. Anadromous Upper Columbia River sockeye salmon juveniles migrate to the ocean from April through early July, with peak migration typically occurring in mid-April to early May. Adult sockeye salmon will spawn from September through October in the lakeshore gravels.

Okanogan sockeye salmon are currently the most abundant sockeye salmon stock in the Columbia River Basin. Most Okanogan sockeye salmon rear in Osoyoos Lake, which spans the U.S.-Canada border. Production of Okanogan sockeye salmon occurs largely in British Columbia.

The majority of Wenatchee sockeye spawn in the White River and Little Wenatchee River, with some spawning also occurring in the Napeequa River (WDFW 2020). These fish rear in Lake Wenatchee, a natural lake on the Wenatchee River in Washington State before outmigrating to the ocean.

### *Coho Salmon*

Upper Columbia River Coho Evolutionarily Significant Unit

Upper Columbia River Coho are not-ESA listed.

Upper Columbia River coho pass the four lower Columbia River dams. While originally these fish were sourced from hatchery coho programs, there are hatchery releases and natural spawning now occurs in the Yakima, Wenatchee, Entiat, and Methow basins.

While the coho salmon hatchery production above Bonneville Dam does not affect a defined ESU or ESUs of coho salmon, it contributes to the rebuilding natural coho salmon populations (listed and unlisted), as well as benefits and risks to other salmon ESUs and steelhead DPSs. These programs can provide benefits to the abundance, productivity, and spatial structure of coho salmon, as well as provide benefits to other species of salmon and steelheads through marine-derived nutrients from the adult carcasses, cleaning and transport of spawning gravels, and as a prey base for other salmon and steelheads. However, they also present risks to these other species in the form of ecological interactions, including competition for scarce resources and direct and/or indirect predation. Additionally, the hatchery facilities where these programs are reared and released pose risks associated with delaying or blocking migration of adult and juvenile fish, as well as risks from water withdrawal and effluent discharge.

Snake River Coho Evolutionarily Significant Unit

Snake River Coho are not ESA-listed.

Snake River coho pass the four lower Snake dams as well as the four lower Columbia River dams. While originally these fish were sourced from hatchery coho programs, there is natural spawning that occurs now in the Snake basin tributaries.

While the coho salmon hatchery production above Bonneville Dam does not affect a defined ESU or ESUs of coho salmon, it contributes to the rebuilding natural coho salmon populations (listed and unlisted), as well as benefits and risks to other salmon ESUs and steelhead DPSs. These programs can provide benefits to the abundance, productivity, and spatial structure of coho salmon, as well as provide benefits to other species of salmon and steelheads through marine-derived nutrients from the adult carcasses, cleaning and transport of spawning gravels, and as a prey base for other salmon and steelheads. However, they also present risks to these other species in the form of ecological interactions, including competition for scarce resources and direct and/or indirect predation. Additionally, the hatchery facilities where these programs are reared and released pose risks associated with delaying or blocking migration of adult and juvenile fish, as well as risks from water withdrawal and effluent discharge.

### Other Non-Endangered Species Act–Listed Anadromous Fish

#### *Pacific Lamprey*

The Pacific lamprey (*Entosphenus tridentatus*), an anadromous species that is parasitic during its ocean phase. It is the most widely distributed lamprey species on the West Coast (Meeuwig et al. 2004). Pacific lamprey occur within the Columbia and Snake Rivers. It was estimated that the population of lampreys in the 1960s and 1970s may have been as many as 1 million adults at Bonneville Dam (Columbia River Inter-Tribal Fish Commission [CRITFC] 2011). However, due to several factors, including impediments to passage, Pacific lamprey abundance declined significantly in the Columbia River Basin to near extirpation in some tributaries (CRITFC 2011a). The Pacific lamprey is not a federal ESA-listed species, but it is a threatened species by the State of Idaho (IDAPA 13.01.06). Pacific lamprey were listed as an Oregon State sensitive species in 1993. In December 2004, the USFWS ruled there was not substantial scientific or commercial information to warrant a Federal listing of Pacific lamprey (69 FR 77158).

Pacific lamprey may migrate through as many as eight Columbia River System projects within the Columbia and Snake Rivers along their migratory route to and from the Pacific Ocean. Individual Pacific lamprey have been detected as far upstream as the Salmon River subbasin. However, Pacific lamprey do not necessarily return to natal locations, but often return to other river systems in the Pacific Northwest. Lamprey occupancy is constrained to below dams that lack fish passage on the Columbia and Snake Rivers (Moser and Close 2003).

All lamprey begin life in freshwater and share similar characteristics as ammocoetes (i.e., larvae), but they exhibit different life histories as they develop. Time to hatch varies based on water temperature, which is an important factor for lamprey embryonic and larval development. Effects of temperature on larval hatching and development were examined and an increase in abnormalities occurred at a temperature of 22°C, while zero development occurred at 4.85°C. The optimal temperature for this study was found to be 18°C (Meeuwig et al. 2005). After emerging, larvae will eventually drift downstream to locations of low velocity and fine silt and begin the burrowing phase (Brumo 2006).

Larval lamprey phase is strongly associated with stream and river sediments. Larvae burrow in sediments for 3 to 7 years after hatching, where they filter feed on detritus and organic material. Larval lamprey prefer areas with accumulated deep, fine substrates (McIlraith et al. 2017). Lamprey may spend up to 10 years as larvae prior to transformation to juvenile phase (called macrophthalmia) and outmigration. Thus, the availability of suitable habitat for larvae is critical to conservation. The effects of contaminants in sediments on Pacific lamprey larvae may impact survival; bioaccumulation of contaminants is occurring in the larval life stage (Nilsen et al. 2015). They gradually migrate downstream, moving primarily at night, seeking coarser sand/silt substrates and deeper water as they continue to grow and enter their next life stage. The Bonneville and The Dalles pools provide habitat and rearing areas for larval Pacific lamprey, with evidence being that lamprey were detected at river mouths in these pools, as well as in the shallow water pool margins in the Bonneville pool (Jolley et al. 2014). The river mouths provide an important habitat for Pacific lamprey larvae, but they are at risk in this environment because of the potential for stranding (Jolley et al. 2014). Notably, breaching Condit Dam provided habitat for lamprey in the Bonneville Reservoir at the mouth of the White Salmon River (Jolley et al. 2014).

Metamorphosis for juveniles occurs from July to December as they develop eyes, teeth, and become free swimming (Jolley, Silver, and Whitesel 2012). As juveniles mature into adults, they begin their migration to saltwater (69 FR 77158). Outmigrant collections at Bonneville Dam indicate a large winter (January to March) peak, with a slightly smaller peak in June. Far fewer metamorphosed lamprey are seen in July and August (McIlraith et al. 2017).

After spending one to three years in the ocean, Pacific lamprey return to freshwater between February and June (69 FR 77158). Upstream migration by adult lamprey may be influenced by an unknown combination of temperature, discharge, and chemical cues. Adults spend multiple months in the estuary before moving into freshwater habitats. Adult passage at Bonneville Dam for Pacific lamprey typically occurs between May and late August, peaking in July. Most Pacific lamprey take about 2 months to migrate upstream through the Columbia River System projects (McIlraith et al. 2017). Radio telemetry and PIT tag studies have found there is substantial attrition of fish between mainstem dams during the upstream adult migration in the Columbia River (Moser and Close 2003; Keefer et al. 2009). The ability to pass multiple dams to reach spawning locations in the upper reaches of the Columbia and Snake River Basins may be dependent on a variety of factors, including body size, migration timing, and genetic variation (Keefer et al. 2009; Hess et al. 2014).

Pacific lamprey are thought to overwinter and remain in freshwater for approximately 1 year before spawning (69 FR 77158). Adult Pacific lamprey overwinter in locations typically consisting of deep pools with rock cover (McIlraith et al. 2017). Spawning occurs over many days in gravel-bottomed streams at the upstream end of riffle habitat (69 FR 77158).

#### *American Shad*

American shad (shad; *Alosa sapidissima*) is a non-native fish that was introduced to the Pacific Northwest from eastern North America in the 1880s (Fuller and Neilson 2018a). Shad is an anadromous member of the Clupeidae family, which includes herring and sardine (Fuller and Neilson 2018a). Shad can reach 29 inches long and 12 pounds with a maximum life span of 13 years (Froese and Pauly 2018). Adult and juvenile shad feed on zooplankton and fish eggs. This species is not federally or state listed.

Shad are now distributed throughout the mainstem Columbia, Snake, and Willamette Rivers, but they have not been recorded in all tributaries of these rivers. The Columbia River supports the largest population of shad in the world (Sanderson, Barnas, and Rub 2009; Hinrichsen et al. 2013; Froese and Pauly 2018).

Shad migration and juvenile survival varies with water temperature and river discharge; once water temperatures reach 16°C, returning adults spawn between June and August in shallow water over sand or gravel (Hinrichsen et al. 2013). Shad require a temperature range of 13°C to

26°C for eggs and juveniles to successfully grow (Hinrichsen et al. 2013). Hinrichsen et al. (2013) found that lower dam discharges allowed more adult shad to migrate farther upstream due to slower water, which requires less energy to swim through. Juveniles use all portions of rivers; however, they are more abundant in off-channels with dense aquatic vegetation.

Juvenile shad outmigrate to the ocean in the fall when they are between 1 to 4 inches (2.5 to 10.2 cm) long (Lower Columbia Fish Recovery Board 2004c) and return as 3- to 4-year-old adults. A portion of the adult shad return to sea after spawning (Lower Columbia Fish Recovery Board 2004c).

Shad are considered competitors with native fish particularly because both adult and juvenile shad feed on zooplankton that native fish would otherwise consume (Lower Columbia Fish Recovery Board 2004c; Haskell, Tiffan, and Rondorf 2013). The large population of shad within the Columbia and Snake Rivers consume as much as 30 percent of the zooplankton present in these rivers (Haskell, Tiffan, and Rondorf 2013). The large number of juvenile shad present in the river basin may subsidize the diets of non-native fish such as bass, catfish, and walleye that feed on fish, including native fish (Harvey and Kareiva 2005; Sanderson, Barnas, and Rub 2009), thereby contributing to an increasing number of non-native aquatic predators. Juvenile shad may compete with juvenile salmon and steelhead for backwater habitat (Lower Columbia Fish Recovery Board 2004c).

Migrating adult shad may occupy fish ladders during periods when adult salmon and steelhead are migrating upstream (Lower Columbia Fish Recovery Board 2004c; Hinrichsen et al. 2013); raising flows at The Dalles' east fish ladder appears to effectively accommodate adult salmon to avoid overcrowding with adult shad.

ODFW and WDFW promote American shad as a recreational fishing opportunity (ODFW 2018a; WDFW 2018), as well as a managed commercial shad fishery (Lower Columbia Fish Recovery Board 2004c). However, the commercial fishery is limited because adult shad migration overlaps with adult salmon and steelhead migration (Lower Columbia Fish Recovery Board 2004c). No efforts are underway to eradicate shad in the Columbia River Basin.

It is important to note that shad are generalists that tolerate a wide range of conditions and CRS projects are not likely to change the population numbers but could influence their migrations and distributions that affect interactions with native fish.

#### *3.5.2.4 Resident Fish*

As described in Section 3.2.1.1, resident fish are fish that spend their entire lives in freshwater; they are either fluvial (using only rivers for spawning and rearing) or adfluvial (using lakes for feeding and rivers for spawning), or they may simply live in one habitat type, such as a lake or river, their entire life cycle. The kinds and numbers of resident fish vary considerably across the basin. Many species interact with each other and their habitats to form local/regional fish communities. Some of these species are important for recreational, cultural, and commercial harvest. Approximately two-thirds of the fish species in the Columbia River Basin are non-native and the extent of their influence and impacts to native fish assemblages is not well understood (Independent Scientific Advisory Board [ISAB] 2008).

In this section, key fish species in the study area will be discussed, including life history, status, and a general description of their interaction with Columbia River System projects. Then, because (1) effects to resident fish are most effectively evaluated by regions or communities; (2) they are managed on a more localized scale than anadromous fish; and (3) effects from projects tend to vary widely across the Columbia River Basin. The resident fish residing within the Columbia River Basin are generally described, followed by a description of the regional resident fish communities in which they reside. Additionally, the species that are ESA-listed (bull trout and Kootenai River white sturgeon) are discussed in their own sections within each region.

#### ENDANGERED SPECIES ACT–LISTED RESIDENT FISH

An inventory of the ESA-listed resident species and their designated critical habitat in the study area appears in Table 3-59. Details on distribution, population status, and threats to each of these species appear in the *Federal Register* notices that NMFS and the USFWS provide for all listing actions; these are cited in the table. Species status and relevant CRSO study area information appear in their respective subsections later in this section.

**Table 3-59. Status and Critical Habitat of Resident Columbia River Basin Endangered Species Act–Listed Species**

| Species and ESU or DPS | ESA-Listing Status | Critical Habitat Designation |
|---|---|---|
| Bull Trout Columbia River DPS (*Salvelinus confluentus*)[1/, 2/, 3/] | Threatened 1999 | 2004 |
| Kootenai River White Sturgeon (*Acipenser transmontanus*)[1/, 2/] | Endangered 1994 | 2008 |

1/ State-listed threatened: Idaho (IDAPA 13.01.06).
2/ State-listed species of concern: Montana (MFWP 2018).
3/ State Species of Concern: Washington (WDFW)

#### Bull Trout

Bull trout (*Salvelinus confluentus*) are members of the char genus and require very cold, clear water. Smaller juveniles eat terrestrial and aquatic insects; as they grow, they shift to eating fish, with a preference for whitefish, sculpins, and other trout as well as anadromous fish eggs, alevin, fry, smolts, and carcasses (USFWS 1997). Bull trout exhibit multiple life history patterns involving movements and migrations that reflect a high degree of local site fidelity (USFWS 2008b). Bull trout in the Columbia River Basin can be resident or migratory. Resident bull trout spend their entire lives in the same stream, while migratory bull trout spend most of their time in lakes, reservoirs (adfluvial), or large rivers (fluvial). Adult bull trout migrate upstream to spawn in the fall in streams with cold, clear water, and eggs hatch in late winter or early spring. Juveniles rear in the spawning tributaries for 1 to 4 years, and then in migratory life history patterns, juveniles move back downstream to larger rivers or lakes. Bull trout will repeat spawn from sexual maturity of 4 to 7 years throughout their life span, which can reach 12 years.

The bull trout was ESA-listed as threatened in 1999 (64 FR 58910), which was reaffirmed in 2008 in its status review (USFWS 2008b), with critical habitat identified in 2004 (70 FR 63898) and updated in 2010 (75 FR 6398). The recovery plan developed in 2015 outlined reasonable actions to recover and protect bull trout (USFWS 2015b). Bull trout occur throughout the Columbia and Snake River Basins in Washington, Oregon, Idaho, and Montana (USFWS 2015). Bull trout critical habitat, which describes specific locations and elements of the environment essential for the conservation and recovery of the species, was designated for the entire mainstem Columbia River upstream to Chief Joseph Dam and mainstem Snake River upstream to Brownlee Dam, as well as upper tributaries of both rivers (USFWS 2015).

The USFWS status review (2008b) reported bull trout were generally stable range-wide, with some core area populations decreasing, some stable, and some increasing. Since the listing of bull trout as threatened in 1999, there has been little change in the distribution of bull trout in the coterminous United States, with the exception of successful reintroduction into the Clackamas River, and occupied bull trout core areas have not been extirpated since the species listing (USFWS 2015).

In the study area, bull trout occur in substantial populations in the headwater regions, including the Flathead, Clark Fork, Pend Oreille, and Kootenai River Basins. In the Columbia River, bull trout occasionally appear in the upper river from the U.S.-Canada border to Grand Coulee Dam, and the mainstem provides feeding, migration, and overwintering habitat for populations in the Wenatchee, Methow, and Entiat populations (USFWS 2015) between Chief Joseph Dam and McNary Dam. The Snake, Salmon, and Clearwater Rivers provide feeding, migration, and overwintering habitat as well as migration connections for several populations of bull trout. Below McNary Dam, very few bull trout have been observed in the mainstem (Fish Passage Center 2018a, 2018b).

**Kootenai River White Sturgeon**

The Kootenai River white sturgeon (*Acipenser transmontanus*) is a land-locked population of white sturgeon confined to just 168 river miles in Montana and Idaho in the United States and in British Columbia, Canada. Kootenai River white sturgeon are large, long-lived fish with a prehistoric appearance due to rows of bony plates called scutes on their sides. The maximum observed size of Kootenai River white sturgeon based on growth data is about 9 feet, and they could theoretically reach almost 11 feet (Paragamian, Beamesderfer, and Ireland 2005). White sturgeon have sensitive, whisker-like barbels on their snouts that help them detect prey with their downward facing mouth on the riverbed (Scott and Crossman 1973). Kootenai River white sturgeon are opportunistic feeders that prey on a variety of organisms available to them; juveniles prefer small organisms in the substrate such as invertebrates and insect larvae, then as adults their diet shifts mainly to fish with some clams, snails, and aquatic insects (USFWS 1999). Kootenai River white sturgeon were harvested for food, caviar, and for sport until a decline in catch and subsequent harvest restrictions limited the number of white sturgeon taken (Scott and Crossman 1973).

The population ranges from Kootenai Falls (approximately 31 RM downstream of Libby Dam) to Corra Linn Dam at the outlet of Kootenay Lake. Since the last ice age, Kootenai River white sturgeon have been isolated from other downstream white sturgeon populations in the Columbia River Basin by a natural barrier at Bonnington Falls, downstream from Kootenay Lake (USFWS 1999).

The Kootenai River population of white sturgeon was ESA-listed as endangered on September 6, 1994. It is listed as a Montana Species of Special Concern (MFWP 2018) and an Idaho endangered species (IDAPA 13.01.106). Critical habitat for this species was established in 2001, and then expanded in 2008 to include 18.3 river miles of the Kootenai River within Boundary County, Idaho. In January 2018, the USFWS initiated a 5-year status review (83 FR 3104), and a revised recovery plan was completed in September 2019 (USFWS 2019).

The Libby Project is the only Columbia River System project that interacts with Kootenai River white sturgeon. Since its completion in 1974, the Libby Project has greatly changed flow regimes of the Kootenai River compared to flow regimes prior to dam construction. The operation of the Libby Project has reduced peak flow magnitude, changed the timing (seasonality) of the hydrograph, and retained upstream sediment supply. Kootenai River temperature and nutrient regimes, which support primary productivity of the food web, have also been modified (USFWS 1999).

## NON-ENDANGERED SPECIES ACT–LISTED RESIDENT FISH

This section includes a review of Columbia River Basin fish species that are not ESA-listed. Some species that may have a state-listing status or have been identified as a species of interest by the public during scoping, are considered key species and discussed specifically in detail. These key species are categorized as either native or non-native. Other species are described as groups or communities of fish.

### Key Native Fish Species

#### *White Sturgeon (Columbia River)*

White sturgeon are large, long-lived fish with a prehistoric appearance due to rows of bony plates called scutes along their bodies. They are considered the largest freshwater fish in North America and are an important cultural, recreational, and commercial resource in the Columbia River Basin. Unlike the Kootenai River population of white sturgeon, white sturgeon in the Columbia River are not ESA-listed. They occasionally appear in marine waters and typically live in the Columbia River from the mouth to the upper Columbia River in Canada, as well as the Snake River up to Shoshone Falls. They use the Willamette River up to and above Willamette Falls and other lower Columbia River tributaries (Hanson et al. 1992). Adults are opportunistic, bottom-oriented feeders and primarily eat invertebrates and fish. They have unique adaptations for bottom feeding that include ventral barbels and a protrusible mouth.

White sturgeon reach sexual maturity when they are older and larger compared to most fish species found in freshwater, with males maturing at 12 to 25 years of age and females at 15 to 30 years (Bajkov 1949; Scott and Crossman 1973; Galbreath 1985; Hanson et al. 1992; Welch and Beamesderfer 1993; IPC 2005). Reproductive frequency also varies between sexes; males can reproduce every 2 to 4 years, while females were thought to reproduce no more frequently than every 5 years (Conte et al. 1988; Chapman, VanEenennaam, and Doroshov 1996; Anders et al. 2002), though more recent information suggests females can spawn more frequently than every four years. Spawning occurs between April and July during the highest spring flows and when temperatures reach 12°C to 14°C (Hanson et al. 1992; Parsley et al. 1993; Parsley and Beckman 1994). They are broadcast spawners, which means females typically release eggs that are fertilized when males release milt (i.e., sperm) over them. Eggs adhere to river substrate and hatch after 8 to 15 days, depending on water temperature (Brannon et al. 1985). High water velocity is key to spawning site selection (NW Council 2013), and sufficient flows during key spawning times are important. Hatched embryos are called yolk-sac larvae; they have a yolk sac that provides sustenance as the larvae hide among the substrate and seek protection from predators. Small spaces in the substrate are important for this life stage. Once the yolk sac is absorbed, they begin a downstream dispersal and transition to external foods, primarily benthic macroinvertebrates, for the next developmental stage (Brannon et al. 1984; Buddington and Christofferson 1985; Muir et al. 2000; Hildebrand et al. 2016).

Growth during larval stage is dependent on temperature, food availability, location, and genetic variability (CRWSPF 2013; Golder 2003a, 2005a, 2006a, 2000b), with optimal temperatures at 14°C to 17°C. Sturgeon at this stage prefer the deeper, slower velocity areas (McCabe and Hinton 1991; Miller et al. 1991; Parsley et al. 1992) and depend on the currents to transport them into the rearing areas. For white sturgeon, the larval stage ends once the fish has grown enough to complete development of their fins and scutes. White sturgeon recruitment success through this life stage is correlated with sufficient flows during the spawning to larval growth timeframe. This is considered the juvenile stage, and juvenile sturgeon look like a miniature version of adult sturgeon. Juveniles are most often captured within the thalweg (i.e., deepest portion of the river) and rarely adjacent to the thalweg in shallower water (Parsley et al. 1992). Juveniles transition to a sub-adult life stage where they are not yet sexually mature but can fully access marine environments, and then finally considered adults at the onset of sexual maturity.

Adult sturgeon have a tendency to remain in localized areas for extended periods (Golder Associates Ltd. 2010a; Nelson and McAdam 2012; Nelson et al. 2013a, 2013b; BC Hydro 2016a) and show repeated movements between specific locations (Parsley et al. 2008; Golder Associates Ltd. 2010a; Robichaud 2012; Nelson et al. 2013a). Large-scale movements within basins are usually associated with specific life functions such as feeding, spawning, and overwintering (Apperson and Anders 1990; Brannon and Setter 1992).

While the Columbia River downstream of Bonneville Dam supports a wild and self-sustaining white sturgeon population segment, abundance elsewhere in the Columbia River Basin is limited. The population structure of white sturgeon in the Columbia River Basin has been greatly altered by overfishing and extensive dam construction. The construction of dams has substantially modified sturgeon habitat by reducing quality, suitability, and connectivity (Hildebrand et al. 2016). White sturgeon population segments that reside in reservoirs are cut off from the estuary and ocean by hydroelectric development. These populations are recruitment limited and, in general, less abundant when compared to white sturgeon below Bonneville Dam. Based on marking studies and dam counts, white sturgeon do not typically move freely between impoundments.

***Burbot***

Burbot (*Lota lota*) is the only freshwater member of the cod family. They are a native predatory fish that is well suited to deep water habitats of large, cold rivers and reservoirs. Burbot primarily feed at night and are voracious predators, but opportunistic feeders. They are unique in that they spawn during the winter, over fine gravel, sand, or silt, and sometimes under the ice. In rivers, burbot spawn in low velocity areas in main channels or inside channels behind deposition bars. The semi-buoyant eggs are broadcast over the substrate and may drift, but eventually settle into the substrate. Burbot free embryos or yolk-sac larvae remain on the substrate until they have nearly exhausted their yolk reserves, at which point they enter the water column and become pelagic. Burbot fry feed on zooplankton and small aquatic macroinvertebrates, and as they grow, their diet shifts to include fish.

In the CRSO area, burbot are found in the Kootenai River in northern Idaho and Montana, and in the Columbia River in Washington primarily above Chief Joseph Dam in Rufus Woods Lake and Lake Roosevelt upstream to the U.S.-Canada border. Thanks to intensive restoration efforts by the Kootenai Tribe of Idaho, Idaho Fish and Game (IDFG), and fishery professionals from British Columbia, and Montana, a harvest fishery for Burbot was opened in the Kootenai River basin in Idaho on January 1, 2019. The fishery had been closed since 1992 in response to drastic declines in Burbot abundance. The decision to open the fishery hinged on the empirically derived estimate that restoration targets for the number of adult Burbot in the river (i.e., 17,500 spawning adults) was met in 2019. Furthermore, with continued growth and success of the restoration program, it is estimated that the adult population will further grow in abundance, exceeding original restoration targets in coming years. It is listed as a State of Idaho endangered species (IDAPA 13.01.06) and is considered a species of concern in the State of Montana. Operated by the Kootenai Tribe of Idaho, the Twin Rivers Hatchery opened in 2014 at the confluence of the Moyie and Kootenai Rivers in Idaho to help produce burbot for stocking the Kootenai River in multiple locations in British Columbia, Idaho, and Montana.

Burbot abundance can actually increase following impoundment of reservoirs because of increased larval survival and adult foraging opportunities (Bonar et al. 2000) but can decline downstream of dams. As winter spawners, reservoir burbot populations can be sensitive to drawdowns in winter and early spring.

***Columbia River Redband Rainbow Trout***

Columbia River redband rainbow trout (also known as inland redband trout [*Oncorhynchus mykiss gairdneri*]) are a native subspecies of *O. mykiss*, the same species as steelhead and rainbow trout. Therefore, they can have the same diverse life histories; populations may have individuals that exhibit anadromous, adfluvial, fluvial, and resident behaviors (Interior Redband Conservation Team 2016). Researchers have documented the demographics and reproductive characteristics of both and resident histories for Columbia River redband trout populations (Holecek et al. 2012). Columbia River redband trout are typically a stream-resident fish that have short migration either within the same stream or often into smaller tributaries. In areas not blocked by unpassable barriers, the resident and anadromous life history forms of redband trout and steelhead occur together and are known to interbreed. The species spawns in gravel-bottomed, fast-flowing, well-oxygenated rivers and streams. The maximum life span is typically 6 years, and the average length is 12 to 16 inches (30 to 41 cm). Redband trout feed on aquatic insect larvae, crayfish, zooplankton, fish eggs, and some terrestrial insects that drop into the water (Behnke 1992).

Columbia River redband trout occur in the interior Columbia River Basin from east of the Cascades upstream to geologic barriers such as Shoshone Falls on the Snake River (Behnke 2002). Redband occur above Kootenai Falls in Montana and naturally reproducing, genetically pure populations still exist in the Kootenai River downstream of Libby Dam in Callahan Creek, East Fork Yaak River, and tributaries of the Fisher River. Lake Roosevelt and tributaries to the Columbia River that flow into the lake support numerous populations of Redband trout with diverse life history strategies. Redband trout are the most widely distributed native salmonid in the Columbia River Basin (Thurow et al. 2007). They are likely to encounter dams in the interior Columbia River Basin; in some areas, populations have become isolated and have developed alternative life history strategies (e.g., rearing in reservoirs instead of in a stream or river) (Thurow et al. 2007; Holecek and Scarnecchia 2013).

#### *Westslope Cutthroat Trout*

Westslope cutthroat trout (*Oncorhynchus clarkii lewisi*) are native trout that are a genetically distinct subspecies of *O. clarki.* They exhibit multiple life history forms, including adfluvial, fluvial, and resident. They typically spawn in tributary streams in spring when water temperature is about 10°C and flows are high with spring run-off (Committee on the Status of Endangered Wildlife in Canada 2016a). Westslope cutthroat trout have specific habitat requirements during various life history stages necessary to maintain populations. These requirements include cold, clean, well-oxygenated water; clean, well-sorted gravels with minimal fine sediments for successful spawning; temperatures below 21°C; and a complex instream habitat structure such as undercut banks, pool-riffle habitat, and riparian vegetation (Committee on the Status of Endangered Wildlife in Canada 2016a). The average length of westslope cutthroat trout is 8 to 12 inches (20 to 30 cm). They mature within 4 to 6 years and may live as long as 12 years. Westslope cutthroat trout spawn between March and July. Their diet is primarily aquatic invertebrates, with larger trout occasionally preying on other fish (Committee on the Status of Endangered Wildlife in Canada 2016a). The species can produce offspring with non-native rainbow trout or their hybrid progeny and descendants (USFWS 2003).

Westslope cutthroat trout occur in the upper Kootenai River and the Clearwater and Salmon River Basins (McIntyre and Reiman 1995). They were common upstream of Libby Dam after impoundment, but are now uncommon because of dam operation, adverse interactions with non-native fish species, and habitat modifications. Flow fluctuations or low nutrient levels have impacted aquatic insects, a key prey item, in the Kootenai River (Corps 2006). Lake Roosevelt and its tributaries support fluvial, fluvial-adfluvial, and lacustrine-adfluvial life history types.

#### *Northern Pikeminnow*

Northern pikeminnow (pikeminnow; *Ptychocheilus oregonensis*) is a native, resident, freshwater fish that occurs throughout the Pacific Northwest, United States, and British Columbia, Canada (Gadomski et al. 2001; Froese and Pauly 2018). Northern pikeminnow is a member of the Cyprinidae family, which includes minnows and carps (Gadomski et al. 2001; Froese and Pauly 2018). This fish species prefers slow water in lakes and rivers. In as little as three years, pikeminnow can reach full maturity (Lower Columbia Fish Recovery Board 2004b), with a maximum size of 600 mm, 2.5 kg mass, and they can live up to age 16 below Bonneville as well as in the Columbia and Snake reservoirs (Rieman and Beamesderfer 1990; Parker et al. 1995). Spawning occurs primarily when temperatures rapidly rise from 14°C to 18°C (June and July) (Gadomski et al. 2001). Gadomski et al. (2001) found most pikeminnow spawn on dam tailraces rather than elsewhere in the reservoirs. Both larval and juvenile pikeminnow rear along the shoreline where water velocities are low (Gadomski et al. 2001). Poe et al. (1991) found smaller Northern pikeminnow consumed primarily invertebrates, which increased with increasing size. Fish above 375 mm fork length ate more salmonids than invertebrates and other fishes combined (based on percent weight). Salmonids composed 21 percent of diet at 300 mm FL and up to 83 percent of diet of larger fish (475 mm) (Vigg et al. 1992, as cited in Beamsderfer et al. 1996) Juvenile pikeminnow feed primarily on invertebrates and become piscivorous around 2 years of age (Fritts and Pearsons 2006; Martinez Garcia 2014). Smaller pikeminnow, less than 12 inches (30 cm) long, eat chiefly invertebrates, while larger pikeminnow prefer smaller fish such as salmon, sculpins, trout, perch, and suckers (Lower Columbia Fish Recovery Board 2004b). According to Beamesderfer, Ward, and Nigro (1996), pikeminnow prey exponentially more on juvenile salmon as pikeminnow increase in size.

Pikeminnow are important in the Columbia River region as a piscivorous predator of outmigrating salmon smolts. Because of this predation on salmon and steelhead smolts, pikeminnow are harvested as part of Bonneville's pikeminnow reward program. Pikeminnow thrive in the Columbia River Basin primarily because of their ability to adapt to changing water depths, flows, and temperature levels; and because pikeminnow consume a diversity of prey species (Lower Columbia Fish Recovery Board 2004b). Northern Pikeminnow prefer temperatures 16-22°C but are often found in warmer waters (Brown and Moyle 1981). Reservoirs associated with dams provide warm water and low current areas that benefit pikeminnow (Martinez Garcia 2014). Salmon and pikeminnow are both native to the basin, but changes in the system to more reservoir environments favor pikeminnow production and by increasing the metabolism of these predators, resulting in higher than natural predation rates. Because of high predation rates on juvenile salmon, pikeminnow have been targeted for control since 1990 through gillnetting and sport-reward fisheries (ODFW 2018b). These programs have been successful at removing the larger pikeminnow that predate on juvenile salmon.

***Mountain Whitefish***

Mountain whitefish (*Prosopium williamsoni*) is a native member of the Salmonidae family and is not an ESA-listed or state-listed species. Mountain whitefish inhabit lakes and large rivers and medium to large cold mountain streams. As a generalized life history, mountain whitefish spawn from October through December in stream riffles or on gravel shoals in lakes (Wydoski and Whitney 2003). Eggs are broadcast into the water column and are distributed throughout a variety of locations and depths depending on river flow conditions during spawning. Hatching of the eggs is assumed to start in January and potentially extend until May. Juveniles feed primarily on aquatic insect larvae in flowing reaches with a cobble gravel substrate, such as the Hanford Reach of the Columbia River (Wydoski and Whitney 2003). Older juveniles and adults primarily use deep, fast-moving water over gravel and cobble substrates. Mountain whitefish may live to 17 years and grow to maximum sizes of 10 to 23 inches (23.4 to 58 cm) (Scott and Crossman 1998).

Mountain whitefish occur throughout the Columbia River Basin but are rare in the impounded sections of the Columbia and Snake Rivers. An unknown proportion of mountain whitefish in the lower, middle, and upper sections of the lower Columbia River undertake long migrations to spawning areas in other sections of the river (BC Hydro 2014). Mountain whitefish in southern Idaho disproportionately use larger streams (wider than 49 feet [15 m]) in the Snake River Basin compared to more northerly locations, where they are more common in smaller streams (Meyer, Elle, and Lamansky 2009). Fish collection at Lower Monumental, Little Goose, and Lower Granite Dams from 2012 to 2017 generally resulted in increases in mountain whitefish catch during this 6-year period, although fewer fish were caught in 2016 and the increases did not occur every year. Whitefish contribute to recreational fisheries throughout the region.

***Other Native Fish Species***

A variety of native minnow, sculpins, and sucker species contribute ecologically to the fish communities in the study area. Native minnows and sculpins tend to be small and are important prey items for many native or recreationally important key predator species. Suckers typically grow larger and feed on aquatic insects or algae, but juveniles and adults provide a key food source for piscivorous fish, birds, and mammals.

Native minnow species (Cyprinidae family) occur in freshwater streams, lakes, and small- to medium-sized rivers in the Columbia River Basin. Minnows occur in shallow waters, around inshore areas of lakes (peamouths, longnose dace, leopard dace, redside shiner, tui chub, chiselmouth, and young Northern pikeminnow), the slow parts of small- to medium-sized rivers (peamouths, longnose dace, speckled dace, leopard dace, Oregon chub, tui chub, and redside shiner), swiftly flowing creeks (Umatilla dace, longnose dace, and chiselmouth), and in riffles (speckled dace) (International Union for Conservation of Nature 2013). As a generalized life history, minnows spawn at 1 or 2 years of age, with peak spawning occurring in late spring and summer. Most of the species prey on small organisms (zooplankton) or are insectivorous for all or a portion of their life cycles. Trout-perch (also known as sandroller) is another small fish species endemic to small to large rivers in the basin with similar requirements.

Sculpins (Cottidae family) are smaller, bottom-dwelling fish in the family Cottidae. Sculpins occur in cold freshwater streams, lakes, and rivers and are widely distributed in the Columbia River Basin. Most of these species inhabit medium- or larger-sized streams with moderate to rapid current, although some species prefer slow-moving parts of streams, rivers, or lake habitats. Sculpins have been found in springs (mottled and slimy sculpins), lakes (Paiute and prickly sculpins), stream pools (margined and reticulate sculpins), small rivers (shorthead, Paiute, prickly, torrent, and reticulate sculpins), medium-sized rivers (shorthead, Paiute, prickly, torrent, and coastrange sculpins), and large rivers (shorthead, torrent, Columbia, and coastrange sculpins). The coastrange and prickly sculpins occasionally enter estuaries, while slimy sculpin have been found in brackish water. As a generalized life history, sculpins spawn at 1 or 2 years of age, with peak spawning occurring between March and May. Juvenile sculpins initially feed on plankton during their pelagic life stage, transitioning to aquatic insects after moving to stream or lake bottoms where they spend the majority of their life cycles.

Suckers (Catostomidae family) within the Columbia River Basin include largemouth sucker (also known as the largescale sucker), bridgelip sucker, longnose sucker, and mountain sucker. None of these four species are ESA-listed or state-listed. They inhabit a variety of habitats such as pools and runs of large rivers and lakes (largemouth sucker); lake margins and backwaters as well as rocky riffles and runs of small rivers (bridgelip sucker); cold, clear deep waters of lakes and tributary streams (longnose sucker); and rocky riffles and runs of clear mountain creeks (mountain sucker). These species typically feed on algae, diatoms, insects, amphipods, mollusks, and may feed on salmon eggs. Young suckers may by preyed upon by some salmon species (Scott and Crossman 1998).

**Key Non-Native Fish Species**

A non-native or nonindigenous species is a species "not native to a particular area, or found living outside of historical range" (USGS 2018b). A non-native species can be benign, or it can be invasive and potentially harmful. Many non-native species in the Columbia River serve as recreational resources but can cause impacts to native fish through competition and predation. An invasive species is non-native to the ecosystem and is likely to cause economic or environmental harm or harm to human health. Invasive species are capable of causing extinctions of native plants and animals, reducing biodiversity, competing with native organisms for limited resources, and altering habitats.

***Non-Native Salmon and Trout***

Non-native resident salmon and trout present in the Columbia River Basin include Arctic grayling (*Thymallus arcticus*), Atlantic salmon (*Salmo salar*), brook trout (*Salvelinus fontinalis*), brown trout (*Salmo trutta*), golden trout (*O. aguabonita*), lake trout (*Salvelinus namaycush*), lake whitefish (*Coregonus clupeaformis*), and tiger trout (a hybrid of brook and brown trout)

(Novak 2014; Froese and Pauly 2018; USGS 2018a). Introduced resident salmon and trout can have a variety of effects on native endangered salmon and trout, including hybridizing (Seiler and Keeley 2009; Dehaan Schwabe, and Arden 2010; Kanda, Leary, and Allendorf 2011), predating on native fish (Levin et al. 2002; McHugh and Budy 2006; Schoen, Beauchamp, and Overman 2012), competing for food and habitat with native fish (McHugh and Budy 2006; Seiler and Keeley 2009), and introducing parasites and diseases (Krueger and May 1991; Burrill 2014).

Some native and non-native trout species are stocked annually in lakes where they would not naturally occur within all watersheds of the Columbia River Basin including the Clearwater, Kootenai, and Salmon River watersheds (USGS 2018a). Hybridization between cutthroat (*O. clarkii*) and rainbow (*O. mykiss*) trout has been documented in drainages throughout Idaho (Kozfkay et al. 2011). Much of this is unnatural due to past stocking of fertile hatchery rainbow trout (Weigel et al. 2003, Campbell et al. 2002), and much more limited stocking of fertile cutthroat trout (Neville and Dunham 2011) in areas where the two species are not naturally sympatric. Some hybridization also occurs naturally between sympatric populations of cutthroat trout and rainbow trout (Kozfkay et al. 2007). Most of the research in Idaho suggests that although hybrids have been detected in many drainages, hybridization and introgression levels are often low, with few hybrid swarms documented (Meyer et al. 2006; McKelvey et al. 2015). These results have been explained by strong assortative mating observed between rainbow trout and cutthroat trout and the reduced fitness of hybrids (Henderson et al. 2000; Gunnell et al. 2008; Kozfkay et al. 2007; Walters 2006; Young et al. 2003). These hybrids are established in Lake Pend Oreille and the lower Columbia, Clearwater, and Snake Rivers and are stocked annually in lakes within several watersheds including the Clearwater River (USGS 2018a). In some locations, sterile hybrid trout are stocked to provide recreational fishing opportunities without substantially altering the established fish communities. The status of brown trout is unknown (USGS 2018a). Atlantic salmon, brook trout, lake trout, and lake whitefish were introduced from eastern North America (Novak 2014; USGS 2018a). Brown trout were introduced from Europe and Asia, and golden trout were introduced from California (USGS 2018a).

#### *Other Non-Native Gamefish*

Many species of non-native warm water fish in the Columbia River Basin were introduced as recreational game species where they thrive primarily because of habitat modification and the creation of slow-moving water, reservoirs, and warm water habitat. Smallmouth bass, largemouth bass, sunfishes, perch, pike, walleye, and catfish provide recreational resources but have become invasive and compete with or cause predation issues for native fish.

Smallmouth bass and largemouth bass (sunfish; Centrarchid family) were introduced from eastern North America in the 1920s (Sanderson et al. 2009; Carey et al. 2011; Fuller, Cannister, and Neilson 2018). They are aggressive, predatory fish that feed on amphibians, fish, birds, and small mammals. Invertebrates constitute a large part of smallmouth bass diet, particularly crayfish and other crustaceans (Poe et al. 1991). Preferred spawning habitat for both species includes slow-water areas of lakes, rivers, or streams in water less than 18 to 20 feet deep.

Once eggs hatch, optimal juvenile fish growth is associated with water temperatures between 26°C and 29°C (Wile 2014). Juvenile bass become piscivorous around 2 years old at approximately 100-150mm in length (Fritts and Pearsons 2006) and live long life spans. Bass are now established and breeding throughout the Columbia River Basin, and they continue to be stocked in some locations (Sanderson et al. 2009; USGS 2018a). Carey et al. (2011) note several studies that predict the expansion of suitable habitat for bass with warming temperatures, which could facilitate an increase in bass populations.

Other non-native sunfish present in the Columbia and Snake Rivers include black crappie, bluegill, pumpkinseed, rock bass, striped bass, warmouth, and white crappie (Froese and Pauly 2018; USGS 2018a). Sunfish occur in streams, lakes, and reservoirs (Froese and Pauly 2018). Black crappie, striped bass, and white crappie prey on juvenile salmon and native resident fish as adults and compete with native fish for invertebrates, zooplankton and small fish as juveniles (Riso 2011; Froese and Pauly 2018; USGS 2018a). Pumpkinseed, rock bass, warmouth, spotted bass, and bluegill compete with native fish by preying on invertebrates and small prey fish (Spurr 2008; West 2009; Arterburn 2014; Park 2014; Froese and Pauly 2018). As a family, sunfish in the Columbia River Basin can tolerate a wide range of water temperatures 0°C to 32°C (Froese and Pauly 2018).

Walleye (*Sander vitreus*) is a member of the perch family that was introduced to the Pacific Northwest in the mid-1900s from eastern North America (Sanderson et al. 2009; Froese and Pauly 2018). Carp, suckers, and sculpins appear to be more important in walleye diets than juvenile salmon (Zimmerman 1999); however, the walleye population in the Columbia River can consume as many as 2 million juvenile salmon per year (Rieman et al. 1991; Sanderson et al. 2009). Poe et al. (1991) found juvenile salmonids were the most important prey (27-60 percent of diet) for walleye less than 300 mm fork length but were frequently of secondary importance for larger walleye (350mm +). Fish composed nearly 100 percent of walleye diet in The Dalles and John Day reservoirs (Williams et al. 2019), and salmonid prey items had the greatest frequency of occurrence in walleye diets than any other prey fish family. Walleye can reach a maximum size of 42 inches long and 24 pounds (107 cm long and 10.9 kg), with a maximum age of 29 years (Wydosky and Whitney 2003). According to Caisman (2011), walleye spawn in spring when the water temperature warms to 3.9°C over a variety of benthic habitats less than 10 feet (3 m) deep. Walleye mature between 2 and 6 years depending on water temperature and their density in the waterbody (Lower Columbia Fish Recovery Board 2004a; Schueller et al. 2005; Caisman 2011). Juvenile walleye initially feed on zooplankton and then switch to benthic macroinvertebrates prior to becoming piscivorous (Caisman 2011). Juvenile walleye are found near the surface while adult walleye prefer deeper water (Lower Columbia Fish Recovery Board 2004a) and have diurnal movements, using deep habitats during the day and shallow habitats at night for feeding (Wydoski and Whitney 2003). Juvenile walleye survival may be limited by changes in water flows. Increased flows can transport juvenile walleye or their prey to less advantageous areas (Lower Columbia Fish Recovery Board 2004a).

Historically, walleye were introduced to Lake Roosevelt and have since dispersed throughout the Columbia River Basin (Caisman 2011) and are established and breeding; suppression efforts by WDFW and the UCUT tribes are aimed at keeping northern pike from becoming widely established in Lake Roosevelt. According to Sanderson et al. (2009), anglers in the Columbia River Basin have caught some of the largest walleye ever recorded at 19 pounds (8.6 kg) in Oregon (ODFW 2018c) and 20 pounds (9.1 kg) in Washington (WDFW 2018). Reservoirs associated with dams provide warm water, low currents for juvenile walleye, and deep pools that benefit adult walleye (Lower Columbia Fish Recovery Board 2004a).

Yellow perch (*Perca flavescens*), introduced from eastern North America in the late 1800s for fishing and sport fish bait (Harmon 2011), are another perch species well-suited to the reservoir conditions present in the basin. Yellow perch can tolerate a wide range of water temperatures 0°C to 30°C (Froese and Pauly 2018). Juvenile yellow perch prey include macroinvertebrates and zooplankton (Froese and Pauly 2018), which reduces prey availability for native fish (Hughes and Herlihy 2012). Once yellow perch reach three years old, they begin to prey on fish as well, including juvenile salmon (Dephilip and Berg 1993; Sanderson et al. 2009).

Four non-native pike species (Esociformes order) occur in the Columbia River Basin. Central mudminnow, northern pike, grass pickerel, and tiger muskie were introduced from eastern North America (Froese and Pauly 2018; USGS 2018a). Tiger muskies, a hybrid between northern pike and muskellunge, are stocked in lakes within the Columbia River Basin (USGS 2018a). Northern pike and grass pickerel are established and breeding in the Columbia River above Grand Coulee Dam, and grass pickerel are established and breeding in the lower Snake River (USGS 2018a).

Northern pike (pike; *Esox lucius*) are resident, freshwater fish that inhabit ponds, slow-moving lakes, and rivers. In the Columbia Basin, they are an invasive species. Pike prefer water temperatures from 10°C to 28°C (Froese and Pauly 2018) and shallow water with benthic vegetation to better ambush their prey (Hennessey 2011). Pike are well-known ambush predators that feed on native fish species and macroinvertebrates (Craig 2008; McMahon and Bennett 1996). Sepulveda et al. (2013) found that juvenile salmon dominated northern pike diet when salmon were present; but pike selected other resident fish for consumption when salmon were not available, thereby impacting both salmon and resident fish. Because of the strong appetite and prolific spawning capabilities of pike, fisheries managers in Washington are concerned that, if pike spread from their current range above Grand Coulee Dam into the Columbia and Snake Rivers below Grand Coulee, they will further endanger ESA-listed salmon (WDFW 2018g). Because of the concern for resident fish, pike are classified as a prohibited species in Washington (WDFW 2018b); however, pike are listed as a gamefish in Idaho and Montana (Idaho Department of Fish and Game [IDFG] 2013; FishMT 2018). Multiple pike suppression efforts are underway with multiagency funding and support, such as “Northern Pike Suppression and Monitoring,” the joint project between the Confederated Tribes of the Colville Reservation, Spokane Tribe of Indians, and WDFW. Additionally, the Columbia River Inter-Tribal Fish Commission encourages tribal fishers to kill any pike and tiger muskie between Bonneville Dam and McNary Dam to document species presence in the Columbia River (CRITFC 2018b).

Non-native catfish (Ictaluridae family) occur in the Columbia River Basin and include black bullhead, channel catfish, brown bullhead, flathead catfish, tadpole madtom, and yellow bullhead. The four species were introduced from eastern North America (Froese and Pauly 2018; USGS 2018a). Brown bullhead and channel catfish are abundant and reproducing naturally (WDFW 2018f, 2018g). Black bullhead, flathead catfish, and yellow bullhead are less common, but present (WDFW 2018e, 2018i; USGS 2018a), while there is little information on tadpole madtom and blue catfish populations.

Catfish are resident, freshwater fish that live primarily near the bottom of slow-moving lakes and rivers. As a family, catfish can tolerate a wide range of water 0°C to 37°C and water conditions (Froese and Pauly 2018). With the exception of the tadpole madtom, of which little is known, all species are predators of native fish and may reduce native fish and invertebrate diversity and abundance (Hughes and Herlihy 2012; USGS 2018a). Hughes and Herlihy (2012) noted that on rivers where non-native species were frequently caught, some historically present native fish were missing or caught in lower numbers than expected. Channel Catfish were considered in the original Northern Pikeminnow Management Program (NPMP) studies but ultimately excluded because, per capita, they constitute a relatively low predation burden (Poe et al. 1991). Almost all channel catfish predation on juvenile salmonids, characterized in earlier studies, occurred in tailrace areas and was confined to spring season, likely due to distribution of channel catfish, which appear to congregate in the upper part of JDA in the spring.

***Other Non-Native Fish***

Non-native minnow species include common carp, fathead minnow, goldfish, grass carp, and tench (Froese and Pauly 2018; USGS 2018a). Minnows are resident, freshwater fish in slow-moving lakes and rivers with dense aquatic vegetation. As a family, minnows can tolerate a wide range of water temperatures 0°C to 38°C and water conditions including low oxygen and high turbidity (Froese and Pauly 2018). Non-native minnows feed on zooplankton, macroinvertebrates, and aquatic vegetation (USGS 2018a). Kaemingk et al. (2016) found common carp affects native resident fish species by increasing turbidity when it uproots benthic vegetation while feeding and competes for invertebrate prey. Other minnow species also increase turbidity and decrease aquatic vegetation when feeding on benthic vegetation (USGS 2018a). Fathead minnow competes with native fish for habitat and food and is a prohibited species in Washington (Holzman 2014; WDFW 2018d).

Other non-native small fish include brook stickleback (*Culaea inconstans*), banded killifish (*Fundulus diaphanus*), mosquitofish (*Gambusia affinis*), and goby. These fish have been introduced into the system through transportation of bait, intentional introductions, or accidental introductions via ballast water or aquarium trade. These are all small, typically less than 4 inches (10 cm) long and typically feed on algae, eggs, larvae, and invertebrates. They provide prey items for piscivorous predators, but also may contribute to the decline of native species via competition and predation of eggs.

## REGIONAL RESIDENT FISH COMMUNITIES

This section describes the regional resident fish communities in the Columbia River Basin. The Basin has been divided into regions based on similar features such as lakes, rivers, streams, what resources are present, and how they are managed. Resident fish communities can vary by region because of limited distributions, passage barriers, specialized habitat requirements, unique life histories, or area of introduction for non-native species. As a result, resident fish communities are managed on a localized scale as compared to anadromous species. The previous sections described the life history and requirements for each species, whereas this section discusses effects to fish communities in each of these regions. The regions are discussed beginning with the uppermost area of the waterbodies affected by CRS projects and follows the water downstream to the mouth and estuary of the Columbia River.

### Region A

#### ***Kootenai River (Lake Koocanusa to U.S.-Canada Border) Region***

Lake Koocanusa is a reservoir formed by Libby Dam on the Kootenai(y) River (Figure 3-127). It is a long reservoir (about 90 miles [145 km] long) with about half in Montana and half in British Columba. Downstream from Libby Dam, the Kootenai(y) River passes over Kootenai Falls 9 miles west of the town of Libby, Montana. The river flows northwesterly through Troy, Montana, and Bonners Ferry, Idaho, eventually turning north and meandering north to cross the border back into British Columbia.

**Figure 3-127. Study Area for Kootenai River (Lake Koocanusa to U.S.-Canada Border) Region**

Bull Trout

In the Kootenai River drainage, three distinct populations of bull trout exist: one downstream of Kootenai Falls, one between the falls and Libby Dam, and one upstream of Libby Dam.

Upstream of Libby Dam, Lake Koocanusa is one of the most secure and stable bull trout refugia across the range of the species, though most of the spawning and rearing habitat is in British Columbia (USFWS 2010). Adfluvial bull trout, originating from fluvial stocks in the Kootenai River that were trapped upstream of Libby Dam, are the only bull trout life history form present in the lake. Canadian headwaters (Kootenay River tributaries and Wigwam River) are believed to support the strongest populations (Marotz et al. 2001). Bull trout in Canada are not subject to protections under the U.S. ESA. The strongest U.S. population upstream of Libby Dam is in Grave Creek (including Clarence and Blue Sky Creeks) in the Tobacco River drainage with 94 to 245 redds per year counted between 1999 and 2008 (USFWS 2010).

Below Libby Dam, the bull trout population uses four tributaries upstream of Kootenai Falls, but contains too few individuals and subpopulations to be considered stable. Below Kootenai Falls, bull trout are found in O'Brien Creek, Callahan Creek and in Bull Lake. The latter is a disjunct population that migrates out of Bull Lake, downstream to Lake Creek then upstream in Keeler Creek. These fish inhabit areas in the lower Kootenai River and Kootenay Lake during most of the year.

Kootenai River White Sturgeon

Approximately 8,000 sturgeon are estimated to have been present in the Kootenai River system in the late 1970s (Paragamian, Beamesderfer, and Ireland 2005). The wild sturgeon population declined from approximately 3,000 individuals in 1990 to 990 in 2011 (Beamesderfer et al. 2014a); the current wild population largely consists of an aging generation of large, old fish. The wild population was found to decline most rapidly from 2008 to 2011 because of decreased survival rates (97 percent annual survival prior to 2008 and 85 percent from 2007 to 2011), presumably, because of increased adult age; sturgeon can live more than 80 years. Low levels of natural recruitment continue, based on low sample numbers of juvenile fish; Beamesderfer et al. (2014a) estimated natural recruitment (i.e., offspring from spawning, not from hatcheries) to the wild population of 13 fish per year.

The size and age at which white sturgeon are sexually mature varies, but females are estimated to begin to be mature at 30 years and males at 28 years (Paragamian, Beamesderfer, and Ireland 2005). Kootenai River white sturgeon do not spawn each year; females spawn about every 3 years, while males spawn approximately in alternate years (USFWS 1999). Kootenai River white sturgeon express a unique, two-step spawning pattern, migrating to staging reaches from the lower Kootenai River and Kootenay Lake, and then on to spawning reaches near Bonners Ferry, Idaho, in the spring (Paragamian 2012). The substrate at current spawning sites in the Kootenai River is much finer than the rocky substrate found in successful white sturgeon spawning sites elsewhere in the Columbia River Basin.

Spawning in sandy locations may lower survival if sand or silt covers the embryos (McDonald et al. 2010). It was speculated that prior to the completion of Libby Dam, this area was likely scoured of sand during high river flows that re-sorted river sediments, providing clean cobble substrate conducive to egg incubation (USFWS 1999). Research revealed that Kootenai River white sturgeon are likely spawning in the same locations as pre-dam, but dam operations have reduced velocities and shear stress; therefore, sediment is now covering the cobbles and gravels (Paragamian et al. 2009).

White sturgeon are broadcast spawners, which means females typically release eggs over an area, then males release milt (i.e., sperm) over the eggs to fertilize them (Scott and Crossman 1973; McDonald et al. 2010). Kootenai River white sturgeon spawn when water temperature is 8.5°C to 12°C (McDonald et al. 2010; Paragamian 2012). After fertilization, their eggs adhere to the riverbed and incubate for 8 to 15 days (Brannon et al. 1985). White sturgeon remain attached to the yolk after hatching, and they begin to forage as “free embryos” until the yolk is depleted after about 7 to 11 days (USFWS 2006). At this time, the larval white sturgeon are distributed by the currents and the juveniles and adults rear in the Kootenai River and in Kootenay Lake (USFWS 2006).

The Kootenai Tribe’s sturgeon aquaculture program, funded by Bonneville, was established in 1988 to prevent extinction, preserve the gene pool, and continue rebuilding a healthy age class structure for this endangered population using conservation aquaculture techniques with wild native broodstock (Kootenai Tribe of Idaho [KTOI] 2012). The wild population of white sturgeon has been augmented with the release of juvenile white sturgeon reared at the tribal hatcheries (USFWS 1999). Fish releases continue pursuant to the Kootenai Tribe of Idaho’s USFWS Section 10 permit. Annual releases have ranged from 3,000 to 37,000 fish per year from 2003 to 2013 and with an average annual release of 20,000 fish; from 2008 to 2013, releases have averaged 18,000 fish (Bonneville 2013).

<u>Fish Communities</u>

*Lake Koocanusa (Libby Reservoir)* – The reservoir supports an important fishery for kokanee and rainbow trout. Burbot are another important gamefish, but their population level has become severely suppressed, and can no longer provide a fishery. Bull trout serve as an intermittent (not every year) sport fishery under Section 4(d) of the ESA; when redd counts meet or exceed established criteria, a limited entry sport fishery is open on the reservoir the following year (subject to Montana fishing regulations), with anglers allowed to keep one bull trout per year. Several warm water species such as largemouth bass, pumpkinseed, and yellow perch inhabit the reservoir but are present only in low numbers compared to other locations where their populations cause problems for native species. The Gerrard strain of rainbow trout, native to Kootenay Lake in British Columbia, is cultured at Murray Springs Fish Hatchery by MFWP. This subspecies attains tremendous size by becoming piscivorous (i.e., eats other fish) at age 2 to 3 years, and has been stocked in the reservoir in increasing numbers since 2006. The average number of Gerard rainbow trout that MFWP stocked from 2010 to 2012 was 32,000 fish per year, and the average for 2016 to 2018 was roughly 70,000 per year (MWFP 2018). The objective for Gerrard rainbow trout in the reservoir is to develop a trophy rainbow trout fishery as well as provide a natural predator on kokanee; a reduction in kokanee numbers in the reservoir would likely increase their average size because of less competition for food, and thus improve the fishery according to angler preference for larger fish. Thus far, the population structure of Gerrard rainbow trout in the reservoir has yet to achieve the density required to reduce kokanee densities or to provide growth opportunities for larger, piscivorous individuals.

The upper portion of Koocanusa Reservoir still contains some genetically pure stocks of fluvial and adfluvial westslope cutthroat trout. In the western United States, however, distribution of westslope cutthroat trout has declined dramatically from historical levels over the past 30 years, and they now occupy only about 59 percent of lotic (i.e., flowing) habitats of their former range (Shepard et al. 2005).

*Kootenai River* – The Montana portion of the Kootenai River downstream of Libby Dam supports a relatively stable and abundant recreational trout fishery of non-native rainbow trout that account for about 10 to 15 percent of the total fish assemblage according to electrofishing surveys conducted in 2008 (Gidley 2010). Mountain whitefish are the most abundant fish species in the Montana portion of the Kootenai River, constituting approximately 60 to 70 percent of the total fish assemblage, but are seldom targeted by anglers (MFWP unpublished data; Gidley 2010). Since the construction of Libby Dam, the Idaho portion of the mainstem Kootenai River fish community has shifted from being dominated by whitefish and trout to consisting primarily of suckers, peamouth chub, and northern pikeminnow.

In the present conditions of Kootenai River, the primary habitat factors limiting resident fish include an altered hydrograph and riparian condition, elevated turbidity and fine sediments, reduced connectivity, and an altered thermal regime (Kootenai Tribe and MFWP 2004). Reduced phosphorus loading to the Kootenai River downstream of Libby Dam limits productivity of resident fish in this reach (Kootenai Tribe and MFWP 2004). In response to this limiting factor, the KTOI and the Idaho Department of Fish and Game co-manage the Kootenai River Ecosystem Improvement Project, which includes nutrient restoration and extensive monitoring of baseline conditions and the effects of the nutrient restoration. The goal of this project is a productive, healthy, and biologically diverse Kootenai River ecosystem, with emphasis on native fish species including white sturgeon, burbot, bull trout, and kokanee. Preliminary results suggest the project has substantially increased ecosystem productivity in the nutrient addition zone of the Kootenai River and the South Arm of Kootenay Lake (Holderman 2012).

Burbot had been a valuable sport and commercial fishery in the Kootenai River; however, the fishery collapsed following the construction of Libby Dam. The fishery peaked in the late 1960s with over 25,000 burbot harvested annually, and by 1987, none were harvested (Paragamian et al. 2000). The average abundance estimates for 1997 to 2003 were only 150 to 200 adult burbot in the Kootenai River (Paragamian et al. 2004). However, a burbot restoration program including extensive conservation aquaculture was established in 2014 by KTOI and IDFG, in cooperation with BC. The program is meeting several objectives including the ability to sustain a harvest fishery, which was re-opened in January of 2019. Current abundance was estimated at 20,000 adults in 2019 (Young, S. and R. Hardy. 2019. KTOI and IDFG, Presentation NW Power and Conservation Council). Burbot are listed as a species of special concern in Idaho and Montana.

Native kokanee salmon runs in lower Kootenai River tributaries in Idaho have experienced significant population declines during the past several decades (Paragamian 1994; Ashley et al. 1997). Adult kokanee in tributaries ranged from about 3,800 to 6,600 fish counted per survey in the early 1980s and dropped to fewer than 10 counted per survey in the early 2000s (Ericksen et al. 2009). In the Idaho reach of the Kootenai River, westslope cutthroat trout are not common and provide only a small portion of the salmonid harvest (Paragamian 1994). Native interior redband, a subspecies of rainbow trout and designated a species of special concern in Montana, exist in only a few isolated Kootenai River tributaries (Callahan and Libby Creeks and tributaries to the Yaak and Fisher Rivers). Mountain whitefish abundance has declined in the Idaho reach of the Kootenai River since the early 1980s, despite availability of ideal spawning habitat (Paragamian 1994; Downs 1999). Reduction in productivity of the Kootenai River was identified as the cause for declining mountain whitefish abundance, so liquid phosphate fertilizer has been added to the river since 2005 to increase phosphorus concentrations in the river to pre-dam levels (14,000 to 16,000 fish; Ross et al. 2018). By 2008, the mountain whitefish population rose to over 17,000 fish and exceeded levels documented in 1980; the population then dropped below this target in 2014 and 2016, potentially because the population has reached capacity and has begun to stabilize (Ross et al. 2018).

Preliminary important environmental relationships for resident fish in this region that could be affected by MOs are as follows:

- High and prolonged peak flows and the shape of the freshet are important for Kootenai River white sturgeon spawning. The difference between the winter peak and the spring freshet are also important for riparian community that supports native fish food supply.
- Libby Reservoir temperatures are important to support Kootenai River white sturgeon, bull trout, and other native fish.
- Libby elevation influences discharge temperature in late winter/early spring, with higher elevations resulting in cooler discharge. Warmer water (10°C) is needed for sturgeon spawning.
- Kootenai River temperatures at Bonners Ferry of 8.5° C to 12° C supports sturgeon spawning, and an appropriate progression from 2°C to 14°C from mid-February to mid-April is needed for the biological progression of Kootenai River white sturgeon and burbot physiology.
- Outflow during March through mid-April influences entrainment rates of burbot through Libby Dam, with higher flows resulting in increased entrainment. For kokanee, entrainment rates are influenced by outflow in early spring and mid-summer.
- River elevation at Bonners Ferry affects floodplain connectivity to off-channel habitats for burbot and other native fish.
- Libby Dam discharge in winter should be low, steady flow, and cold temperature for burbot. High and variable flows can interrupt spawning.

- Libby Reservoir elevation during summer months determines productivity of plankton to support forage species. In addition, the minimum Libby elevation in one year influences insect larva production the following year, and the maximum elevation is related to the volume and surface areas and the proximity of the surface to terrestrial insect production, which is also important to bull trout food production. This food web is especially important to bull trout, westslope cutthroat trout, redband rainbow trout, and kokanee.

***Flathead and Clark Fork Rivers from Hungry Horse Reservoir Tributaries to Montana-Idaho Border***

The study area for this region (Figure 3-128) includes from the tributaries to Hungry Horse Reservoir following the flow of water downstream to where the Clark Fork River flows across the Montana-Idaho border. Specifically, starting with tributaries of Hungry Horse Reservoir, water flows through the reservoir, through the dam outlet into South Fork Flathead River, which then flows into the Flathead River near Columbia Falls. The Flathead River flows downstream through the Flathead Lake (a large natural lake), past Seli'š Ksanka Qlispe' Dam (formerly referred to as Kerr Dam) (a non-Federal dam), and joins the Clark Fork River near Paradise, Montana. The Clark Fork River continues through a series of non-federal hydropower projects (Thompson Falls, Noxon Rapids, and Cabinet Gorge). The Cabinet Gorge Reservoir pool is mostly in Montana, with the dam just across the state border in Idaho. This analysis region's downstream extent is the state border.

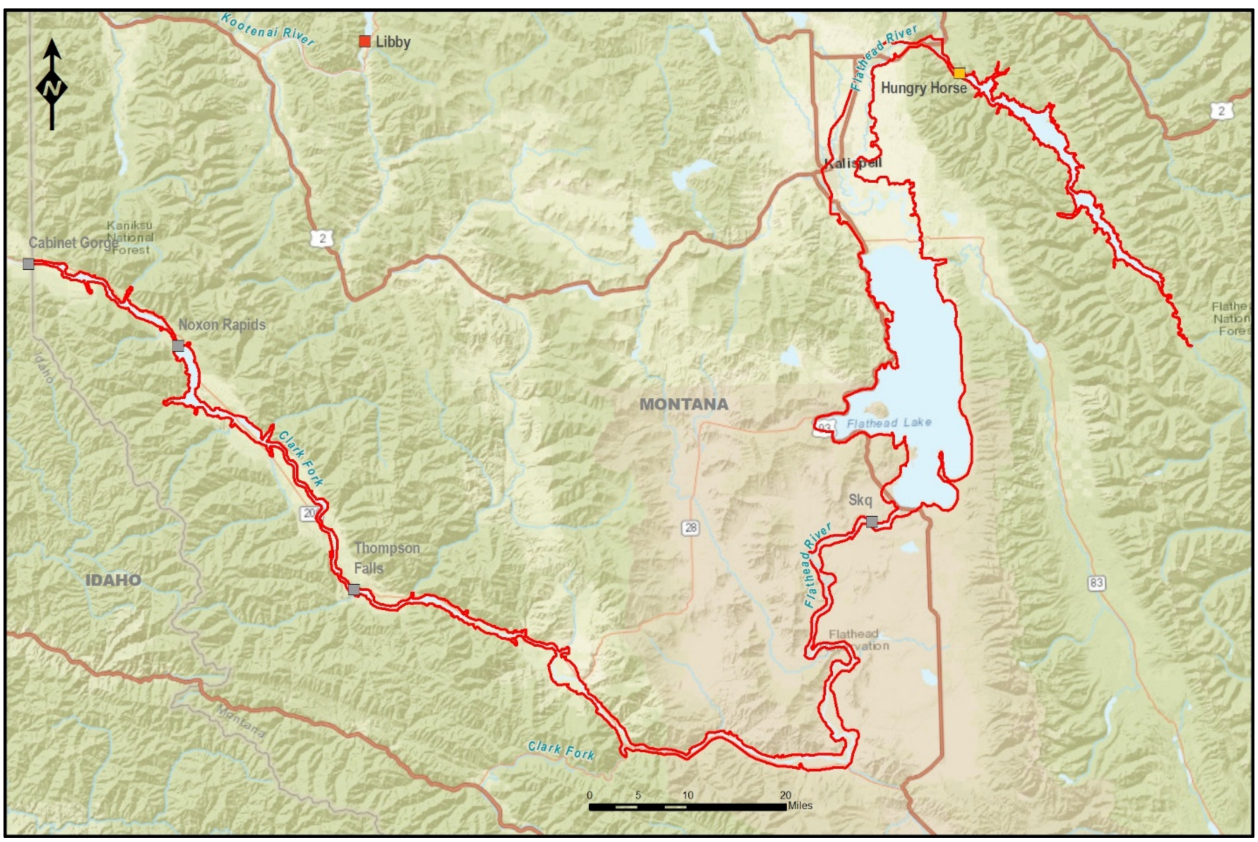

**Figure 3-128. Study Area for the Flathead and Clark Fork Rivers from Hungry Horse Reservoir Tributaries to Montana-Idaho Border**

Bull Trout

Hungry Horse Reservoir contains a substantial population of 2,500 to 10,000 adfluvial bull trout that are stable in number (USFWS 2008a). Hungry Horse is among the most robust and least threatened populations of bull trout in the recovery area (USFWS 2015). The population is strong enough to allow for a limited harvest fishery, ongoing since 2004. These bull trout spawn in the tributaries above Hungry Horse Reservoir and the South Fork Flathead River upstream of the reservoir. Hungry Horse Reservoir is designated critical habitat for bull trout (75 FR 63898). Within this area of bull trout habitat, Hungry Horse Dam operations affect reservoir levels and water temperatures, which influences bull trout habitat and food production.

The South Fork Flathead River below Hungry Horse Dam is only transitional habitat for bull trout as very few from Hungry Horse Reservoir populations are entrained through the dam downstream into this reach. Bull trout from the Flathead River wander into this reach occasionally, but there has been no documentation of spawning by bull trout in this reach. The few juvenile and subadult bull trout may use this transitory habitat more frequently due to improved temperatures after the installation and operation of a selective withdrawal-temperature control device at Hungry Horse Dam. This reach of the South Fork Flathead River is not designated critical habitat for bull trout.

Flathead Lake adfluvial bull trout reside in Flathead Lake and migrate to spawn in tributaries of the North Fork and Middle Fork Flathead Rivers, and occasionally in the South Fork Flathead River. In early summer, adult adfluvial bull trout migrate from Flathead Lake into the river and move toward staging areas. They then move into spawning tributaries in August, and following spawning in September, move rapidly (within several days) back downstream to Flathead Lake (Confederated Salish and Kootenai Tribes [CSKT] and MFWP 2004, as cited in Corps 2006). Fluvial populations of bull trout spawn and rear in Flathead River tributaries and move downstream to mature and reside in the Flathead River (CSKT and MFWP 2004, as cited in Corps 2006). The Flathead River and Flathead Lake are included in designated critical habitat for bull trout (70 FR 56212).

It is assumed that prior to dams being built on the Clark Fork and the lower Flathead River supported the Lake Pend Oreille-Clark Fork River bull trout metapopulation and hosted a considerable migratory component. Today, bull trout exist as relatively isolated populations of likely less than 100 spawning adults in the Jocko River drainage, and bull trout use the Mission Creek drainage only as a migratory corridor (CSKT and MFWP 2004, as cited in Corps 2006). Bull trout found in the lower Flathead River are likely those that were entrained through Seli'š Ksanka Qlispe' Dam (formerly Kerr Dam) or upstream migrants from the Clark Fork River.

Thompson Falls, Noxon Rapids, and Cabinet Gorge Dams have a series of impoundments stretching over 70 miles of the Clark Fork River. These dams were an interruption of bull trout migration and blocked access from portions of the tributary system to the productive waters of Lake Pend Oreille and Flathead Lake. However, substantial effort was made to reconnect these areas. Cabinet Gorge Dam has a trap and haul program that started in 2001, and permanent passage is expected beginning in 2020 or soon thereafter; Thompson Falls Dam had a fish ladder installed in 2010; Noxon Dam has a trap and haul program that started in 2017. The remaining habitat is degraded for bull trout because of water temperature and water quality (USFWS 2002, as cited in Corps 2006).

The expansion of non-native competitive species such as lake trout, northern pike, and brook trout, as well as forestry practices, livestock grazing, agricultural water withdrawals, transportation systems, mining, impoundments, and other development activities have impacted and continue to affect bull trout in the lower Clark Fork River. Since construction of the dams that blocked migration routes, the catch of bull trout during gill net surveys in the reservoirs (between 1960 and 1985) indicates bull trout declined in Noxon Reservoir but remained somewhat stable in Cabinet Gorge Reservoir (USFWS 2002, as cited in Corps 2006).

In the tributaries of the Clark Fork River, spawning and rearing habitats for bull trout remain, but foraging, migrating, and overwintering habitats for migratory adult and subadult bull trout are largely degraded or gone. Over time, the fish expressing the migratory life history pattern (fluvial and adfluvial) of the lower Clark Fork River were largely replaced by bull trout that expressed the resident life form in the tributaries, thus reducing genetic diversity and geographic range (USFWS 2002, as cited in Corps 2006).

Fish Communities

*Hungry Horse Reservoir* – Hungry Horse Reservoir contains primarily native fish species, including westslope cutthroat trout, mountain whitefish, and bull trout. Hungry Horse Dam has helped isolate the native fish populations in most of the South Fork Flathead River drainage from non-native species (such as lake trout), which occur downstream from the dam. Consequently, the reservoir's population of westslope cutthroat trout is one of the most secure metapopulations in existence compared to other reservoirs that have a higher number of introduced species that are competitors or predators (Shepard et al. 2003). Non-game species include northern pikeminnow, largescale and longnose suckers, and sculpins.

MFWP does not artificially stock the reservoir, and fish populations are maintained solely through natural spawning and rearing. Westslope cutthroat and bull trout are the most important game fish species. When sexually mature, these fish migrate to and spawn in the tributary streams that feed the reservoir, including the South Fork Flathead River upstream of Hungry Horse Reservoir and its tributaries. Juvenile fish typically rear in these streams for 3 years before they migrate downstream to the reservoir where they grow to maturity. Beginning in 2004, an experimental bull trout season was initiated that allowed limited (two per year) angler harvest of bull trout from Hungry Horse Reservoir (CSKT and MFWP 2004).

*South Fork Flathead River* – Most of the fish species in the South Fork Flathead River below Hungry Horse Dam and the mainstem Flathead River spend a large portion of their life in Flathead Lake. Native game fish species in the South Fork River and the mainstem Flathead River include mountain whitefish, westslope cutthroat trout, and bull trout. Non-native species include lake trout, rainbow trout, lake whitefish, and kokanee.

Since 1995, with operation of the selective withdrawal system and VarQ, releases from the dam follow a more natural thermal regime approximating conditions in the unregulated reach of the Flathead River. The observed trend is increasing numbers of native trout, no lake trout, and very few brook trout, increasing numbers of bull trout and very high numbers of westslope cutthroat trout. MFWP (personal communication, Brian Marotz 2015) indicated mountain whitefish numbers have increased since operation of the selective withdrawal system.

Hybridization between rainbow and westslope cutthroat trout is prevalent in the upper Flathead River. Hybridization, competition, and loss of habitat have contributed to declines of westslope cutthroat trout, but they are still widely distributed in tributary streams. Westslope cutthroat trout and bull trout grow to sexual maturity in Flathead Lake and migrate up the Flathead River to spawn and rear in tributaries. Juvenile cutthroat trout and bull trout leave rearing streams in early summer and remain in the reach throughout summer and fall as they move downstream to Flathead Lake. Fluvial populations of cutthroat trout spawn in tributaries but mature in the mainstem Flathead River without spending time in Flathead Lake.

*Flathead Lake* – Flathead Lake is colder and less productive but with better water quality compared to most large lakes in the world (CSKT and MWFP 2004, as cited in Corps 2006). The lake supports native bull trout, westslope cutthroat trout, mountain whitefish, largescale and longnose suckers, northern pikeminnow, peamouth chub, redside shiner, and longnose dace. At least 11 non-native fish species have been introduced (legally or illegally) into the system since the late nineteenth century. Historically, bull trout and westslope cutthroat trout were the dominant piscivorous fishes in Flathead Lake. The introduction of non-native fish, coupled with the introduction of the non-native opossum shrimp (*Mysis relicta*) in Flathead Lake, has caused widespread changes in the lake's food web and ecosystem (CSKT and MFWP 2004, as cited in Corps 2006). Lake trout and northern pike are now the dominant predator fish species in the lake (CSKT and MFWP 2004, as cited in Corps 2006). Kokanee, once the dominant fish of Flathead Lake with more than 100,000 spawners in the 1980s, have nearly disappeared such that no fishery is possible. Westslope cutthroat trout and bull trout populations have declined as well.

Lake trout (*Salvelinus namaycush*) were introduced in 1905 and are now a primary factor in reduction of the native salmonid populations in Flathead Lake. The total population grew from about 2,000 lake trout in 1999 to about 36,000 in 2005 (Hansen et al. 2008); the population is most recently estimated at nearly 800,000 fish (Hansen, Hansen, and Beauchamp 2016). Recreational fisheries and lake trout removal by the CSKT are controlling the population, but an increased fishing effort is needed to enable bull trout recovery (Hansen, Hansen, and Beauchamp 2016). Other abundant non-native fish species found in Flathead Lake include lake whitefish, brook trout, and yellow perch.

*Lower Flathead River* – Downstream from Flathead Lake, in the lower Flathead River, prominent fish species include mountain whitefish, brown trout, rainbow trout, northern pike, largemouth bass, cutthroat trout, and northern pikeminnow. Introduced species have affected native species, such as bull trout. Historical operations of Seli'š Ksanka Qlispe' Dam inundated vegetated areas and changed shoreline areas to mud and rock (CSKT and MFWP 2004, as cited in Corps 2006). However, new minimum flows established by Federal Energy Regulatory Commission (FERC) relicensing in 1995 have had resulted in stabilized water releases that more closely approximate the natural flow regime (CSKT and MFWP 2004, as cited in Corps 2006). These changes are expected to substantially improve habitat conditions for aquatic species on the lower Flathead River (CSKT and MFWP 2004, as cited in Corps 2006).

*Clark Fork River* – The Clark Fork between Lake Pend Oreille and the Flathead River hosts 29 fish species. The most common fish are sunfish, yellow perch, northern pikeminnow, shiners, suckers, and bass (FERC 2000). Salmonid populations in the reservoirs are relatively small yet self-sustaining and consist primarily of westslope cutthroat trout, rainbow trout, brown trout, brook trout, bull trout, lake whitefish, and mountain whitefish. The section of the Clark Fork River from the confluence with the Flathead River downstream at RM 245 passes through several run-of-river hydroelectric dams at Thompson Falls, Noxon Rapids, and Cabinet Gorge before flowing into Lake Pend Oreille. Noxon Rapids and Cabinet Gorge Dams were previously barriers to upstream fish movement at all times of the year, but more recently have had trap and haul programs. As a result, they have isolated fish populations, selecting against migratory life histories for westslope cutthroat trout (FERC 2000, as cited in Corps 2006).

The Cabinet Gorge and Noxon Reservoirs are long (10 to 35 miles [16 to 56 km]) and experience water temperatures that range up to 24°C during the warmest part of the summer. Because of this, warm and cool water species such as largemouth and smallmouth bass thrive and cold water fisheries are not present (FERC 2000, as cited in Corps 2006). These projects now support productive bass fisheries. Attempts at establishing a cold water fishery on the Cabinet Gorge and Noxon Reservoirs were unsuccessful even with stocking efforts (FERC 2000, as cited in Corps 2006).

Preliminary important environmental relationships for resident fish in this region that could be affected by MOs are as follows:

- Hungry Horse Reservoir elevations affect primary productivity and zooplankton production important to the fish community, including those that provide the food source for bull trout. Higher lake elevations in the warm summer months provide better conditions, and the maximum elevation draft in a given year affects insect larvae production the following year with deeper maximum drafts resulting in less food supply. The rate of Hungry Horse drawdown and refill also affects food production with a gradual rate maximizing productivity compared to a faster rate.
- Hungry Horse Reservoir elevations influence exposure to angling exploitation and predation, as well as access to spawning areas for bull trout, westslope cutthroat trout, and other native fish.
- Water temperatures affect habitat suitability; the thermal structure of the pool is affected by the surface elevation.

- Entrainment out of Hungry Horse Reservoir is believed to occur to some extent but not measured; entrainment could change with different outflows.
- Within day fluctuations in Hungry Horse Dam outflows and river elevations below the dam affect productivity in the South Fork Flathead River.
- Bull trout and other fish below Hungry Horse Dam can be susceptible to GBT effects if TDG increases.
- The South Fork Flathead River has a more normalized temperature regime that improves native fish habitat due to selective withdrawal at Hungry Horse outlet; changes in Hungry Horse Reservoir elevations could reduce the ability to operate selective withdrawal structures as designed and thereby limit the more normalized temperature regime. Water temperatures affect the suitability for bull trout and other native fish, as well as the ability for them to compete with non-native fish.
- Minimum instream flows of 400 to 900 cfs (sliding scale) protect habitat in the South Fork Flathead River.
- Higher than normal flows from flow augmentation in summer can decrease suitability of habitat for native fish; higher flows in winter can hinder establishment of riparian vegetation and reduce suitability of habitat for native fish.
- Increased outflows from Hungry Horse Reservoir increase the effect of lake erosion at the upper end of Flathead Lake.
- Decreased spring peaks in the hydrograph of the Flathead River leads to less frequent channel maintenance flows; higher and more frequent peaks help maintain habitat for native fish.
- Inflows to Flathead Lake determine lake operations; differing operations could affect fish in Flathead Lake via temperature changes, entrainment of fish through Seli'š Ksanka Qlispe' Dam (the operating structure for Flathead Lake), and effects to the mysis population that supports lake trout.
- Flows in the Clark Fork River affect the suitability for native fish to compete with non-native fish such as smallmouth bass and northern pike. Increased flows can increase flushing of non-native predators. Flows can also affect the ability to run current trap and haul operations that support bull trout populations.

***Lake Pend Oreille and Pend Oreille River***

This region includes the Clark Fork River where it flows across the Montana-Idaho border, through Cabinet Gorge Dam and into Lake Pend Oreille; Lake Pend Oreille and any tributaries affected by lake operations or used by migratory fish from the lake; and the Pend Oreille River that flows out of Lake Pend Oreille, through Albeni Falls Dam, and downstream through the non-Federal Box Canyon and Boundary Dams, and on to the U.S.-Canada border.

Bull Trout

The Lake Pend Oreille subpopulation of bull trout is composed of migratory (fluvial and adfluvial) fish.  It is the largest-known bull trout population in Idaho. Adult and sub-adult bull trout use Lake Pend Oreille (USFWS 2010). Although considerably reduced from historical numbers, the population of bull trout in Lake Pend Oreille is considered one of the strongest populations of bull trout. Meyer et al. (2014) provided an adult population estimate of 12,513 for 2008 for Lake Pend Oreille; the population has appeared relatively steady since 1994. At least six streams where spawning has been documented are direct tributaries of Lake Pend Oreille (USFWS 2010a). This combination of productivity and wide distribution amounts to at least 15 local populations (USFWS 2015b). Redd monitoring in the 7 years following the 1999 listing suggests abundance has increased and the population is stable or increasing.

The three dams on the lower Clark Fork River (Thompson Falls, Noxon Rapids, and Cabinet Gorge) eliminated upstream migration and spawning access from Lake Pend  Oreille to 86 percent of the Clark Fork Basin, until 2001 when trap and haul programs began, substantially reducing the spawning and rearing habitat available for Pend Oreille bull trout (USFWS 2002).

No bull trout spawning has been recorded in lower Pend Oreille River tributaries downstream of Albeni Falls Dam since 2000, so there are no local populations attributed to this section of the river. It is likely any prior bull trout populations were extirpated following the construction of Albeni, Box Canyon, and Boundary Dams, which were built between 1955 and 1967 and blocked useable habitat for migratory bull trout in the river (USFWS 2002, 2008, 2010a, 2015b). Migratory bull trout from Lake Pend Oreille, entrained from the Priest River Basin or from Lake Pend Oreille (the source of bull trout between Albeni Falls Dam and Box Canyon Dam), may use the river for foraging or refuge during non-summer months. These bull trout may perish if they cannot be collected below Albeni Falls Dam and released in Lake Pend Oreille (Scholz 2005a, 2005b; Bellgraph et al. 2010).

Historically, adult bull trout have migrated out of Lake Pend Oreille, go down the Pend Oreille River, and forage in the river from October to June and then return to their tributary streams to spawn, with the progeny eventually returning to the lake (USFWS 2010). Sub-adult bull trout and non-spawning adults may remain and rear in the lake year-round (McCubbins and Hansen 2016). Each year, bull trout have potential to be entrained through the Albeni Falls Dam powerhouse or spillway and prevented from returning to spawn in lake tributaries by the lack of fish passage facilities at Albeni Falls Dam. USFWS (2018) estimated that around Albeni Falls Dam, it is likely that a maximum of 50 bull trout may be present above and 50 below at any time. Recent studies have indicated entrained adfluvial bull trout will not pioneer into tributaries below the dam and spawn (Geist et al. 2004; Scholz et al. 2005).

Conditions for bull trout habitat and migration in this reach of the study area (Figure 3-129) are controlled by lack of passage at the dams. Studies indicate bull trout study fish released downstream of Albeni Falls Dam did not survive through the summer during high water temperatures in selected years due to lack of thermal refuge (i.e., cold water habitat) below the dam (Scholz 2005; Bellgraph et al. 2010). Bull trout populations are lower than the natural carrying capacity due to impassable dams that prevent access of migratory fish to spawning and rearing areas in headwater areas of tributaries to the Pend Oreille River and Lake Pend Oreille. Fish passage and bull trout reintroduction efforts are in planning stages for this section of the Pend Oreille River. Fish passage at Box Canyon Dam below Albeni Falls Dam is set to be operational in 2020. Construction of a fish trap and haul facility at Albeni Falls Dam may be constructed during the timeframe of the CRSO analysis period. Bull trout and other salmonid species that are entrained and pass downstream through the dam likely survive at relatively high rates that can exceed 95 percent or more (Normandeau 2014).

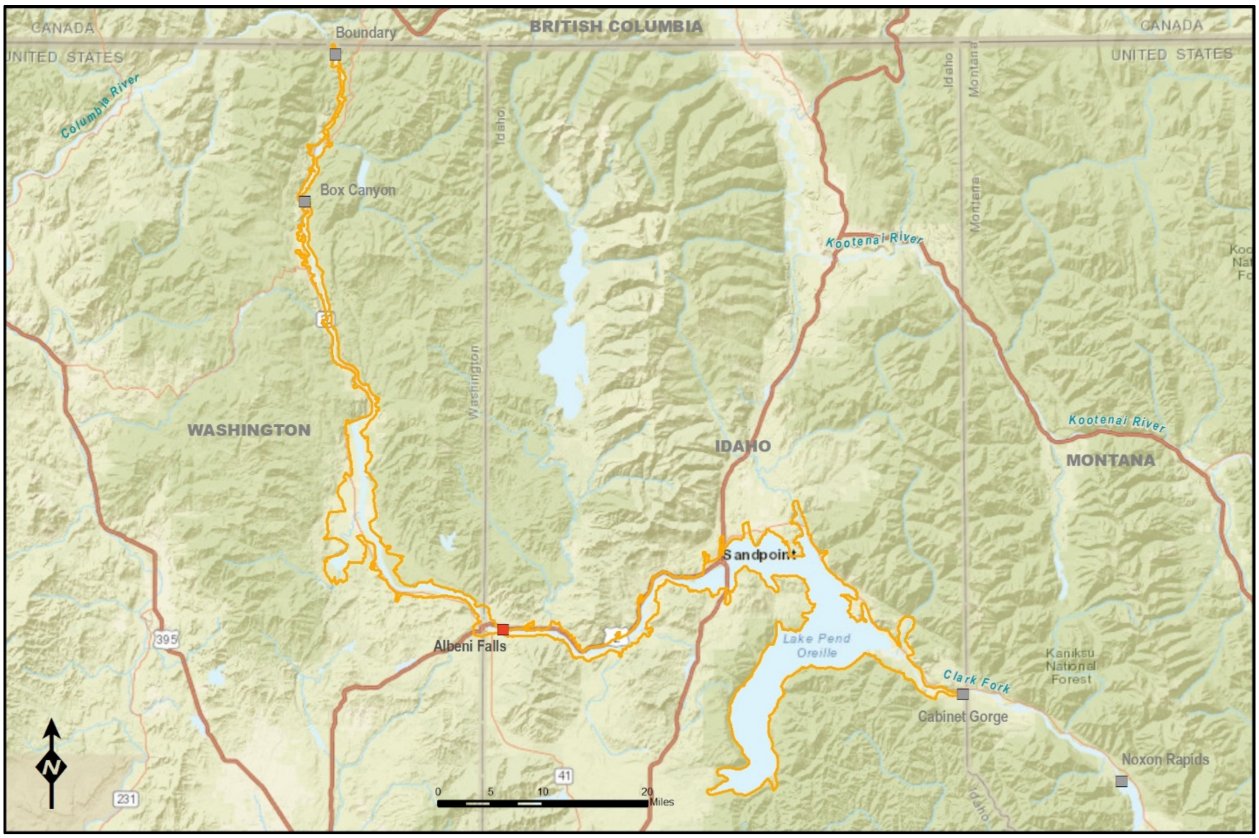

**Figure 3-129. Study Area for Lake Pend Oreille and Pend Oreille River**

Fish Communities

The Clark Fork River between Cabinet Gorge Dam and Lake Pend Oreille supports cold water and cool water sport fish. Cold water species including kokanee, rainbow trout, brown trout, and westslope cutthroat trout are common in the riverine reaches, whereas cool and warm water species such as yellow perch and largemouth bass are more abundant in the delta region of Lake Pend Oreille (FERC 2000, as cited in Corps 2006).

*Lake Pend Oreille* – Lake Pend Oreille is home to a wide diversity of catchable species such as whitefish, cutthroat and brown trout, kokanee, Gerard rainbow trout (also known as Kamloops), mackinaw or lake trout, large and smallmouth bass, crappie, pumpkinseed sunfish, perch, and bullhead (catfish). The list goes on with peamouth, northern pikeminnow, tench, suckers, sculpin, and a variety of smaller minnows contributing to the fish community. Non-native species have been introduced to Lake Pend Oreille from both legal and illegal planting of fish in lakes and rivers within the basin, including lake trout and Gerard rainbow trout, which are popular trophy fisheries. Cold water species (native and non-native) such as trout and kokanee tend to occupy the deeper waters of the lake, while warm water species such as bass, perch, crappie, and suckers (most of which are non-native, but some native species can tolerate warm water) are more prevalent in the nearshore areas and the Pend Oreille River between Sandpoint and Albeni Falls Dam. The dam provides habitat value, especially to the non-native warm water species in the summer, by decreasing velocities in the river between the lake and the dam. Conversely, available habitat for warm water species is adversely affected by the annual winter drawdown. Water velocities are typically higher and off-channel habitat more limited during winter lake elevations. Habitat with no velocity disappears as quiet bays and backwaters are dewatered. Winter drawdown of the lake interrupts spawning or egg incubation and thereby reduces numbers of non-native species like tench, largemouth bass, pumpkinseed, and black crappie compared to the population size that would exist if there were no winter drawdown (DuPont and Bennett 1993).

Kokanee are critical to the fish community in Lake Pend Oreille. Not only do they provide an important fishery for anglers, they also serve as the primary forage for predatory salmonids, including ESA-listed bull trout. In 1925, lake trout were introduced to Lake Pend Oreille. These fish expanded rapidly, competing directly with other predators for kokanee. Mysis shrimp were introduced in the 1960s to provide additional food resources for kokanee but began competing directly with kokanee for zooplankton. The combination of predation from lake trout and competition from mysis nearly caused the collapse of the kokanee population (Corsi et al. 2019). To protect bull trout, no-kill regulations were implemented, and bull trout population increased by about 6 percent annually from 1996 to 2006 (Hansen et al. 2010). To address the regional spread of lake trout, several natural resource agencies and the Kalispel Tribe of Indians used suppression as a management strategy for controlling lake trout populations (Martinez et al. 2009). Angling and netting combined have removed over 165,000 lake trout from 2006 through 2013, causing a 72 percent decline in juvenile lake trout net catches and a corresponding increase in the kokanee population (IDFG 2014). Currently, there is a tenuous balance between predator and prey in Lake Pend Oreille.

*Pend Oreille River* – In the late 1980s, native mountain whitefish, peamouth chub, northern pikeminnow, and redside shiner were the most abundant fish in the Pend Oreille River above Albeni Falls Dam (DuPont and Bennett 1993). Other native fish include cutthroat trout and suckers. The Kalispel Tribe of Indians' 2008–2012 electrofishing efforts to capture bull trout below Albeni Falls Dam provide more current information on species composition and size ranges of fish within the local area; mountain whitefish had a relatively high abundance at 14 to 33 percent, while bull trout were less than 1 percent in each year (Kalispel Tribe, unpublished data). Some of these species are lake-dwelling fish such as kokanee, lake whitefish, walleye, and lake trout. Fish species found downstream of Albeni Falls Dam are similar to those found above the dam, as fish can be passed downstream through the spillway and powerhouse.

Northern pike have become established in Box Canyon Dam Reservoir and Boundary Dam Reservoir on the Pend Oreille River where they are considered a serious threat to trout and other fish species there and throughout the region. Fish surveys conducted in the Box Canyon reservoir between 2004 and 2011 documented a rapid increase of northern pike in Box Canyon Reservoir (nearly a hundredfold increase in number of fish captured) and a decline in abundance (as much as 50 percent drop in catch rate) of forage species such as native minnows and non-native sunfish, largemouth bass, and yellow perch (WDFW 2013). As of 2018, the Kalispel Tribe of Indians is effectively reducing the population and has removed approximately 18,000 northern pike from the Pend Oreille River, nearly all of them from the reservoir behind Box Canyon Dam (NW Council 2018).

Preliminary important environmental relationships for resident fish in this region that could be affected by MOs are as follows:

- Albeni Falls Dam outflow can affect entrainment rates through the dam. Entrainment can reduce populations of native fish such as bull trout, westslope cutthroat trout, kokanee, etc., in the lake as well as hastens the spread of non-native fish from the lake into the river downstream.
- Upstream fish passage at Albeni Falls Dam may be implemented during the timeframe of the CRSO analysis period.
- Predation and competition between non-native and native fish can be influenced by operations that change outflows, temperatures, and reservoir levels.
- Flexible winter power operations result in changing lake elevations in the winter. A greater range of elevations can increase erosion rates and affect spawning success of kokanee and mountain whitefish.
- Pool elevations affect spawning habitat availability for several species.
- Albeni Falls operations affect sedimentation and erosion of lake shorelines, which could affect the availability of tributary access for bull trout, westslope cutthroat trout, and other fish that spawn in tributaries.
- Kokanee are the main food source for predatory fish such as bull trout in Lake Pend Oreille. Drawdowns after kokanee spawn can dewater eggs and reduce recruitment, however due to management guidelines the likelihood of egg dewatering is very low.
- Winter flows in the Pend Oreille River can affect spawning success of native fish.
- Water temperature in the Pend Oreille River gets too warm for many native fish such as bull trout, but once entrained, they cannot move back upstream to cooler water.

**Region B**

***Columbia River – U.S.-Canada Border to Chief Joseph Dam***

The Columbia River enters the United States and flows south into Lake Roosevelt, which is impounded by Grand Coulee Dam (Figure 3-130). Lake Roosevelt extends 151 miles (243 km) northeast almost to the U.S.-Canada border and impounds the lower reach of the Spokane River. The next segment between Grand Coulee Dam and Chief Joseph Dam is about 51 miles (82 km) of impounded pool called Rufus Woods Lake.

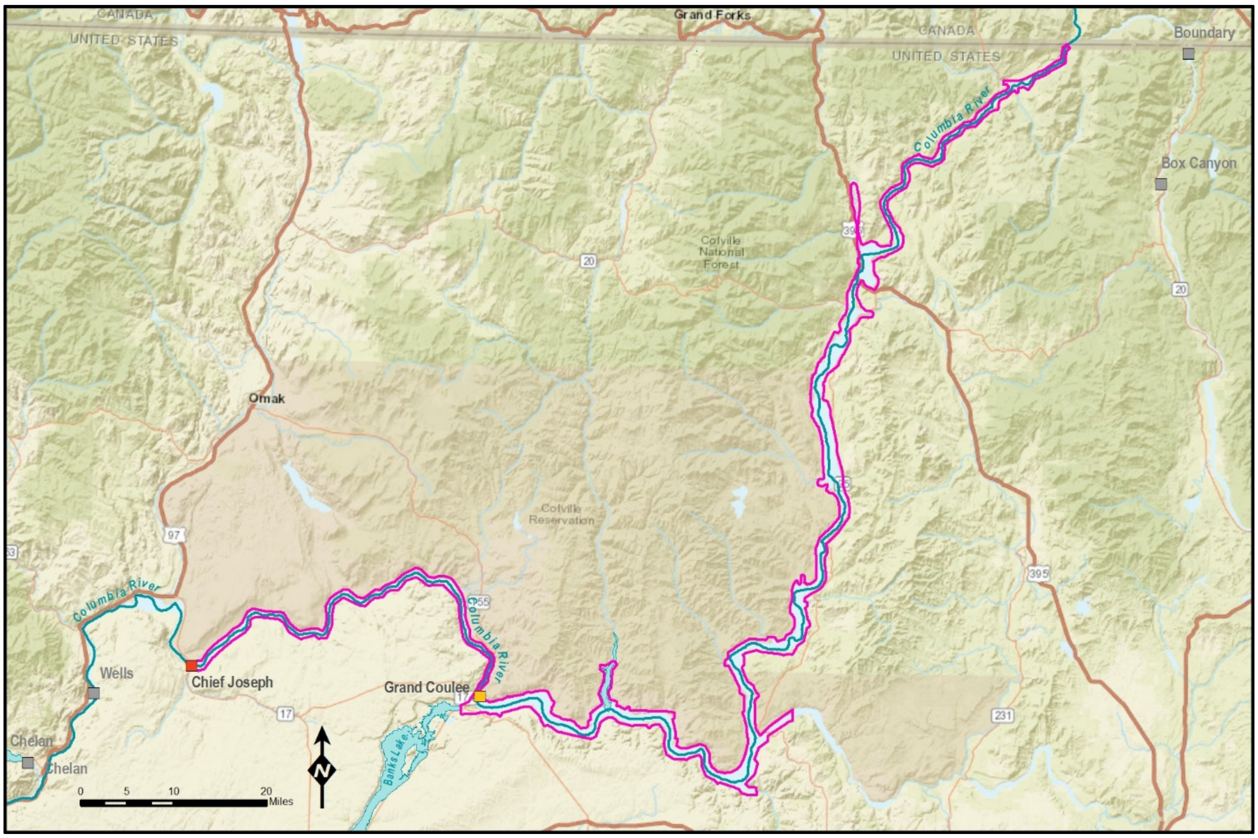

**Figure 3-130. Study Area for Columbia River (U.S.-Canada Border to Chief Joseph Dam)**

<u>Bull Trout</u>

Fluvial bull trout occur in the Grand Coulee Dam reach, this reach is classified as a research needs area (USFWS 2015). Since 2011, observations of bull trout have been increasing in Lake Roosevelt and tributaries in the northern end of the lake, typically in high-flow years (USFWS 2015). In 2012, 19 bull trout observations were reported throughout Lake Roosevelt. These fish are most likely occasional strays from populations in river systems north of the U.S.-Canada border (USFWS 2015). The Rufus Woods Lake segment includes the tailrace of Grand Coulee Dam and the Chief Joseph pool, known as Rufus Woods Lake. This segment of the project reach lies outside of designated critical habitat for bull trout, and the likelihood of bull trout occurrence in this waterbody is negligible. Bull trout accounted for less than 0.1 percent of the catch during the most recent fish inventory of the lake in 1999 (LeClaire 2000; Beeman et al. 2003). Bull trout present in Rufus Woods Lake may have been entrained through Grand Coulee Dam (Beeman et al. 2003). The Colville Confederated Tribes and the NPCC concluded bull trout use of Rufus Woods Lake was minimal (Confederated Tribes of the Colville Reservation 2000). This reach was not included in critical habitat designated in 2010 (50 CFR 17). Bull trout have been collected in the turbines at Chief Joseph Dam. It is unknown if these fish were entrained through the turbines or were migrants from the downstream populations that entered through the draft tubes.

<u>Fish Communities</u>

*Lake Roosevelt (including the Columbia River upstream to the U.S.-Canada border)* – Lake Roosevelt hosts 15 native and 12 non-native fish species. Lake Roosevelt provides a regionally and economically important sport fishery; WDFW describes Lake Roosevelt as “Washington’s biggest summertime playground” due to the robust fisheries for rainbow trout, kokanee, walleye, smallmouth bass, and burbot (WDFW 2018). Lake Roosevelt also supports an important population of native redband rainbow trout. All three life history types have also been documented within the Sanpoil River drainage, including a small fall run of lacustrine adfluvial fish (Brown et al. 2013). The Sanpoil is the only documented tributary in Lake Roosevelt supporting fall migrating adult Redband Trout (Jones and McLellan 2018).

Management of the Lake Roosevelt fishery is guided by the Lake Roosevelt Guiding Document (LRMT 2009) developed by the three co-managers (Colville Tribe, Spokane Tribe, and WDFW), with a goal to maximize recreational and subsistence harvest opportunities while minimizing adverse impacts to other native populations.

Primary harvest fisheries include rainbow trout, kokanee salmon, and walleye. The lake supports popular fisheries and fishing tournaments for trout, walleye, and bass. Other game fish include yellow perch, lake and mountain whitefish, black crappie, bullhead, sunfish, and catfish. Non-game species such as suckers, redside shiners, dace, and sculpins provide a prey base. Bull trout, westslope cutthroat trout, brook trout, and brown trout are encountered but much less frequently than the key sport fishery species in Lake Roosevelt (Underwood and Shields 1995; Cichosz et al. 1999). The non-salmonid community, once composed of lamprey, burbot, white sturgeon, suckers, and native cyprinids such as northern pikeminnow is now dominated by walleye and smallmouth bass. In addition, mountain whitefish have been displaced, though not entirely, by lake whitefish (Cichosz et al. 1999).

White sturgeon occur in Lake Roosevelt and the Columbia River upstream from the reservoir. Following the construction of the Columbia River Treaty Dams in British Columbia, Canada, and Montana approximately 40 years ago, white sturgeon in the Transboundary Reach of the Columbia River (Grand Coulee Dam to Hugh Keenleyside Dam) have experienced almost complete recruitment failure (Hildebrand and Parsley 2013). Thus, the wild population consists of a few thousand large adults. An international recovery effort was established to address the declining white sturgeon population in the upper Columbia River. Research and conservation aquaculture programs were implemented to investigate the lack of natural white sturgeon production and to restore demographics and preserve genetic diversity. These activities have determined upper Columbia River white sturgeon spawn annually at two primary locations, which occur at the confluence of the Pend Oreille and Columbia Rivers below Waneta Dam and near the town of Northport, Washington, as well as three less substantial sites near Hugh Keenleyside Dam in British Columbia, and China Bend in Lake Roosevelt. Collectively, this data suggests the recruitment bottleneck occurs at the stage when larvae are transitioning to natural foods. There are several hypotheses for the lack of natural recruitment of upper Columbia white sturgeon including habitat alteration, changes to the hydrograph, increased abundance of non-native predators, declines in food abundance, and contaminant exposure. Tens of thousands of white sturgeon larvae are captured each year in upper Lake Roosevelt, and hatchery produced fish released as yearlings survive well and are transferred to a jointly managed conservation aquaculture program. This program has experienced tremendous success, leading to the opening of tribal and recreational fisheries in 2017.

In 1986, the Lake Roosevelt Development Association began a rainbow trout net pen program to supplement the rainbow trout fishery in Lake Roosevelt (Underwood et al. 2000). Wild kokanee salmon and rainbow trout fisheries are supplemented through hatchery and net-pen operations through a multi-agency effort, the Lake Roosevelt Fishery Enhancement Program (LRFEP). LRFEP is a cooperative effort between the Spokane Tribe of Indians, Colville Confederated Tribes, WDFW, Eastern Washington University, the Lake Roosevelt Development Association (now known as the Lake Roosevelt Voluntary Net Pen Program) (Lake Roosevelt Forum 2011; Reclamation 2009). The purpose of the LRFEP is to develop a collaborative multi-agency artificial production program to provide a mitigation fishery in Lake Roosevelt. Investigations suggest the hatchery and net pen programs have enhanced the Lake Roosevelt fishery while not adversely affecting native stocks within the lake (Lake Roosevelt Forum 2011).

Habitat conditions and the resident fish assemblage of Lake Roosevelt is typical of a reservoir-based ecosystem that experiences large annual fluctuations (up to 80 ft) in reservoir levels. Many native fish species such as northern pikeminnow, suckers, chubs, native minnows, and many of the mussel species endemic to the upper Columbia River have a status of extirpated or depressed populations because of extreme habitat changes (LRMT 2009). Native fisheries such as kokanee and redband rainbow trout are sensitive to mechanisms controlled by operations such as entrainment through Grand Coulee Dam and powerplant, and effects to the food web based on water travel time through the reservoir.

The non-native and highly invasive northern pike were first observed in Lake Roosevelt in 2011. The species has been found in Kettle River (NE Washington tributary of the Columbia River) (https://www.nwcouncil.org/news/northern-pike-invade-upper-columbia-river) but has not currently been documented downstream of Lake Roosevelt. Since that time, northern pike abundance has increased and their distribution is expanding downstream. The increasing observations of northern pike in Lake Roosevelt prompted the Lake Roosevelt co-managers to implement surveys to investigate abundance, diet, growth, origin, spawning locations, and movement patterns. Aggressive removal plans are underway throughout the reservoir.

*Rufus Woods Lake* – Thirty-three species of fish occur in Rufus Woods Lake, presently or historically. The fish community includes 19 native species and 12 non-native. Non-native species include brook trout, brown trout, and rainbow trout. Native species include bridgelip sucker, sculpin, dace, and mountain whitefish (Hunner and Jones 1996). The major contributors to Rufus Woods fisheries are walleye, rainbow trout, kokanee, smallmouth bass, lake whitefish, and burbot. Mountain whitefish support mid-winter tributary fisheries. Kokanee spawn in the Nespelem River, the largest tributary of Rufus Woods Lake, while a large number of kokanee, potentially up to 30 percent of stocked fish, are entrained through Grand Coulee Dam (WDFW 2002; LeCaire and Nine 2006).

Because of the steep gradient of this reach (relative to other major rivers and reservoirs in North America) and narrow canyon morphology, much of the upper reservoir has retained more riverine characteristics than lower Columbia River reservoirs. Erickson et al. (1977) and others suggest short water retention times (1.2–4.0 days) in Rufus Woods Lake might limit plankton and fish production, and thus a major source of fish recruitment in the reservoir may be young-of-the-year fish (under 1 year old) entrained through Grand Coulee Dam. The fish community resembles a riverine more than a lake-like fish assemblage.

Entrainment through Grand Coulee Dam from Lake Roosevelt has influenced the fish assemblage in Rufus Woods Lake. Fish are most likely to be entrained during the spring freshet and winter drawdown (LeCaire and Nine 2006). The limnetic fish (i.e., fish typically found in open water away from shore) abundance and distribution compared to monthly entrainment estimates through Grand Coulee Dam (Baldwin and Polacek 2002), showed that entrainment varied seasonally; it peaked in late spring and summer then dropped off by fall (Baldwin and Polacek 2002).

A commercial net-pen rearing operation for rainbow trout exists in Rufus Woods Lake. Some of these fish escape from the net pen and some are intentionally stocked in the reservoir for a sport fishery. The rainbow trout fishery is important as a subsistence fishery for members of the Colville Tribes and a quality sport fishery for non-members. Net-pen released rainbow trout can be entrained through the dam during higher rates of spill; monitoring of individual rainbow trout shows high use areas near the forebay and in areas around the net pens (Brown et al. 2012).

High flows during late-spring/early-summer, a common spawning period for many resident fishes, may flush eggs and larvae from protected rearing areas. Periods of low water levels may reduce survival of eggs of shallow-spawning species, such as kokanee, and disrupt benthic invertebrate prey sources (Cushman 1985). In addition, water level fluctuations may affect shoreline habitat structure such as vegetation abundance.

Preliminary important environmental relationships for resident fish in this region that could be affected by MOs are as follows:

- White sturgeon recruitment success is a function of Columbia River flows at the U.S.-Canada border greater than 200 kcfs and water temperatures near 14° for three to four weeks in late June and early July, coupled with reservoir elevations low enough to provide adequate riverine habitat for adequate juvenile development prior to reaching reservoir conditions.

- Retention time in Lake Roosevelt is a very important metric for the food web interactions. Long retention times produce more plankton production that is more evenly distributed throughout the reservoir; shorter retention times can reduce productivity and also concentrate the food sources further downstream near the dam. Additionally, retention time can influence the plankton species composition and size.
- Lower retention times that concentrate food further downstream increases entrainment risk to kokanee, bull trout, redband rainbow trout and other native fish, as well as potentially increasing the entrainment of non-native predators downstream out of Lake Roosevelt.
- Outflows from Grand Coulee influence the potential entrainment rates of several species.
- Reservoir conditions favor non-native predators that affect white sturgeon, burbot, kokanee, and redband rainbow trout.
- Contaminants in the river sediments affect fish, especially sturgeon and burbot, and flows could influence the risk to these fish if they mobilize more sediment or disperse the sturgeon larvae where they are more susceptible to exposure.
- Reservoir conditions provide rearing habitat for juvenile sturgeon once they get past the larval stage and for hatchery -reared larvae, as well as burbot.
- Reservoir drawdowns in winter and early spring dewater burbot eggs, and if reservoir levels decrease in September through February kokanee eggs can be dewatered.
- Reservoir temperatures affect habitat suitability for fish; kokanee, burbot, and bull trout are particularly sensitive to warm temperatures.
- Northern pike, walleye, and smallmouth bass are non-native predators that thrive in Lake Roosevelt but can cause predation issues on native fish in the reservoir as well as downstream in the Columbia River salmon migration corridor.
- Reservoir drawdowns in spring can strand adult northern pike, but low water in spring that allows vegetated shorelines followed by higher elevations creates spawning habitat for northern pike.
- The relationships for westslope cutthroat trout and redband rainbow trout generally also apply to the resident rainbow trout mitigation fishery (except spawning issues).
- Net pens in Lake Roosevelt are susceptible to water quality (temperature, TDG, DO) at the mouth of the Spokane River.
- Reservoir elevations affect the river/reservoir interface into the Spokane arm, which can affect the rate of freezing. Lower elevations can result in earlier freezing conditions and necessitate earlier release of net pen fish than is ideal.

- Date of initiation of reservoir refill affects release date of net pen fish. Delay of refill initiation results in either fish being released earlier when they likely encounter more stressful rearing conditions due to higher temperatures and TDG or releasing fish prior to refill initiation where they are more susceptible to entrainment due to higher outflows.
- Deep drafts of reservoir elevations could limit the ability to launch boats to implement the northern pike suppression program.

### *Columbia River - Chief Joseph Dam to McNary Dam*

Below Chief Joseph Dam, the Columbia River runs for 149 miles (240 km) through a series of five narrow reservoirs impounded by run-of-river dams (Wells, Rocky Reach, Rock Island, Wanapum, and Priest Rapids Dams) constructed and operated by public utility districts (PUDs) (Figure 3-131). Below Priest Rapids dam there is a free-flowing stretch known as the Hanford Reach, an approximately 50-mile (80-km) section that extends into the upper portion of McNary Reservoir.

#### Bull Trout

The entire reach from Chief Joseph Dam to McNary Dam is designated as critical habitat. Major tributaries within this area with local bull trout populations include the Methow, Entiat, Wenatchee, Yakima, and Walla Walla Rivers.

Bull trout from the Methow, Entiat, Wenatchee, and Walla Walla Rivers have been documented using the Columbia River as overwintering and migratory habitat in spring, fall, and winter. Bull trout from these tributaries have been observed at Rock Island, Rocky Reach, Wells, and McNary Dams on the Columbia River. Bull trout from the Yakima River have not been found in the Columbia River.

Subadult and adult bull trout from the Methow River have been found in the Columbia River from below Rock Island Dam upstream to the Okanogan River Subbasin, while bull trout from the Entiat River have been documented at Priest Rapids, Wanapum, Rock Island, Rocky Reach, and Wells Dams on the Columbia River.

Bull trout from the Walla Walla River are still fluvial and have been documented below McNary Dam and Priest Rapids Dam.

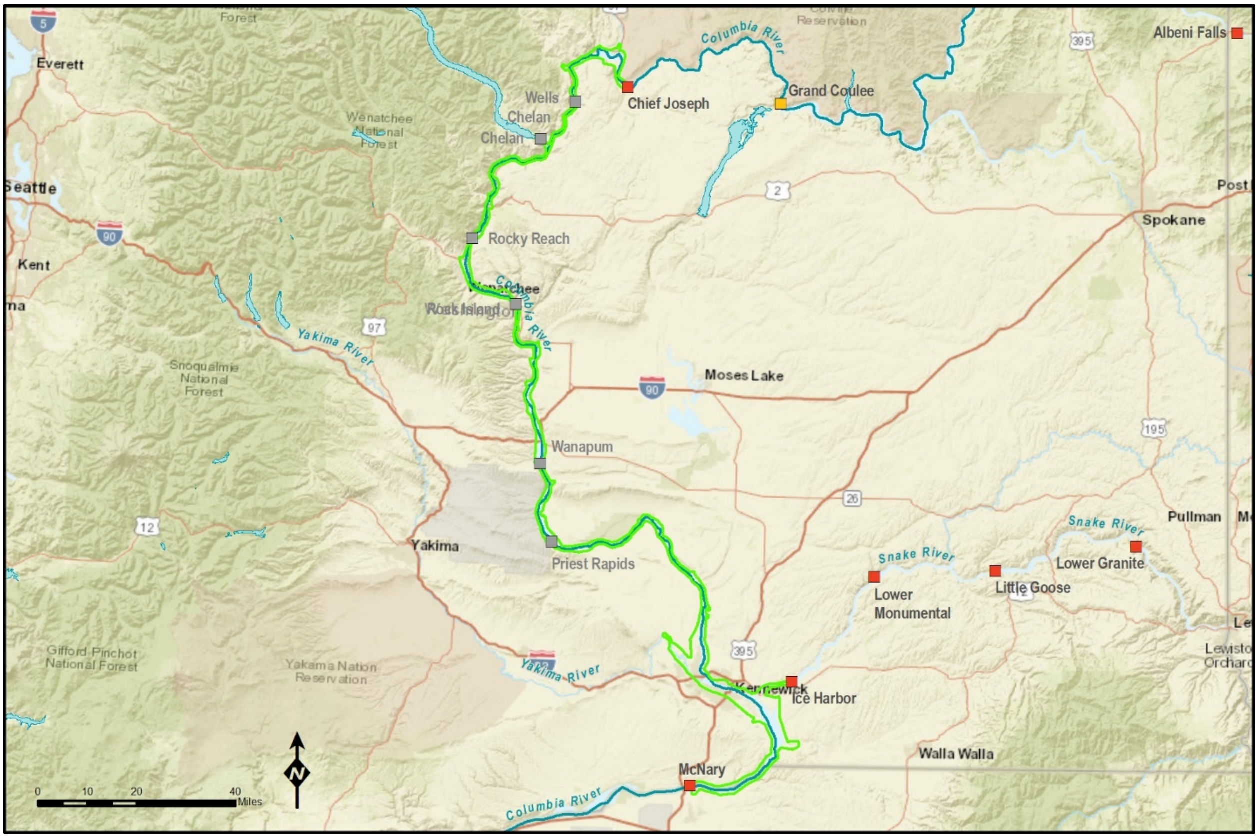

**Figure 3-131. Study Area for Columbia River – Chief Joseph Dam to McNary Dam**

<u>Fish Communities</u>

The reservoirs have relatively undeveloped shoreline and littoral zones (aquatic nearshore areas) and low water retention time. These two factors are not conducive to a high abundance of many types of resident fish. Species associated with each reservoir and the unimpounded Hanford Reach are discussed in their individual sections below.

*Wells Reservoir* – The resident fish assemblage in Wells Reservoir and downstream tailrace is composed of a diverse community of native and introduced, warm water and cold water, and recreational and non-recreational fish species. Since the construction of Wells Dam in 1967, several assessments have either directly or indirectly studied the resident fish assemblage in the Wells Reservoir (McGee 1979; Douglas County PUD 2008). These assessments have identified more than 20 species of resident fish including pumpkinseed, rainbow trout, black crappie, smallmouth bass, mountain whitefish, yellow perch, peamouth, northern pikeminnow, dace, shiners, suckers, and sculpins (See Resident fish matrix in Appendix E). The resident fish assemblage in Wells Reservoir is similar to the assemblages in nearby regions, such as Rocky Reach and Rock Island Reservoirs, and Lake Roosevelt.

*Rocky Reach and Rock Island Reservoirs* – BioAnalysts (2000) identified 41 fish species in the Rocky Reach Dam area, including cool, cold water, and warm water species. Of the species identified in this local area, 61 percent are native. The introduced species include brown trout, brook trout, lake whitefish, Atlantic salmon, pumpkinseed, walleye, yellow perch, and smallmouth bass. All warm water species in the Rocky Reach area have been introduced. Bull trout, cutthroat trout, and burbot are rare in the Rocky Reach area (Dell et al. 1975; Burley and Poe 1994; BioAnalysts 2000), and the number of white sturgeon appears to be quite low (DeVore et al. 2000). Compared to upstream reservoirs, cooler water temperatures in this local area limit production of the warm water piscivorous species including smallmouth bass and walleye, and low turbidity and poor recruitment might limit walleye production (BioAnalysts 2000).

*Priest Rapids and Wanapum Reservoirs* – Within the Priest Rapids Dam area, resident fish include a diverse mix of native and non-native species, some of which, including smallmouth bass and walleye, support important sport fisheries; 38 resident fish species occur in the Priest Rapids project area. Pfeifer et al. (2001, as cited in FERC 2006) indicate most species sampled were associated with fine substrates and shallow depths; however, some of the more abundant fish species in the Priest Rapids Dam area are successful in both river and lake habitats. Six species of native game are present in the Priest Rapids project area including rainbow trout, cutthroat trout, bull trout, lake and mountain whitefish, and burbot. Of these species, rainbow trout and mountain whitefish are common throughout the local area, while the other species are either uncommon or rare.

*Hanford Reach of the Columbia River* – The Hanford Reach extends from the base of Priest Rapids Dam (RM 393) downstream to the upper portion of McNary Reservoir (Lake Wallula) at about RM 343. The Hanford Reach is the only un-impounded section of the Columbia River in Washington above Bonneville Dam, and as such is an important refuge for native resident fish species. Extensive flow management at upstream dams has created an aquatic environment subject to substantial water level fluctuations that influence the species composition.

The Hanford Reach has 43 documented fish species, and most are resident species (Gray and Dauble 1977). Relatively common species include redside shiners, carp, largescale suckers, northern pikeminnow, peamouth, and smallmouth bass. Tench, three-spine sticklebacks, and mountain whitefish are rarely captured in Hanford Reach. Within the Hanford Reach National Monument, irrigation-fed ponds and lakes support introduced carp, bass, sunfish, and panfish (USFWS 2014).

Surveys conducted to evaluate the effects of water level fluctuation on age-0 resident fish composition, distribution, and abundance in the Hanford Reach indicated resident fish occurrence is greater in the riverine Hanford Reach compared to the more lake-like environments of the Columbia River reservoirs (Gadomski and Wagner 2009). This increased abundance could be attributed to the increased availability of spawning and rearing habitat, which might mitigate the effects of variable flow regimes.

The white sturgeon population in the Hanford Reach is intermediate in size and supports intermittent spawning, although the frequency at which juveniles reach 1 year of age has not been measured (Jager et al. 2010). Populations of white sturgeon from the lower Columbia River up to the McNary impoundment are largely genetically similar despite separation of population segments by dam construction in the 1950s and 1960s (CRITFC 2011b; Joint

Columbia River Management Staff 2012). There does appear to be some genetic influence on the mid-Columbia River populations (Bonneville Dam to McNary Reservoir) from upstream Snake River populations, potentially due to juveniles entering downstream populations (CRITFC 2011b). Harvest from 2001 to 2010 averaged 312 white sturgeon annually, and in 2010, the fishery above McNary Dam was restricted from year-round to February 1 through July 31 because of concerns for increased harvest levels (Joint Columbia River Management Staff 2012). Subsequently, harvest of white sturgeon above McNary Dam has closed indefinitely.

## Region C

### *Snake River*

The Snake River Subbasin includes the Snake River from its confluence with the Columbia River up to Hells Canyon Dam (Figure 3-132). It also includes Dworshak Reservoir and the North Fork of the Clearwater River down to its confluence with the Clearwater River, the Clearwater River down to the Snake River, and the Salmon River Basin. Within this subbasin there are five Columbia River System projects, including one storage dam, Dworshak Dam on the North Fork Clearwater River, and four run-of-river dams on the Snake River. These include Lower Granite, Little Goose, Lower Monumental, and Ice Harbor Dams. All four of the lower Snake projects are equipped with fish passage facilities.

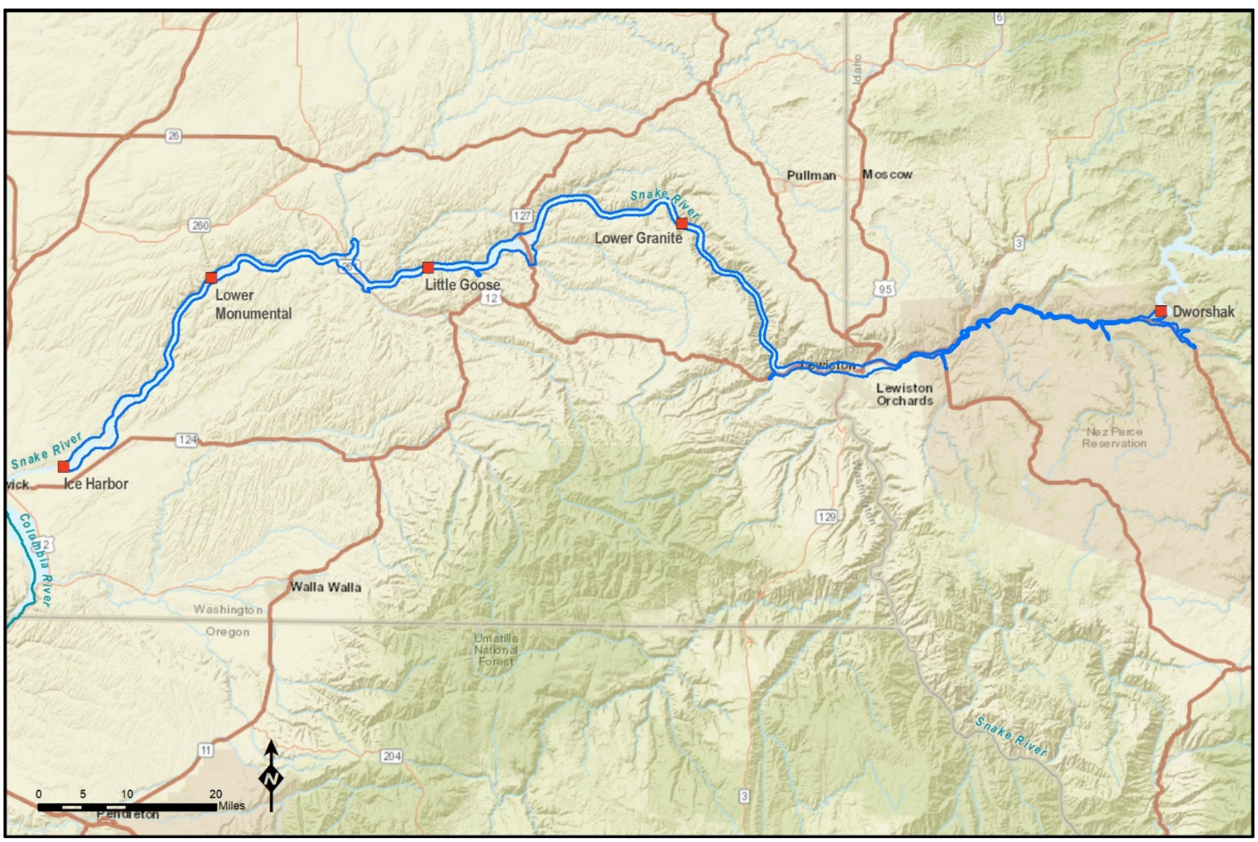

**Figure 3-132. Study Area for the Snake River**

Bull Trout

Adult bull trout that migrate between the lower Snake River reservoirs and tributaries (*adfluvial*) spend about half of every year in the lower Snake River reservoirs from November to May. These fish most likely forage in shallow areas where the majority of prey live. Depending on water conditions, bull trout will occupy deeper areas of the reservoir where water temperatures are cooler 7.2°C to 12.2°C and move to the surface when water temperatures drop to or below 12.2°C.

During recent sampling of shallow-water habitats in the lower Snake River reservoirs, single bull trout have been collected some years at a sampling site in the Lower Tucannon River (Seybold and Bennett 2010; Arntzen et al. 2012). Researchers speculated this sampling was probably not indicative of widespread bull trout use of the lower Snake River reservoirs; instead, it is potentially indicative of an adfluvial life history strategy (Seybold and Bennett 2010). During sampling and tracking of bull trout in the lower Tucannon River, bull trout have been found to enter the lower Snake River during October to January, returning to their natal streams from January to March (Bretz 2011; DeHaan and Bretz 2012).

Adult and subadult bull trout have been detected at all four of the Snake River CRS dams. Passage at these dams allows genetic exchange between the Walla Walla River, Tucannon River, Asotin Creek, Grande Ronde River, and Imnaha River Subbasins. The number of bull trout migrating to the mainstem has been quantitatively estimated in only the Tucannon, Imnaha, and Walla Walla Subbasins. Bull trout from the Tucannon River have been observed passing five mainstem dams of which three are downstream (McNary, Ice Harbor, Lower Monumental) and two are upstream (Little Goose and Lower Granite). Bull trout from the Imnaha River have been detected passing downstream through Lower Granite and Little Goose Dams and bull trout from the Walla Walla River have detected moving upstream and downstream through McNary Dam. There is limited evidence that Asotin Creek bull trout may use areas of Lower Granite Dam reservoir, and no documented evidence of bull trout from the Clearwater River entering the mainstem (Barrows et al. 2016). While Dworshak Reservoir and the North Fork Clearwater River contain healthy populations of bull trout, there is no documented evidence that these fish regularly reach the Snake River. Likewise, there is no data that bull trout from the Salmon River Subbasin use the mainstem Snake River for migratory or overwintering habitat. On the mainstem Snake River, adults tend to move back toward their headwater spawning area in the spring and summer. Bull trout from the Tucannon River Subbasin enter the mainstem Snake River from October through February and return from March through July (Barrows et al. 2016).

Bull trout spawn from August to September during periods of decreasing water temperatures. Migratory bull trout frequently begin spawning migrations as early as April and move upstream as far as 155 miles to spawning grounds. Temperature during spawning ranges from 4°C to 11°C, with redds often constructed in stream reaches fed by springs or near other sources of cold groundwater (Goetz 1989). Water temperatures exceeding 15°C limit bull trout distribution. Bull trout require spawning substrate consisting of loose, clean gravel relatively free of fine sediments.

<u>Fish Communities</u>

The Snake River Subbasin contains over 40 resident fish species (Bennett et al. 1983; Bennett et al. 1991; Mundy and Witty 1998; NPCC 2004a; Seybold and Bennett 2010; Arntzen et al. 2012; Sholz et al. 2014; Corps 2014). Eighteen of these species are native fish. Some of the more common fish in the Snake River include bridgelip sucker, smallmouth bass, walleye, peamouth, and northern pikeminnow.

The Salmon and Clearwater Rivers also provide habitat for resident fish species. Species composition is similar to those found in the mainstem Snake River, but with fewer warm water species. Resident fish common in these basins include cutthroat trout, bull trout, rainbow trout, mountain white fish, sand roller, smallmouth bass, northern pikeminnow, suckers, and in the lower Salmon Bain, sturgeon. In Dworshak Reservoir, kokanee and smallmouth bass are important fisheries.

Native cold water resident species (such as trout and whitefish), while not as common in the lower Snake River, are still abundant in the Clearwater and Salmon River Basins. Their predominance in the Snake River has been replaced by cool and warm water species (Corps 2014).

Resident fish in the lower Snake River reservoirs occupy numerous habitats and often use different habitats for different life history stages (Bennett et al. 1983; Bennett and Shrier 1986; Hjort et al. 1981; Bennett et al. 1991). Warm water species such as small and largemouth bass, crappie, bluegill, yellow perch, and carp use backwater areas for spawning and rearing (Bennett et al. 1983; Bennett and Shrier 1986; Hjort et al. 1981; Bennett et al. 1991; Zimmerman and Rasmussen 1981). Spawning and incubation times vary between species; however, most of these backwater species spawn from May through mid-July (Corps 1999b).

Juvenile fish occur in abundance in backwater and open-water areas associated with slower water velocities. Adult distribution is similar to spawning and juvenile distribution, but often varies depending on feeding strategies of the particular species. Adults may occur throughout different habitats and move seasonally or daily to different areas (Bennett et al. 1983; Bennett and Shrier 1986; Hjort et al. 1981). Although adults use a variety of habitat types, lake-dwelling species are generally more abundant in shallow, slower-velocity backwater areas, and native riverine species occur abundantly in areas with flowing water found in the tailrace zone (Hjort et al. 1981; Bennett et al. 1983; Bennett and Shrier 1986; Mullan et al. 1986). Backwater conditions created by the dams have greatly enhanced nutrient retention (Doyle et al. 2003).

During recent sampling of all four reservoirs in the lower Snake River, studies found smallmouth bass were the most common predator of the eight predatory species (northern pikeminnow, smallmouth and largemouth bass, walleye, yellow perch, white and black crappies, and channel catfish) (Seybold and Bennett 2010). Smallmouth bass were most abundant in Lower Granite

Reservoir, while northern pikeminnow were more abundant at sampling stations downstream of Lower Granite Dam. Walleye, which were caught only in the Lower Monumental and Ice Harbor Reservoirs, are now increasingly caught in Little Goose Reservoir.

Preliminary important environmental relationships for resident fish in this region that could be affected by MOs are as follows:

- Bull trout migration into and throughout the main rivers (Snake, Clearwater) for feeding, migration, and overwintering habitat can be impeded by the project facilities. Bull trout can be entrained through the Snake River dams with fish tending to move downstream more readily than upstream.
- Water temperatures in Dworshak Reservoir influence the distribution of bull trout; when further down in the reservoir, they are more susceptible to entrainment.
- Generally, warmer temperatures are correlated to higher predation risk to native fish such as bull trout, redband rainbow trout, etc., to non-native predatory fish.
- White sturgeon in the Snake River are very limited in recruitment in this region due to the limited length of riverine stretch available for larval development between projects. Most recruitment comes from upstream projects; they generally do not move upstream.
- White sturgeon and other fish can sustain physical injury from turbines if they pass through them.
- Reservoir tailraces provide a limited amount of cobble/gravel substrate for rearing habitat for the yolk-sac larvae of white sturgeon; the rest of the reservoir habitats are very limited in suitable habitat. This habitat is likely limiting sturgeon recruitment.
- Water temperatures in the lower Snake River affect all species. White sturgeon require temperatures between 8°C and 18°C.
- Outflows of Dworshak Dam influence kokanee entrainment susceptibility.
- In Dworshak Reservoir, spawning tributaries become inaccessible to spawning kokanee at an elevation below 1,450 feet in September and October.
- Run-of-river reservoir conditions in the Snake River tend to favor predatory fish such as walleye, smallmouth bass, and pikeminnow with relatively slow, deep, warm water.
- Water temperatures and flows affect the production of plankton that form the basis of the food web to support fish.

**Region D**

***Columbia River – McNary Dam to Bonneville Dam***

This region extends for 145.9 river miles from McNary Dam at RM 292.0 downstream to John Day Dam, The Dalles Dam, and finally Bonneville Dam at RM 146.1 (Figure 3-133). These projects are run-of-river dams that generate hydroelectric power and are equipped with fish passage facilities designed for salmonids. Impoundments formed by these dams include Lake Bonneville, Lake Umatilla, Lake Celilo, and Lake Wallula.

Bull Trout

Bull trout have been observed or detected moving upstream at Bonneville Dam and McNary Dam in the spring and summer (Barrows et al. 2016). The species has been observed or detected at The Dalles Dam in December and at John Day Dam from April through May.

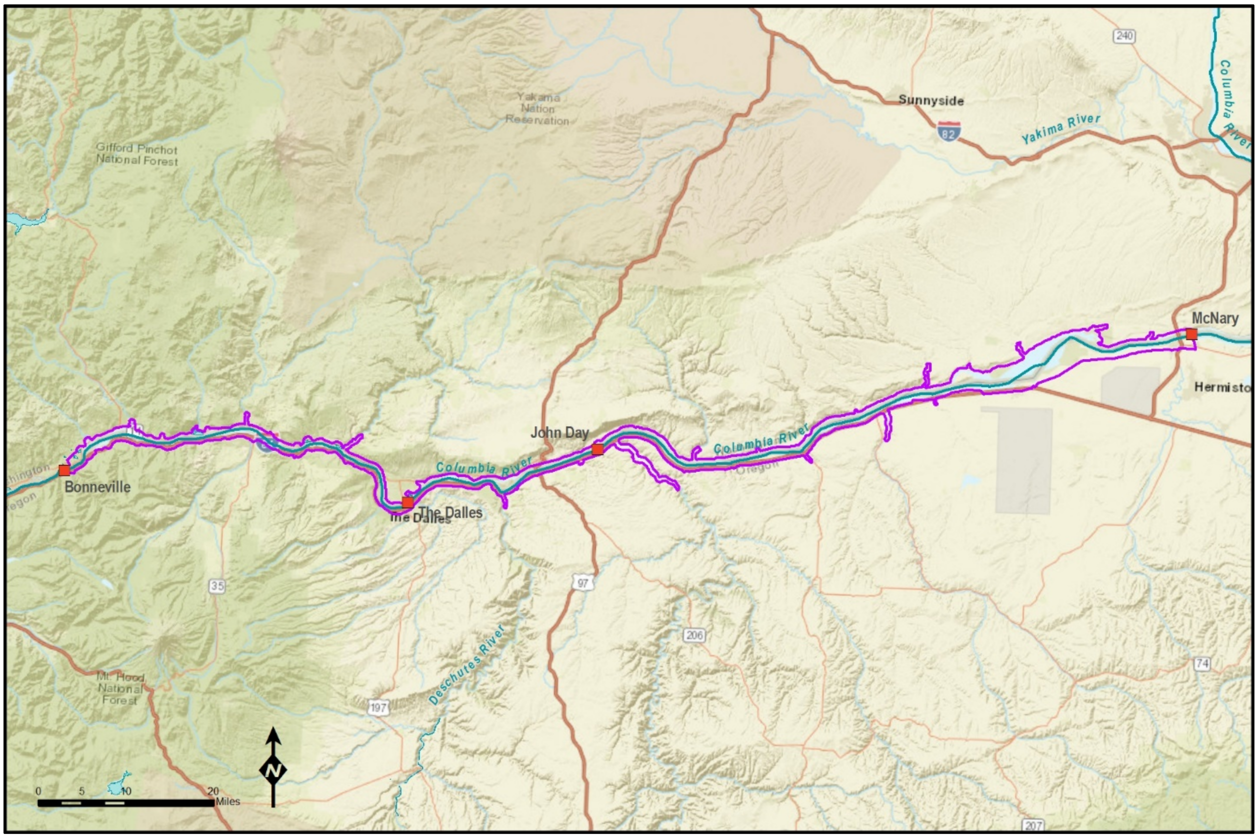

**Figure 3-133. Study Area for Columbia River – McNary Dam to Bonneville Dam**

Fish Communities

At least 45 resident fish species, of which over half are native, have been documented in the Columbia River between Bonneville and Wanapum Dams (NPPC 2001; Ward et al. 2001). Some native resident fish (e.g., white sturgeon) use reservoir habitat within this reach of the Columbia River throughout their life cycle whereas others (e.g., bull trout) live primarily in tributaries and occasionally use reservoir habitats for foraging or migration (NPPC 2001). Within this reach of the lower to middle Columbia River, the mainstem dams are barriers to upstream movements by most resident fish. However, white sturgeon (Warren and Beckman 1989) and other residents including bull trout are known to pass through fishways at the dams, although in very low numbers. The degree of entrainment of resident fish downstream through

Bonneville and The Dalles Dams is largely unknown (NPPC 2001). Resident piscivores in this reach of the Columbia River include northern pikeminnow, smallmouth bass, and walleye.

The Corps has identified legacy contamination on and around Bradford Island in the Bonneville Lock and Dam Project. The Corps has published results of sampling sediment, clams, and fish tissue. Elevated levels of PCBs were found in smallmouth bass. The Corps continues to investigate potential clean up options.

Hjort et al. sampled lower Columbia River reservoirs in 1981 for resident fish and observed several species of resident minnows. They found mountain whitefish, largescale sucker, bridgelip sucker, peamouth, and redside shiner in Lake Bonneville. Bridgelip sucker, chiselmouth, redside shiner, sand roller, longnose dace, peamouth, and largescale sucker were found in Lake Umatilla, and Lake Celilo contained longnose dace, peamouth, chiselmouth, largescale sucker, and bridgelip sucker (Hjort et al. 1981).

Preliminary important environmental relationships for resident fish in this region that could be affected by MOs are as follows:

- White sturgeon recruitment is correlated with flows greater than 250 kcfs from McNary Dam when temperatures are between 10°C and 18°C.
- White sturgeon larvae need substrate with small spaces between gravel for growth and survival of yolk-sac larvae. The magnitude and duration of high spring flows affects this habitat.
- White sturgeon and other species can be affected by high levels of TDG.
- Project facilities can impede the upstream migration of white sturgeon and bull trout that typically rely on migration and can result in isolated populations. Project configurations and operations can influence factors that increase or decrease risk.
- Bull trout and white sturgeon can migrate downstream through turbines, where they are susceptible to injury or mortality. Operations of projects can influence factors that increase or decrease risk.
- Access to thermal refugia is important to bull trout and other species.
- Fluctuations in pool elevation in the Bonneville Reservoir can suppress vegetation on the delta at the mouth of the Klickitat and Hood Rivers. This can make bull trout subject to predation when using this area.
- Reservoir conditions typically favor non-native fish such as walleye and smallmouth bass, as well as predatory pikeminnow; changes in operations, outflows, and reservoir levels can affect success of these fish.
- The presence and abundance of shad can subsidize the diets of predatory fish to increase their survival, and then when the shad are gone, the predators switch to native fish such as juvenile migrating salmonids.

***Columbia River – Below Bonneville Dam***

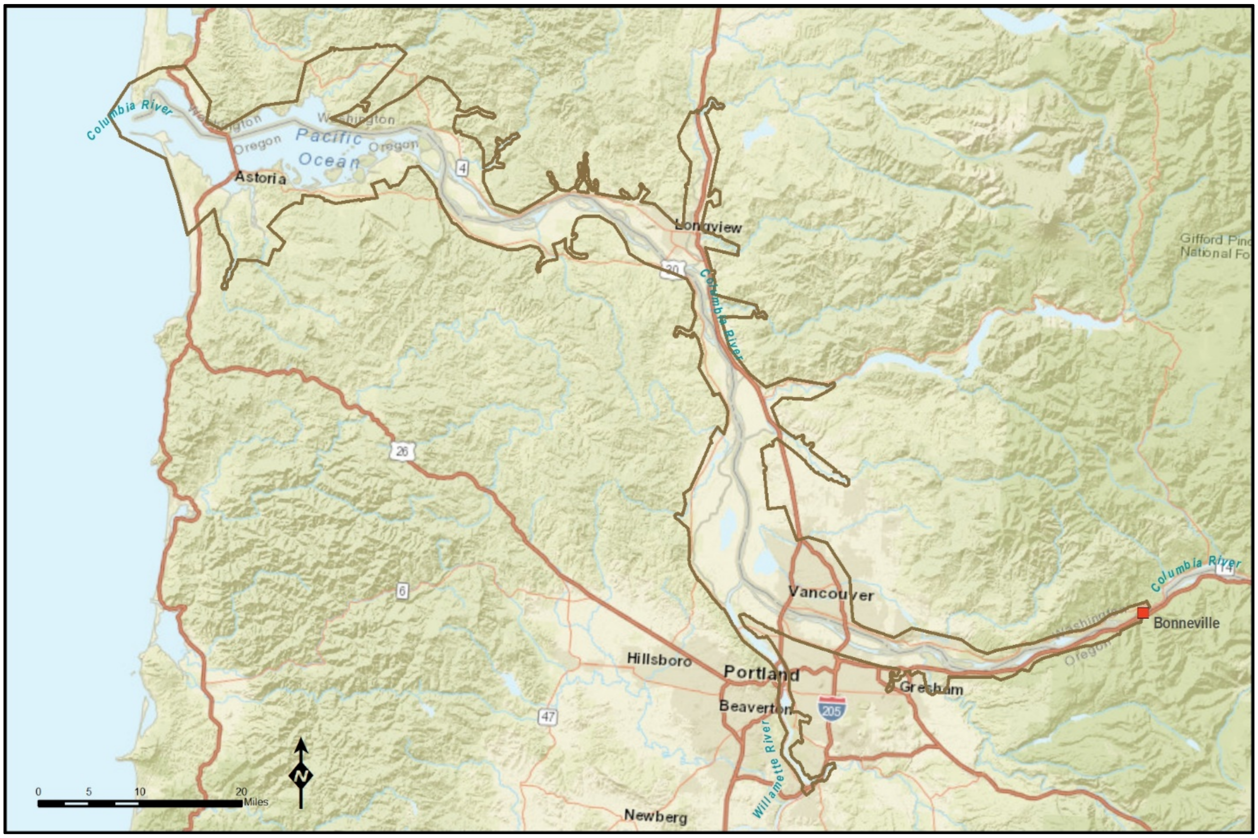

**Figure 3-134. Study Area for Columbia River – Below Bonneville Dam**

Bull Trout

Bull trout found below Bonneville Dam include fish from the Lewis, Hood, and Klickitat Rivers. The only basin that contains bull trout below Bonneville Dam is the Lewis River. Lewis River bull trout could be present in the mainstem Columbia River downstream from Bonneville Dam, but the three Lewis River dams and reservoirs restrict downstream movement and it is likely that very few individuals are able to migrate to the Columbia River.

Limited data for bull trout at Bonneville Dam and within Lake Bonneville suggest downstream movement from Hood River potentially occurs throughout the year. Bull trout intending to return to the Hood River from downstream of Bonneville Dam must pass upstream via one of several fish ladders. Only one PIT-tagged bull trout has been detected moving upstream through the fish ladders at Bonneville Dam. The detection history of this fish suggested it passed upstream through the ladder without being delayed and subsequently returned to the Hood River Subbasin.

#### *3.5.2.5 Aquatic Macroinvertebrates*

The Columbia River Basin is diverse in native aquatic macroinvertebrates. Although there is little information on the basinwide number and type of native aquatic macroinvertebrates inhabiting the study area, their importance has been well established through ecological studies. These benthic (bottom-dwelling) macroinvertebrates of river and reservoir habitats occupy habitats according to several parameters such as flow velocity, depth, temperature, and substrate types. They can serve as indicators of the overall integrity of an ecosystem and presence or absence of pollutants. Benthic organisms contribute vitally to the diets of fish, bird, and amphibian species. Freshwater aquatic macroinvertebrates provide energy transfer from detritus and algae to salmon and trout in the Columbia River Basin (Cederholm et al. 2000). Types of aquatic macroinvertebrates include insects, worms, and mollusks, and they are described in the following subsections according to whether they are native or non-native.

**NATIVE AQUATIC MACROINVERTEBRATES**

Native aquatic insects and worms are not well studied in the study area. According to BioAnalysts (2006), aquatic insect and worm taxa richness increased when more diverse habitat (e.g., vegetation, substrate) was present.

The five orders of aquatic insects most important to aquatic ecosystems in the study area are stoneflies (Plecoptera), mayflies (Ephemeroptera), caddisflies (Trichoptera), the aquatic beetles (Coleoptera), and many species of true flies (Diptera). Many insects lay their eggs in water, with early life stages (larvae) residing primarily on or associated with the river or reservoir bottom after hatching. They are important to aquatic ecosystems because they serve as food for many species and for the roles they play in nutrient cycling and detritus processing. Aquatic insects are classified into several functional categories including shredders (e.g., giant stoneflies), scrapers (e.g., case-maker caddisflies), and collector-gathers (e.g., minnow mayflies) based on feeding habits (Cummins and Klug 1979; Merritt and Cummins 1984). Food requirements can determine aquatic insect location and abundance in the study area (Cederholm et al. 2000).

Large aquatic insects, such as caddisflies, feed on larger organic particles and inhabit cooler water, while small aquatic invertebrates, such as *Daphnia* and other zooplankton, feed on fine organic particles and inhabit slow-moving water (Rondorf, Gray, and Fiarley 1990; Cederholm et al. 2000). Aquatic macroinvertebrates are important for nutrient recycling, in part because the macroinvertebrates break down dead organic matter, such as adult salmon carcasses and non-viable salmon eggs and fry, and then serve as food for juvenile salmon and resident fish (Rondorf, Gray, and Fiarley 1990; Cederholm et al. 2000).

In reservoirs, larger, long-lived species dominate the permanently wetted zone, whereas the varial zone contains mainly small, short-lived species. Larvae recolonize previously dewatered substrates as the reservoir fills, and shoreline areas are dominated by dipterans (flies) that produce cohorts throughout the warm summer months (Chisholm et al. 1989). Zooplankton are an important food source to fish in deep reservoirs. As benthic production may be constrained by water-level fluctuations, planktonic communities can be very productive and abundant in the euphotic zone of these waterbodies.

Along the length of the rivers that have been impounded, the prey base has changed since the construction of the dams, shifting from dominance of benthic organisms to dominance of open-water zooplankton. Benthic diversity in the lower Snake River reservoirs is relatively low and is dominated by midges and worms. The density of other taxa such as amphipods (*Corophium* sp.) and nematodes is also low. Mollusk diversity is substantially lower since the impoundment of the Snake River from over 30 mollusk species to just 7 (Frest and Johannes 1992). However, crayfish appear to be well established along rock substrate and riprap in the lower Snake River reservoirs; they provide an important food source for several fish species including northern pikeminnow, white sturgeon, channel catfish, and smallmouth bass, but not for juvenile salmonids.

Native, freshwater mollusks include clams, mussels, snails, and limpets (Adams 2003). Their importance in the Columbia River Basin comes from their ecosystem functions, and some species have cultural importance as food. Freshwater mollusks filter algae, bacteria, and plankton from water, and then expel unneeded materials, which becomes food for aquatic insects (Nedeau et al. 2009). Mussels stir benthic sediments, releasing nutrients and providing habitat for insect larvae for adherence to a substrate (Nedeau et al. 2009). Mollusks are also an important food source for mammals such as otters and raccoons (Nedeau et al. 2009).

The California floater mussel (*Anodonta californiensis*) and Columbia pebblesnail (*Fluminicola fuscus*) live in the Columbia River Basin (Oregon Biodiversity Information Center 2016). Freshwater mussels, such as the California floater, are long-lived and rely on fish as an intermediate host between the larval and juvenile mussel stages (Nedeau et al. 2009). Their life histories and habitat requirements are not well-known (Nedeau et al. 2009). According to Nedeau et al. (2009), three-quarters of the freshwater mussels in North America are in danger of becoming extinct and up to 35 species are possibly extinct. California floaters can live to 100 years old and prefer clear waterbodies with soft substrate (Pacific Biodiversity Institute 2018a). The Columbia pebblesnail is short-lived and prefers clear, cold streams (Pacific Biodiversity Institute 2018b). Little is known about other freshwater mollusk species in the Columbia River Basin.

**NON-NATIVE AQUATIC MACROINVERTEBRATES**

USGS lists 52 macroinvertebrates in the Columbia River Basin and coastal waters off Oregon and Washington as non-native aquatic species (USGS 2018a). Of these species, 30 invertebrates occur in the study area including copepods, gastropods, crayfish, amphipods, isopods, and one shrimp species, to name a few. Asian clam (*Corbicula fluminea*), New Zealand mudsnail (*Potamopyrgus antipodarum*), Siberian prawn (*Exopalaemon modestus*), and the copepod (*Pseudodiaptomus forbesi*) are widespread within the Columbia River Basin (USGS 2018a). Introduced (non-native) species can occasionally become invasive if there are no natural controls on their populations such as predators, lack of food, or harsh climate conditions. Established aquatic invasive macroinvertebrates tolerate high temperatures, increased turbidity, and slow water found in Columbia River System reservoirs (USGS 2018a).

Asian clam, Chinese mitten crab (*Eriocheir sinensis*), and New Zealand mudsnail primarily affect infrastructure (USGS 2018a). Asian clams and New Zealand mudsnails can clog pipes, while Chinese mitten crabs may destabilize banks or levees (USGS 2018a). Established aquatic invasive macroinvertebrates tolerate high temperatures, increased turbidity, and slow water found in Columbia River System reservoirs (USGS 2018a).

The Japanese fishlouse (*Argulus japonicus*), Chinese mitten crab, Northern crayfish (*Faxonius virilis*), and New Zealand mudsnail are the species with the greatest potential impact to native species in the study area (USGS 2018a). Japanese fishlouse parasitize native resident fish and affect feeding and growth (USGS 2018a). New Zealand mudsnails outcompete other benthic macroinvertebrates for space and food (USGS 2018a). Chinese mitten crabs and Northern crayfish outcompete native crabs for food and space. Northern crayfish increase turbidity, which can prevent native species from thriving (USGS 2018a). Other non-native macroinvertebrate species do not appear to interact with native species.

Siberian freshwater shrimp (or prawn; *Exopalaemon modestus*) were discovered in the lower Columbia River in 1995 and have since expanded to the lower Snake River reservoirs (Emmett et al. 2002; Erhardt and Tiffan 2016). The effects of the Siberian prawn on the Columbia River System have not been fully studied yet, but this species may compete with juvenile salmon by preying on native amphipods or by providing a food source for resident fish that consume salmon such as smallmouth bass, northern pikeminnow, or walleye (Haskell et al. 2006; Sanderson et al. 2009). The Siberian prawn diet contains a large percentage of opossum shrimp (*Neomysis mercedis*), which are native to the brackish lower Columbia River and can occupy freshwater lakes and slow-moving rivers (Haskell and Stanford 2006).

The opossum shrimp range has expanded 430 miles upstream from the mouth of the Columbia to the Lower Granite Reservoir in the Snake River; within the Columbia and Snake Rivers, their abundance is limited in areas with high water velocity (Haskell and Stanford 2006; Tiffan et al. 2017). The range expansion of opossum shrimp may have aided the establishment of Siberian prawn by providing a steady food source; in addition, opossum shrimp are consumed by fish such as smallmouth bass, a predator of juvenile salmon (Erhardt and Tiffan 2016; Tiffan et al. 2017). Opossum shrimp are omnivorous, and their diet consists of several species of zooplankton and what is likely detritus (organic particulate matter) from the river bottom (Tiffan et al. 2017). Although diet overlap may create competition for zooplankton between opossum shrimp and juvenile salmon, opossum shrimp can be a prey source for juvenile salmon (Tiffan, Erhardt, and St. John 2014; Tiffan et al. 2017). More information is needed to fully describe the food web effects of opossum shrimp (Tiffan, Erhardt, and St. John 2014).

Two macroinvertebrates that are not found in the Columbia River Basin but occur in adjacent watersheds are the zebra mussel (*Dreissena polymorpha*) and quagga mussel (*Dreissena rostriformis bugensis*) (USGS 2018a). Both species are of great concern because these species have become invasive; they clog water infrastructure pipes and grow out of control (USGS 2018a).

In 2014, the NPCC created a plan for fish and wildlife to help detect the presence of aquatic invasive species (NPCC 2014). The Council and its partners are monitoring for the presence of aquatic invasive species and are assisting with public education outreach to help educate stakeholders about the threats of aquatic invasive species to native species and aquatic ecosystems. The states of Idaho, Montana, Oregon, and, Washington have aquatic invasive species detection programs that include mandatory watercraft inspection stations located at strategic locations along or near state borders. Additionally, the states are monitoring for presence of these species and providing public education programs (Idaho.gov 2018; Montana.gov 2018; Oregon.gov. 2018; WDFW 2018).

### 3.5.3 Environmental Consequences

Operation, maintenance, and configuration of the CRS affect fish and aquatic habitat in multiple ways. Anadromous fish traveling to and from the ocean pass dams and reservoirs with passage both upstream and downstream, while resident fish may pass dams and reservoirs in their use of mainstem areas. Juvenile salmon and steelhead may pass through juvenile bypass systems, spillways, or turbines, or be collected and transported. Adult salmon and steelhead migrating upstream to their spawning grounds must use fish ladders, also called fishways. Dam operations may also alter river flows, affect water quality and temperature, create changes in reservoir elevations, affect the time it takes juvenile salmon to migrate downstream from their natal streams to the estuary (travel time). Dam operations also affect access to, and the quality of, critical and essential habitat. Section 3.2, *Hydrology and Hydraulics*, provides a detailed discussion of CRSO effects on hydrology, and Section 3.4, *Water Quality*, provides a detailed discussion of CRSO effects on water quality.

The environmental consequences analysis for anadromous fish (Section 3.5.1) is organized by species rather than by Regions A, B, C, and D in order to facilitate descriptions common to the species across specific runs throughout the Columbia Basin. The environmental consequences analysis for resident fish (Section 3.5.2) is organized by region because the effects on those species are similar in these geographic areas. With regards to potential effects in the Canadian portions of the Kootenai and Pend Oreille rivers downstream of CRS projects, the effects in this resource area under the No Action and multi-objective alternatives are expected to be similar to the effects described on those tributaries in the United States.

In both sections, effects to ESA-listed fish are generally displayed first, followed by unlisted fish. Changes to physical habitat characteristics important to fish, such as reservoir elevations, river flows, and water temperatures, are analyzed in detail in other sections (i.e., water quality [Section 3.4], hydrology and hydraulics [Section 3.2], and river mechanics [Section 3.3]) and only briefly reiterated in the fish analyses as important drivers of fish effects.

#### *3.5.3.1 Methodology*

**CONCEPTUAL ECOLOGICAL MODELS**

Conceptual ecological models (CEMs) were developed for key species to document a common understanding of the relationships between a species' needs and their environment and how controlling factors such as CRS operations can influence those environmental factors. CEMs consist of four levels:

- The species' life stages to fulfill their life cycle (i.e., eggs, larvae, juveniles, adults).
- The critical activities and processes an individual needs in order to successfully complete that life stage and move on to the next (i.e., habitat needs, food, predation avoidance, and migration).
- The environmental habitat elements that influence those critical activities and processes (i.e., water temperature, substrate, flows, nutrients, prey, and predators)
- Controlling factors that affect those habitat elements that, in turn, affect the critical activities or processes that species needs to successfully complete its life cycle.

Each of these levels is connected with a series of links (arrows) to demonstrate how controlling factors, habitat elements, critical activities and process, and life stages are related; how important that relationship is (magnitude); and how certain the scientific basis of these relationships is (link understanding). See Appendix E for more details and for CEMs developed.

**WORKSHOPS**

Multiple full day effects analysis workshops were held in Oregon, Washington, and Idaho during January through June 2019. Participants included fish experts from the three co-lead agencies as well as from many cooperating agencies. At the workshops, CEMs helped identify key relationships between the MOs and fish species, and application of those relationships at the location-specific level were discussed. Data from the water quality, hydrology/hydraulics, and other sources were then analyzed to produce quantitative or qualitative assessments of effects under the No Action Alternative and changes under the four MOs. Key relationships and how they would be affected under each alternative were recorded. This information was then used to draft the environmental consequences of the MOs. Different tools were used as appropriate to evaluate different anadromous fish species or resident communities.

**MODELS AND OTHER TOOLS TO ANALYZE EFFECTS TO ANADROMOUS FISH**

Tools available for anadromous salmonids varied by species, ESU, and DPS; the tools are described in the following sections. Salmon and steelhead ESUs and DPSs that had a basis for numerical modeling were the upper Columbia River spring Chinook salmon, upper Columbia River steelhead, Snake River spring Chinook salmon, and Snake River steelhead. Modeled outputs described below were used to evaluate the effects to these ESUs and DPSs that were numerically modeled. Other salmon and steelhead that exhibit similar migration characteristics (such as mid-Columbia and lower Columbia steelhead and salmon, sockeye salmon, and coho salmon) were evaluated using both qualitative and "surrogate" methodology where the outputs for a modeled species were used to provide insights to the effects of the other species (Table 3-60). Where an appropriate model or surrogate was not available, a qualitative evaluation of hydrology and water quality data was used to evaluate changes to the environmental factors important to the processes of the life stages, as illustrated by the CEMs. Species evaluated only qualitatively include fall-run Chinook salmon, Pacific eulachon, green sturgeon, Pacific lamprey, and American shad.

Fish models were available to predict several juvenile and adult survival metrics for upper Columbia spring Chinook salmon, upper Columbia steelhead, Snake River spring Chinook salmon, and Snake River steelhead. Where more than one model was available (i.e., both COMPASS and CSS), results from both are presented and discussed. Unless otherwise noted, quantitative results from COMPASS, CSS, and the Life Cycle Model (LCM) are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results.

Anadromous Fish models used in this analysis and the results they produced are discussed below, and with additional detail in Appendix E. All models described below that will be used for decision-making will go through the Corps of Engineer's required Independent External Review Process.

- Comprehensive Passage Model (COMPASS) – The COMPASS model produced juvenile survival metrics for upper Columbia and Snake River ESUs of spring Chinook salmon and steelhead. COMPASS estimates passage and survival rates based on relationships that were developed using a mix of hatchery and wild fish as its data source, therefore results for this EIS analysis are based on hatchery and wild stocks combined. COMPASS breaks survival into multiple individual route of passage survivals for each reach (spill, bypass, turbine, and other configuration routes for each dam).
- National Marine Fisheries Service (NMFS) Life Cycle Model (LCM) – The LCM used COMPASS inputs to produce estimates of adult return metrics for one population of upper Columbia spring Chinook salmon (Wenatchee) and for three major population groups of Snake River spring-run Chinook salmon (South Fork Salmon, East Fork Salmon, and Upper Salmon). The results were used for comparison purposes to illustrate the response of the upper Columbia and Snake River spring-run Chinook salmon ESUs, respectively, to each of the MOs. The NMFS LCM models were developed using a combination of hatchery and wild fish data and the results presented in this EIS analysis reflect expected responses from the combined hatchery and wild components of each population/MPG.

  Similar to analyses performed during the development of the 2019 NMFS BiOp on Columbia and Snake River operations, the LCM also used a sensitivity analysis to assess potential effects of reductions in latent mortality. The purpose was to better understand to what degree the other latent effects hypotheses could affect the NWFSC life cycle modeling outputs. The additional four NWFSC scenarios were 10 percent (1.10 multiplier), 25 percent (1.25 multiplier), 50 percent (1.50 multiplier), and 100 percent (2.0 multiplier) and were applied to the ocean survival of smolts that were estimated to have migrated in river, i.e. those juveniles not collected and transported at Lower Granite, Little Goose, or Lower Monumental Dams did not receive the multiplier benefit. The results of this analysis produced estimates of changes in adult return abundance should ocean survival improve due to reduced latent mortality

- Comparative Survival Study (CSS) – The CSS cohort modeling considered all fish originating from the Snake basin and related SARs and in-river metrics. The CSS also used a Grande Ronde LCM to produce juvenile and adult metrics for the Grande Ronde/Imnaha major population group of the Snake River spring-run Chinook and steelhead. CSS models treat the entire CRS as an aggregate of two routes of passage (number of powerhouses passed vs spilled on average). CSS models make statistical estimations of the effect of the freshwater CRS on latent ocean mortality. Results were used for comparison of the Snake River spring-run Chinook and steelhead ESUs to the MOs. The CSS models were developed using a combination of hatchery and wild fish data and the results presented in this EIS analysis reflect expected responses from the combined hatchery and wild components of each population/MPG. The CSS group also produced results that were based on wild fish only at the request of the co-lead agencies. Those results were considered but did not show fundamental differences from the combined hatchery/wild estimates. Because the CSS wild only estimates still do not reflect what survival would be for wild fish in the absence of hatchery fish, and in an effort to maintain as much consistency with the data used in the LCMs, the wild only data was not reported in this chapter but it is included as a memo in Appendix E.

***Indicators and Primary Metrics***

<u>Specific juvenile- and adult-modeled metrics</u>

The following measurements are included in ESU/DPS-specific sections for upper Columbia River spring Chinook salmon, upper Columbia River steelhead, Snake River spring Chinook salmon, and Snake River steelhead, where applicable:

- Average juvenile survival.
- Average juvenile travel times.
- Proportion of juveniles originating upstream of Lower Granite Dam that are destined for transport.
- Average number of powerhouse passage events[3] for a juvenile fish passing from Lower Granite or Rock Island Dam (as applicable) to Bonneville Dam. Transported fish or fish that do not survive to Bonneville would only experience a portion of the average powerhouse passage value listed for each ESU/DPS.
- Smolt to adult return rates (SARs) are expressed as a percentage of smolts migrating downstream from one specific point and returning to a specific point as an adult.
- Estimates of adult abundance for the populations modeled. It is important to note that adult abundance models are available only for a portion of the populations, and abundance should be used as an index to compare MOs rather than actual predicted abundances.
- All fish model metrics are presented in the primary results tables as a mean without estimates of either natural variance, or standard error representing sources of model

[3] The COMPASS and CSS cohort models use differing assumptions regarding structures that are surface and powerhouse passage routes. COMPASS characterizes turbine and bypass routes as powerhouse passage routes in calculations for powerhouse passage events, while CSS adds ice and trash sluiceways to the list of routes that are powerhouse passage routes.

uncertainty. The 80-year water record used as input for the models represents the long-term variance in seasonal flow, temperature and other environmental variables. In the appendix, 95 percent confidence intervals and standard deviation are presented for the in-river juvenile survival metric, and 50 percent and 95 percent quantiles are presented for adult abundance for the NWFSC life cycle model.

**COMPARISON OF COMPASS AND CSS MODELS**

COMPASS and CSS are models used to evaluate the effects of the Columbia River System. They can be viewed as best available model systems developed over two decades through collaborations of universities, state and federal agencies, and stakeholders. The models both describe fish survival and migration through the system and ocean but use different processes and selections of data. COMPASS links independently calibrated system (COMPASS 2008) and ocean survival models (Scheuerell et al. 2009) and in the future other factors (personal communication, Widner and Falkner). CSS describes the entire life cycle calibrated in a single integrated statistical process (McCann et al. 2017).

The models predict different outcomes for potential system actions, such as increased spill and dam removal. COMPASS predicts small increases in returns while CSS predicts increasing spill to 125 percent TDG would roughly double the adult salmon returns. These divergent predictions are striking because both models fit smolt system passage and adult return data from the late 1990s to the present reasonably well. Thus, it is difficult to evaluate the models based on their fits to data alone. While the models apply different assumptions and predict survival with different environmental variables on different temporal scales, the divergent predictions are the result of only a few critical assumptions. The paragraphs below highlight the assumptions, identify the critical ones, and illustrate how they along with critical data shape the different predictions.

- **System survival**: The models calibrated system survival using different data. COMPASS used hydroacoustic, PIT, radio and acoustic tagged juveniles after 1990 to calibrate daily reservoir and dam survivals. The covariates explaining the survival included daily river flow, temperature, and route-specific passage through the dams. CSS used "freeze-brand" marking method prior to 1990 and PIT tag data thereafter. In addition, the CSS calibration used SAR data collected by various methods from the 1960s. The number of powerhouses (PH) that juveniles passed through and the water travel time (WTT) explained the biweekly and seasonal survival. System survivals to Bonneville Dam were similar in the two models. Thus, the differences in assumptions and data do not explain the differences in the effect of system operations on adult returns.
- **Ocean survival:** The differences in how the models link system experience to ocean mortality is the critical factor in explaining effects of system operations on adult returns. In the COMPASS model, the day of year that juvenile fish arrive at Bonneville Dam and the daily river temperature residual both affect ocean survival (Scheuerell et al. 2009). In general, later arriving fish experience lower ocean survival. In turn, ocean arrival date depends on the date fish enter the system, river flow, and passage delay at dams. Higher

flows and spill reduce WTT and delay at dams, which together promote earlier ocean arrival and higher ocean survival. Importantly, the survival-arrival date relationship is only weakly linked to spill or PH passage. In contrast, CSS links PH passage to ocean survival such that the construction of dams through the 1970s resulted in greater PH passage with successive decreases in freshwater and ocean survival. Likewise, bypassing the PH and instead passing via spillways or surface passage routes increases ocean survival. Both models include environmental variables; COMPASS includes the residual of the daily river temperature and CSS includes an index of the ocean temperature anomaly, the Pacific Decadal Oscillation (PDO), plus an index of coastal upwelling.

- **Independent Scientific Review:** Both COMPASS and CSS have been through multiple rounds and various forms of scientific peer review. The COMPASS model was published in a peer-reviewed scientific journal when it was released in 2008 (Zabel et al. 2008). Similarly, as noted above, many of the underlying drivers to the results from the CSS model(s) are based on mechanisms that were published in peer reviewed journal submissions (e.g., Haeseker et al. 2012).

In addition to these reviews, the NW Power and Conservation Council's Independent Scientific Advisory Board (ISAB) has reviewed both models over the course of their development. The ISAB reviewed the initial stages of development for the COMPASS model when it was first released in 2007 (ISAB 2007-1 and ISAB 2008-3) for use during NMFS's preparation of the 2008 Biological Opinion. The ISAB has also review each CSS annual review report since the CSS 10-year retrospective analysis was released in 2007 (ISAB/ISRP 2007-6). The ISAB has provided both technical comments and guidance for the direction of future research areas.

As noted above, highly divergent predictions of smolt to adult return rates between the CSS and COMPASS models are driven by differing approaches to latent mortality employed by the two models. These different approaches have been one of the primary focuses of ISAB reviews.

The ISAB reviews have evolved over the past decade but still have not settled on a preferred approach to attribute the cause or magnitude of the effect of latent mortality. Guidance from the ISAB has evolved from a 2007 recommendation to stop attempting to measure absolute latent mortality (ISAB 2007-1). In 2012, ISAB recommended a continuation of research efforts to assess the potential causal mechanisms of observed latent effects associated with bypass systems (ISAB 2012-1) to determine if fish were being damaged by the bypass systems or if smaller weaker fish were being passed at higher rates through the bypass systems.

In 2017 (ISAB 2017-1), as part of its review of NMFS's life cycle modeling efforts that were being developed for use in the upcoming 2019 Biological Opinion, the ISAB again reviewed components of both the COMPASS and the CSS models. The large differences in predicted smolt-to-adult returns between the two modeling approaches elicited support from the ISAB to continue research and other analytical efforts to resolve remaining questions of whether increased spill levels could increase the SARs of salmonids that migrate through the CRS. In a response to that review, two separate spill test proposals were developed by the CSS and by NMFS (ISAB 2018-2). That review was at least a partial genesis for several of the multiple objective alternatives in this EIS analysis (i.e. block spill test in MO1 and spill to the 125 percent TDG cap in MO4).

Both groups continue to develop their models to address the ISAB's ongoing questions surrounding the magnitude and the causal mechanisms associated with latent mortality through the hydrosystem. The CSS continues to analyze and report each year on patterns in overall SARs. NMFS has recently focused on the ISAB's questions on the condition of fish using the powerhouse (more specifically the bypass systems). Their most recent publication (Faulkner et al. 2019) demonstrated size selective tendencies at many of the bypass systems in the CRS which would potentially reduce the benefit of increased spillway passage shown by the CSS model. Faulkner's efforts are consistent with McMichael et al. (2010) analyzed the passage of yearling Chinook with JSATs acoustic transmitters at multiple CRS dams, and found that on average, smaller fish used the bypass routes. The CSS has also investigated this issue and found that the location where fish were collected and tagged for study is also an important component. This could be one potential reason for the discrepancies between the model outputs. As the ISAB noted in their 2017 review of the CSS (ISAB 2017-2) (closely linked to the life cycle model review [2017-1] noted above), "Modeling flow, spill, and dam breach scenarios is very useful for policy makers. Consequently, it is important that all assumptions be clearly stated and that the results are robust to these assumptions. The same scenarios should be run through both models and discrepancies resolved."

- **Summary:** The COMPASS and CSS model systems both predict the effects of hydrosystem smolt passage on adult returns of salmon. The models express the freshwater and ocean mortalities using different variables and equations linking the variables to survival and adult returns. Both models fit the available SAR reasonably well but predict very different responses of SAR to spill. The COMPASS model attributes most of the recent variations in runs to ocean conditions and predicts small effects with changes in spill. The CSS model attributes approximately two-thirds of the 50-year decline in salmon runs to powerhouse passage and predicts significant run recovery by increasing spill. The essential differences in the models involves how they express the effect of freshwater passage experience on ocean mortality.
- **University of Washington TDG model-** This model, which is separate and distinct from either the COMPASS or CSS juvenile survival models, estimated juvenile survival by reach based on reach average exposure to TDG, average juvenile fish migration depth, and exposure timing. Water that passes through the spillway at mainstem dams can cause downstream waters to become supersaturated with dissolved atmospheric gasses. Supersaturated TDG conditions can cause GBT in adult and juvenile salmonids, resulting in injury and death (Weitkamp and Katz 1980). Because this model has not been evaluated thoroughly the survival metrics predicted by this model are reported in the appendices but are not discussed in the body of this analysis and are not expected to be used as a basis for

decision-making. TDG exposure predictions are used to show relative changes in TDG amongst the alternatives.

As noted above, the similarities and differences in the two CSS models as well as COMPASS will be the subject of IEPR, the results of which will inform the final version of this EIS. The UW TDG model will also be analyzed in the IEPR process. These models are all discussed in additional detail in Appendix E.

**SURROGATES/QUALITATIVE ANALYSIS**

For some fish species, there is limited or no information on species-specific relationships for CRS dam and reservoir passage.

Consequently, how these species may respond to system changes is qualitatively assessed using modeling results from a similar species (surrogate) where similarities have been established between the species in order to assume similar impacts. Surrogate species were selected based on outmigration characteristics, life history, and timing similarities. Species with surrogates for passage effects analysis are shown in Table 3-60. The results of both COMPASS and CSS passage modeling were considered for the designated surrogate species, if available, and any key differences in passage between non-modeled and surrogate modeled species are noted. Use of species surrogates is consistent with Recovery Plans and previous ESA consultations. A more detailed description of the evaluation of surrogate data is presented in Appendix E.

**Table 3-60. Fish Species for Which Surrogates Were Used for Effects Analysis**

| Species Evaluated | Surrogate Used for Analysis |
|---|---|
| Lower Columbia River Chinook | Snake River spring/summer-run Chinook |
| Middle Columbia Spring Chinook | Upper Columbia River spring-run Chinook |
| Lower Columbia River steelhead | Snake River steelhead |
| Middle Columbia River steelhead | Upper Columbia River steelhead |
| Upper Columbia sockeye | Upper Columbia River spring-run Chinook |
| Snake River sockeye | Snake River spring/summer-run Chinook |
| Lower Columbia River coho | *Juveniles*- Snake River spring/summer-run Chinook<br>*Adults*- Snake River fall Chinook (qualitative) |
| Upper Columbia River coho | *Juveniles*- Upper Columbia River spring-run Chinook<br>*Adults*- Columbia River fall Chinook (qualitative) |
| Snake River coho | *Juveniles*- Snake River spring/summer-run Chinook<br>*Adults*- Snake River fall Chinook (qualitative) |
| Columbia River chum | Snake River spring/summer-run Chinook |

## Resident Fish

All resident fish were evaluated during the workshops to qualitatively assess changes to the important relationships described by the CEMs and considered local knowledge of how fish species interact with their environment and one another at the fish community level. See Appendix E for the suite of CEMs developed for this EIS. Resident fish in the basin have far less quantitative information that anadromous species; no numerical predictive models were used.

Effects to resident fish were analyzed by eight subbasin teams using predicted metrics, such as water flow, elevation, temperature, and DO. Relationships between these metrics and biological metrics, as informed by the CEMs, were used to describe expected changes to habitat elements, such as productivity, the number of resident fish that are swept downstream past the dams due to flows (i.e., entrainment), and habitat losses based upon existing literature or local information. Where possible, quantitative data such as the volume of productive reservoir, percent changes in outflows, retention time, feet change in elevations, etc. were used to describe habitat effects, otherwise qualitative analyses were completed using existing literature and expert knowledge from local managers. The teams used this information to qualitatively analyze effects to fish resources. See Appendix E, Qualitative Analyses, for a more detailed description of the effects analysis and documentation methodology.

**Macroinvertebrates**

Consistent data regarding macroinvertebrate habitats and populations in the Columbia River Basin are lacking. To analyze the effects of MOs to these resources, the teams used existing literature to compare expected outcomes from the MOs using the hydrology and water quality outputs, similar to resident fish analyses.

#### *3.5.3.2 Summary of Findings from Primary Analyses of Alternatives*

Table 3-61 and Table 3-62 below provide a very high-level overview of the detailed analysis of each alternative that follows in this chapter. Quantitative estimates presented in the tables below generally represent the average result from model runs that incorporated 80 different annual river flow scenarios, each with a different volume and run-off timing component. Because the quantitative results below are not presented with any estimates of uncertainty or statistical precision (e.g. standard error, or confidence bounds) these estimates are best suited for relative comparisons of the differences between alternatives, rather than comparisons between models. It is also important to note that for any given measurement type, the CSS, and LCM models may produce results for differing river reaches.

**Table 3-61. Overview of Alternative Analysis**

### *3.5.3.3 No Action Alternative*

**ANADROMOUS FISH**

**Salmon and Steelhead**

Several different ESUs and DPSs of salmon and steelhead share a similar life cycle and would experience similar effects under the No Action Alternative but also have specific traits that affect the units differently from one another. Common effects analyses across all salmon and steelhead are discussed first, followed by analysis of effects specific to each ESU/DPS. Note the common effects described in this section are not repeated in the species-specific sections but assumed to apply unless stated otherwise. Also, unless otherwise noted, quantitative results from COMPASS, CSS, and the Life Cycle Model (LCM) are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results.

***Ongoing Existing Mitigation Programs***

There are numerous actions to benefit salmon and steelhead in the Columbia River Basin. Below Chief Joseph Dam, ongoing activities for anadromous fish would continue, including tributary habitat improvement actions for ESA-listed anadromous stocks, estuary habitat improvement actions for juvenile salmonids and steelhead species, and fish hatchery programs as discussed in a few examples below.

<u>Habitat</u>

Throughout Regions C and D, the Bonneville F&W Program annually funds tributary habitat improvement actions for ESA-listed anadromous stocks, such as Snake River steelhead distinct population segment, Snake River spring/summer Chinook salmon evolutionary significant unit, and the Middle Columbia steelhead distinct population segment. Examples of these habitat improvement actions include the following: fish passage and barrier removal; fish screening; instream flow acquisition; habitat protection through acquisition; river, floodplain and wetland habitat improvements; and riparian planting and fencing. For example, the Shoshone-Bannock Tribes of the Fort Hall Reservation have enhanced over five miles of the Yankee Fork Salmon River to promote anadromous and resident fish habitat.

Further, in Region D, co-lead agencies would continue to implement habitat restoration actions in the Columbia River Estuary. These actions primarily focus on the restoration of disconnected tidally influenced floodplain ecosystems for all juvenile salmonids and steelhead species in order to provide greater opportunity, access, and capacity for juvenile salmonid and steelhead rearing conditions.

<u>Hatcheries</u>

In Region B, the Confederated Tribes of the Colville Reservation operate the Chief Joseph Hatchery on the Colville Reservation below Chief Joseph Dam, releasing smolts to increase the abundance of adult summer/fall and spring Chinook to the Okanogan River and Columbia River mainstem above the Okanogan River confluence for conservation and harvest purposes, and assist in re-establishing a fourth population of upper Columbia River spring Chinook in the Okanogan River Basin through reintroduction of an experimental population under the ESA.

In Region C, Bonneville F&W Program-funded hatchery programs include the captive propagation for critically endangered Snake River sockeye, Snake River spring/summer Chinook supplementation, Snake River fall Chinook supplementation and the reconditioning of Snake River steelhead kelts. For example, the Nez Perce Tribal Hatchery produces Snake River spring/summer Chinook and Snake River fall Chinook. Further, the Springfield Hatchery, located near American Falls, Idaho, was constructed to address recovery objectives for ESA-endangered Snake River Sockeye Salmon. Dworshak National Fish Hatchery produces juvenile steelhead to mitigate for the construction of Dworshak Dam.

In Region D, Bonneville F&W Program-funded hatchery programs include coho reintroduction and supplementation in the Mid-Columbia, through hatcheries like the newly constructed Melvin R. Sampson Hatchery operated by the Yakama Nation, and reconditioning of Mid-Columbia steelhead kelts. Bonneville also funds WDFW to produce chum salmon fry in the Columbia River estuary. The Dalles and John Day Dams Mitigation Program produces fall Chinook to mitigate for the construction of the dams.

***Effects Common Across Salmon and Steelhead***

<u>Summary of Key Effects</u>

A variety of factors, including project structures, surface passage modifications, natural mortality, and predation affect juvenile migration and survival at the lower Columbia River and lower Snake River projects. Adult migration is affected by dam passage, predation, and temperature and flow conditions. The measures in the No Action Alternative are not expected to change these factors, although temperature and flow conditions may be impacted by climate change. Unless otherwise noted, quantitative results from COMPASS and the Life Cycle Model (LCM) are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results.

<u>Juvenile Migration/Survival</u>

Juvenile salmon and steelhead can pass dam structures on the Columbia River by spillways, turbines or bypass structures. For each species of salmon, each route has an associated frequency and median survival rate. In general, bypass and spillway routes are associated with relatively higher juvenile salmon survival than turbines routes. Spill levels, spill patterns, and turbine priorities also have significant effects on the survival rates of migrating juveniles via their influence on tailrace hydraulics and the formation of eddies. As a result, alternatives that route more fish through turbines would be associated with lower juvenile survival. Currently, the majority of all juveniles pass the federal dams via spillway routes. Estimates from studies to evaluate route specific survival show that between 70 and 97 percent of all juvenile salmon pass via spillway routes. Currently, survival rates from these routes range from 97 to 99 percent (Ploskey et al. 2012). Under the No Action Alternative, these survival rates would continue.

Spill affects juvenile migration routes through the projects. Increased spill generally reduces travel time as fish find spill routes more readily than turbine routes. The forebays of dams provide habitat for reservoir predators, and the likelihood of encountering predators is increased as juvenile salmon spend more time searching for a passage entrance. Additionally, more spill generally means fewer powerhouse encounters, which would increase survival because turbines are generally associated with lower juvenile survival. Spill is not expected to change under the No Action Alternative. However, under this alternative, the co-lead agencies have incorporated expected improvements from new turbines designed for improved fish passage (IFP). Three new IFP turbines are currently being installed at Ice Harbor dam, and all turbines at McNary Dam are expected to be replaced between 2022 and 2032.

All four lower Columbia River and four lower Snake River CRS projects have available surface passage routes and/or structures in addition to 24-hour spring and summer spill programs to facilitate faster juvenile passage and higher survival. The surface passage modifications operated at the dams are generally among the highest survival routes available for juvenile salmonids, and their influence on improving spill passage efficiency and reducing forebay delay has been tested and monitored over time to meet performance criteria. Dam tailraces can increase predation risk when juvenile fish are pulled in eddies or countercurrents, and entrainment into spillway stilling basins increases the risk of injuries. Optimum tailrace hydraulics are achieved when flows are balanced among all spillway and turbine routes to achieve uniform downstream flow, which is influenced by overall discharge and spill levels. Most bypass outfalls at CRS dams have been relocated to ensure that smolts are not released into areas prone to eddies or slow velocities. Most Snake River fish pass the four lower Snake and four lower Columbia CRS projects, while the upper Columbia River fish pass up to five non-Federal middle Columbia River dams and four lower Columbia River CRS projects. Depending on model output and data availability, effects were generally evaluated for federally owned and operated projects but in some cases included passage effects associated with passage at the middle Columbia PUD projects. A variety of factors other than project structures, such as river flows, can affect the rate of downstream migration of juveniles and may affect juvenile migration and survival.

Several measures in the No Action Alternative can affect juvenile fish transportation rates, including *Storage Project Operations*, *Lower Columbia and Snake River Operations*, *Spill Operations to Improve Juvenile Passage*, and *Fish Passage Plan*, and the extent of these effects differ by fish population. The greatest effects to transport result from impacts from flows and the proportion of flow spilled. The greater the proportion of the flow that is spilled, the fewer fish available for transport. Under the No Action Alternative, approximately 39 percent of all Snake River Chinook and 40 percent of all Snake River steelhead would be destined for transport. Only Snake River species are transported.

Biological monitoring shows that the incidence of GBT in migrating smolts remains between 1 and 2 percent when TDG concentrations in the upper water column remain below 120 percent of saturation in CRS project tailraces (NMFS 2019). TDG modeling predicted that the average exposure to juveniles on their migration route for all species would be about 115 percent for the No Action Alternative. This value is relatively high, but current observations of similar values have not revealed high levels of injury or mortality for yearling Chinook salmon.

Colonial waterbirds that eat fish (i.e. piscivorous birds)—especially terns, cormorants, and gulls—are having a measurable impact on juvenile salmonid survival in the Columbia River (NMFS 2019), both as proximate and direct sources. Management efforts are ongoing toto reduce salmonid consumption by terns in the lower Columbia River, and similar efforts are in progress to reduce the nesting population of double-crested cormorants in the estuary. The Corps has been implementing the Caspian Tern and Double-crested Cormorant Management Plans. Predation rates have been reduced at the managed locations in the estuary and inland nesting sites, but due to the reduction in habitat and hazing actions, terns and cormorants have dispersed to other locations within the basin that are outside of the authority of the co-lead agencies. Moderate reductions in predation by colonial waterbirds in the Columbia River System and estuary resulting from the avian management plans are expected to continue under the No Action Alternative through the measures of *Reduce Caspian Terns on East Sand Island in the Columbia River Estuary* and *Double-crested Cormorant Management*.

Native northern pikeminnow, and non-native walleye, smallmouth bass, and channel catfish are major predators of juvenile salmonids in the Columbia River (reviewed in ISAB 2015). The Northern Pikeminnow Management Plan was initiated in 1990 to reduce predation of juvenile salmon and steelhead. Before the start of the Northern Pikeminnow Management Plan in 1990, northern pikeminnow were estimated to eat about 8 percent of the 200 million juvenile salmonids that migrated downstream in the Columbia River each year. Williams et al. (2017) compared current estimates of northern pikeminnow predation rates on juvenile salmonids to before the start of the program and estimated a median reduction of 40 percent. Under the No Action Alternative, these rates are expected to continue. Additionally, non-native northern pike are present in Lake Roosevelt and, despite current suppression efforts, are likely to invade further downstream, adding another piscivorous (i.e., fish eating) predator to salmon and steelhead migration routes. Non-native walleye, smallmouth bass, channel catfish, and northern pike would continue to consume an additional unknown number of juvenile salmon and steelhead under the No Action Alternative.

Adult Migration/Survival

CRS factors that affect the survival rates of migrating adults include dam passage, where adults must find and ascend ladders and re-ascend the ladders if they fall back through spillways or other routes. Another factor is straying to non-natal tributaries either naturally or as a result of impaired homing stemming from transport, hatchery rearing (Westley et al. 2013), or other factors, such as temperature and flow conditions that can increase energetic demands of migrating fish and predation (Keefer et al. 2004; NMFS 2008a). In general, higher flows and higher spill levels lead to longer migration timing and can contribute to site specific delays for adult salmonids through the CRS projects. High water temperatures can cause migrating adult salmon to stop or delay their migration or can increase fallback after ascending fish ladders. During upstream migration, a temperature difference of more than 2°C in the fish ladders compared to river water can also delay adult migration. Under typical conditions, after accounting for harvest, adult salmonids typically have relatively high migration success through lower Columbia River and lower Snake River dams and reservoirs within the CRS (Keefer et al. 2016).

Adult migration success is not expected to change over time due to these factors under the No Action Alternative, but water temperature and flow changes expected from climate change, and their potential effects on fish species, are discussed in Chapter 4, Climate Change.

Seals and sea lions (pinnipeds) eat returning adult salmon and steelhead in the estuary and upstream to Bonneville Dam (Brown et al. 2017; Chasco et al. 2017; NMFS 2019), though occasionally some pinnipeds move up into the Bonneville pool as well. Similar to many natural fish passage impediments (e.g., waterfalls, cascades), dams or dam operations can also delay or create concentrations of adult fish searching for ladder entrances (Quinones et al. 2015), which can in turn make adult salmon and steelhead in those locations more vulnerable to predation by pinnipeds (Stansell 2004; Naughton et al. 2011). Given that the populations of Steller's and California sea lions have experienced average annual increases of 4.888 percent and 6.2 percent, respectively since the1980s, pinniped predation rates are expected to continue increasing under the No Action Alternative. However, the predation rates at Bonneville Dam can be affected through pinniped hazing and removal. Spill operations under the No Action Alternative do not appear to affect sea lion predation downstream of Bonneville Dam.

Biological monitoring shows that the current incidence of GBT in migrating adults remains between 1 to 2 percent when TDG concentrations in the upper water column remain below 120 percent TDG saturation in CRS project tailraces (NMFS 2019). GBT can reduce adult salmon and steelhead fitness and the number of fish returning to spawn. Operations under the No Action Alternative target spill levels less than 120 percent TDG through the *Spill Operations* and *Water Quality Plan for TDG and Water Temperature* measures; however, high river discharges can occasionally result in TDG levels above 120 percent.

***Upper Columbia River Salmon and Steelhead***

Upper Columbia River salmon and steelhead migrate past up to five non-Federal dams and reservoirs that also impact the survival and passage of these species. The co-lead agencies do not dictate generation or spill levels at these projects operated by the Public Utility Districts of Douglas, Chelan, and Grant counties; therefore, adult and juvenile metrics, such as powerhouse encounter rate, are not directly affected but are influenced by river flow levels coming through the upper Basin. The timing and volume of flow levels affected by CRS operational decisions are reflected in model analysis from McNary Dam to Bonneville Dam or from Rock Island Dam to Bonneville depending on model output. CSS model results are not available for upper Columbia stocks. Additional model output is presented in Appendix E.

Upper Columbia River Spring-Run Chinook Salmon

*Summary of Key Effects*

COMPASS estimates juvenile survival of upper Columbia River spring-run Chinook salmon from McNary Dam to Bonneville Dam would be 69.5 percent under the No Action Alternative. While no estimates of adult survival were generated as part of the CRSO EIS, the 10-year average survival for adult upper Columbia River spring-run Chinook salmon from Bonneville to McNary Dam is 91.5 percent. The CSS did not analyze effects of any alternative on Upper Columbia Chinook salmon so there are no results presented in this section. For context, CSS estimates of smolt-to-adult returns based on run reconstruction are provided but these estimates do not necessarily entirely reflect the No Action Alternative.

*Juvenile Migration/Survival*

The COMPASS model was used to estimate juvenile survival, travel time, for upper Columbia River spring-run Chinook salmon from McNary Dam to Bonneville Dam, and powerhouse encounters from Rock Island to Bonneville under the No Action Alternative. TDG average exposure was calculated as the level of TDG that a specific group of fish would experience as they migrate, at depth, through the system.

Under the No Action Alternative, J upper Columbia spring-run Chinook salmon survival rates from McNary Dam to Bonneville Dam under the No Action Alternative would be approximately 70 percent. By comparison, Widener et al. (2018) reported that hatchery-origin juvenile upper Columbia River spring-run Chinook salmon survival rates for this same reach of river averaged 84 percent from 2008 to 2017. TDG average exposure was calculated as the level of TDG that a specific group of fish would experience as they migrate, at depth, through the system. Table 3-63 shows TDG conditions at Bonneville, McNary, and Chief Joseph dams. Modeling also shows that these fish would be exposed to an average TDG during migration of nearly 116 percent under the No Action Alternative. This value is relatively high, but current monitoring of similar values has not revealed high levels of injury or mortality (Table 3-64).

**Table 3-63. Juvenile Model Metrics for Upper Columbia River Spring Chinook Salmon (Hatchery and Wild Fish Combined) under the No Action Alternative.**

| Metric (Model) | NAA |
|---|---|
| Juvenile Survival (COMPASS) (McNary to Bonneville) | 69.5% |
| Juvenile Travel Time (COMPASS) (McNary to Bonneville) | 6.1 days |
| % Transported (COMPASS) | No upper Columbia River spring-run Chinook transported |
| Powerhouse Passages (COMPASS) (Rock Island to Bonneville) | 3.29 |
| TDG Average Exposure (TDG Tool) (McNary to Bonneville) | 115.9% TDG |

**Table 3-64. Percent of Days with TDG above 120 Percent and 125 Percent at Bonneville, McNary, and Chief Joseph Dam, in the No Action Alternative.**

| Project | % of days above 120% TDG | % of days above 125% TDG |
|---|---|---|
| Bonneville Dam | 10.8 | 3.2 |
| McNary Dam | 6.8 | 2.1 |
| Chief Joseph Dam | 0.0 | 0.0 |

*Adult Migration/Survival*

Upstream passage survival estimates were not generated for adult salmon. However, the historic 10-year average survival estimate for upper Columbia River spring-run Chinook salmon from Bonneville to McNary Dam is 92 percent. These survival estimates account for total losses caused by the operation and existence of the dams and reservoirs, as well as any losses in these reaches resulting from any flow effects, temperature, disease, straying, or other natural causes (NMFS 2019). Columbia Basin spring-run Chinook salmon stray rates have consistently been less than 5 percent, though some case studies have had estimates ranging to more than 20 percent (Keefer and Caudill 2012). Adult migration success is not expected to change over time due to these factors under the No Action Alternative.

The NWFSC LCM estimated that SARs for the Wenatchee upper Columbia River spring-run Chinook salmon population would be 0.94 percent under the No Action Alternative. As an index to compare the No Action Alternative to the MOs, the NWFSC LCM predicts that the median abundance of the Wenatchee population would be 498 adult fish returns.

Prospective CSS cohort and lifecycle modeling was not available across MOs for the upper Columbia salmon populations. However, though not a representation of the No Action Alternative, the CSS calculated SARs for upper Columbia populations from their reconstructions of adult and juvenile population abundance trends at about 1 percent for Wenatchee population and two percent to three percent for the Methow population (Table 3-65).

**Table 3-65. No Action Alternative Model Metrics for Adult Upper Columbia River Spring-Run Chinook Salmon**

| Metric (Model) | NAA |
|---|---|
| SARs (NWFSC LCM – RIS to BON) | 0.94 |
| NWFSC LCM abundance | 498 |

<u>Upper Columbia River Steelhead</u>

*Summary of Key Effects*

COMPASS modeling estimates that juvenile upper Columbia steelhead survival from McNary Dam to Bonneville Dam would be 65.8 percent under the No Action Alternative. While no estimates of adult survival were generated; the ten-year average survival for adult upper Columbia River steelhead migrating upstream from Bonneville Dam to McNary Dam is 92 percent.

*Juvenile Migration/Survival*

COMPASS model estimates of juvenile survival, travel time and powerhouse passage for upper Columbia River steelhead under the No Action Alternative are shown in Table 3-66. CSS modeling was not available for upper Columbia River steelhead.

The predicted juvenile upper Columbia River steelhead survival of 65.8 percent for the No Action Alternative is within the range of observed data. Widener et al. (2018) estimated that the average hatchery-origin juvenile steelhead survival rates from McNary Dam tailrace to Bonneville Dam was 74 percent for 2008 to 2017. The method of estimating survival through this area of the Columbia River has been done historically with PIT tagged fish. Low PIT tag detection efficiencies at and below Bonneville Dam have resulted in increased variability around the average survival estimate, ranging from 49 to nearly 100 percent in 2008 to 2017. Similar to results for upper Columbia spring-run Chinook salmon, modeling for upper Columbia steelhead, shows they would be exposed to an average TDG during migration of over 115 percent under the No Action Alternative. This value is relatively high, but current monitoring of similar values has not revealed high levels of injury or mortality.

**Table 3-66. Juvenile Model Metrics for Upper Columbia River Steelhead (hatchery and wild fish combined) under the No Action Alternative.**

| Metric (Model) | NAA |
|---|---|
| Juvenile Survival (COMPASS) (McNary to Bonneville) | 65.8% |
| Juvenile Travel Time (COMPASS) (McNary to Bonneville) | 6.6 days |
| % Transported (COMPASS) | No transport of upper Columbia steelhead |

| Metric (Model) | NAA |
|---|---|
| Powerhouse Passages (COMPASS) (Rock Island to Bonneville) | 2.72 |
| TDG Average Exposure (TDG Tool) (McNary to Bonneville) | 116% TDG |

Predation on juvenile steelhead from the Upper Columbia River has been estimated in the interior Columbia plateau at two managed sites, Goose Island (Potholes Reservoir) and Crescent Island in the mainstem Columbia River. In the Potholes Reservoir, avian predation by Caspian terns on upper Columbia River steelhead has declined from up to nearly 23 percent in 2009 to approximately 4 percent in 2017 and has been eliminated at Crescent Island since management actions commenced and loss of nesting habitat occurred in 2015 (Collis et al. 2018; Evans et al. in press; Appendix E). As the number of nesting Caspian terns were reduced at Goose Island and upstream at Crescent Island, there was an increase in abundance at Blalock Islands in the John Day reservoir. This shift in abundance has generally increased avian predation rates on juvenile steelhead in this reach, more specifically an increase in juvenile upper Columbia River steelhead predation from less than one percent to up to eight percent. Similar predation rates would be expected for upper Columbia River steelhead under the No Action Alternative.

Adult Migration/Survival

Upper Columbia steelhead would continue to experience upstream adult migration as described in Section 3.5.2.1, *Common Effects to Salmon and Steelhead*.

No life cycle modeling was completed for adult upper Columbia River steelhead. However, the 10-year average historic survival estimates for these fish, migrating upstream from Bonneville Dam to McNary Dam, is 92 percent (range of 88 to 97 percent). In addition, substantial losses (about 24 percent) of adult upper Columbia River steelhead appear to be occurring between McNary and Priest Rapids dams. These survival estimates account for total losses caused by the operations and existence of the dams and reservoirs, as well as any losses in these reaches resulting from any flow effects, temperature, disease, or other natural causes (NMFS 2019). Some of these losses may result from straying. However, most estimates of steelhead straying in the Columbia River basin have been for Snake River summer-run populations. Median straying estimates were typically between 3 to 10 percent, although some point estimates were considerably higher (Bumgarner and Dedloff 2011; Keefer and Caudill 2012). Adult migration success is not expected to change over time due to these factors under the No Action Alternative.

Downstream migration of iteroparous steelhead (i.e., steelhead that spawn more than one time, also known as kelts) occurs from March through July (Keefer et. al. 2016). Kelt migration can be affected by the extreme energetic demands of spawning and iteroparity, harvest, and the Columbia River System (Colotelo et al. 2014) and non-federal dams. Normandeau et al. (2014) conducted an direct survival adult steelhead balloon tagging study at McNary Dam and found that mean survival of steelhead passing through the temporary spillway weirs was 98 percent and 91 percent through the turbine route, for overwintering adults presumed to be in good condition. As part of a two-year study, Colotelo et al. (2013) estimated that 67 percent survived from the McNary forebay to the Bonneville Dam face. See discussion of Snake River adult steelhead for an expanded discussion of the kelt research described above.

<u>Upper Columbia River Coho Salmon</u>

See upper Columbia spring-run Chinook salmon analysis as a surrogate for juvenile upper Columbia coho salmon. Upper Columbia fall Chinook salmon analysis is considered as a qualitative surrogate for adult Upper Columbia coho salmon.

*Summary of Key Effects*

The primary challenges for upper Columbia River coho salmon are the conditions they encounter during upstream and downstream migrations. Downstream survival and migration for juveniles is dependent on water flow and routing at the dams. Higher flows and higher spills generally lead to higher survival. See Upper Columbia River spring run Chinook salmon for estimated, surrogate measures of juvenile survival.

<u>Upper Columbia River Sockeye Salmon</u>

See Upper Columbia River Chinook salmon analysis as a surrogate for Upper Columbia River sockeye salmon.

*Summary of Key Effects*

The primary challenges for upper Columbia River sockeye salmon are the conditions they encounter during upstream and downstream migrations. Downstream survival and migration for juveniles is dependent on water flow and routing at the dams. Higher flows and higher spills generally lead to higher survival.

For adults, the primary issue is high water temperatures during summer upstream migration. Upper Columbia sockeye salmon do not have significant hatchery influence so inferences would only apply to the naturally spawning population.

After passing upstream of McNary Dam, adult upper Columbia sockeye migrate past three to five PUD owned dams and reservoirs that also impact the survival and passage of this species. The federal agencies do not dictate generation or spill levels at these projects so juvenile metrics such as powerhouse encounter rate are not directly affected but are influenced by river flow levels coming through the upper Basin. The timing and volume of flow levels affected by CRS operational decisions are reflected in model analysis from McNary to Bonneville and can be referenced for surrogate species, Upper Columbia River spring Chinook salmon.

*Juvenile Migration/Survival*

Juvenile travel time affects the upper Columbia River sockeye survival during this life stage. Upper Columbia River spring-run Chinook salmon survival is used as a surrogate for upper

Columbia River sockeye. Under the No Action Alternative, juvenile sockeye are assumed to continue a similar survival rate with the same proportion of fish encountering powerhouses (e.g., the number of sockeye expected to pass through turbines and bypass systems would be similar to the number of upper Columbia River spring-run Chinook). Passage route selection in acoustic telemetry studies of upper Columbia River sockeye that were conducted by Grant County PUD support this statement (Timko et al. 2010, 2011).

River flows can affect the downstream migration rate of juvenile sockeye. Looking at the low-flow conditions (in which 75 percent of years exceed the discharge) of April 15 through June 15 when sockeye are migrating downstream, the discharge is approximately 208,000 cfs. In the No Action Alternative, the surrogate species of upper Columbia spring-run Chinook salmon may provide a conservative estimate of upper Columbia River sockeye salmon travel times. Acoustic telemetry studies have been conducted by the mid-Columbia River public utility districts and provide ancillary information, specifically Grant County PUD between 2006 and 2010, where they found that sockeye survived at a higher rate and traveled faster than yearling Chinook salmon and juvenile steelhead (Timko et al. 2011; Blue Leaf 2012). Survival of juvenile sockeye in reaches between Rock Island and McNary dams was higher in all reaches by a minimum of 5 percent and a maximum of 15 percent when compared to yearling Chinook and juvenile steelhead migrating through the same reaches with similar run timing and passage histories. Travel times by juvenile sockeye in 2006-2010 through these reaches were also faster by approximately five days, compared to those modeled in the NAA alternative of surrogate species (e.g., 15 days by upper Columbia River yearling Chinook salmon).

Juvenile sockeye are susceptible to predation by other larger fish during their downstream migration. Under the No Action Alternative, an unknown number of juvenile sockeye would be removed from the population by predators. Literature estimates that smallmouth bass, walleye, and northern pikeminnow remove large numbers of smolts. While it is difficult to measure and quantify losses of sockeye, temperature during outmigration can be used as a surrogate for estimating risk of loss to predators. The mean water temperature from April 15 through May 31 at McNary Dam is 1200°C under the No Action Alternative and can be used for comparisons of qualitative increases or decreases in predation risk for the MOs in relation to the No Action Alternative.

Avian predation on juvenile salmon is another important factor of surviving their outmigration. Predation rates on juvenile upper Columbia River sockeye are not well documented; however, since 2010, predation rates by the Caspian tern nesting colony at the Blalock Islands Complex on Snake River sockeye has averaged one percent (Evans et al. in press). Nesting habitat and avian predation rates would remain the same under the No Action Alternative and therefore predation rates should remain similar (one percent or less).

TDG during the migration period can affect juvenile and adult sockeye in the form of GBT; the condition is more stressful for juvenile fish, which are more susceptible because they tend to swim at shallower mean depths (Backman and Evans 2002). The No Action Alternative is expected to continue at the same rate as presently occurs each year and similar to the surrogate species, upper Columbia River spring-run Chinook salmon.

*Adult Migration/Survival*

See the Effects Common across Salmon and Steelhead section (Section 3.5.2.4), for an overview of adult migration/survival effects on salmon and steelhead under the No Action Alternative.

Higher water temperatures correspond to lower adult survival during upstream migration and survival can be less than 50 percent when water temperature is greater than 18°C. When the Okanogan River gets to 21° to 22°C, fish stop moving into the river; survival then depends on temperatures in the Columbia River where they hold in refuge. The migration period is early June through mid-August; therefore, the important metric is the percentage of days the daily mean temperature exceeds 18°C at McNary and Chief Joseph Dams. Recent data shows McNary Dam has 72.4 percent of days in this period above 18°C and Chief Joseph Dam has 24.9 percent of days above 18°C. These conditions are expected to continue under the No Action Alternative and have adverse effects to the species when present. Survival is expected to continue to be less than 50 percent during years that are warmer than average.

<u>Upper Columbia River Summer/Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

Key effects to upper Columbia summer/fall-run Chinook salmon include high predation rates of juvenile fish and elevated water temperatures during adult upstream migration. An estimated 50 percent of all juvenile Chinook salmon do not survive from Priest Rapids Dam to McNary Dam (Harnish et al. 2014). These fish are lost through predation by birds or other fish. In addition, elevated water temperatures can delay adult migration. Water temperatures currently reach over 68°F approximately 1 in 3 days during the summer/fall migration.

*Larval Development/Juvenile Rearing*

Adequate spawning habitat is limited in the Columbia River. The Vernita Bar, located downstream of Priest Rapids Dam, is a critical spawning site for upper Columbia summer/fall-run Chinook salmon in the Columbia River. Water level management is important for spawning in this reach and can have adverse effects if water levels are dropped by desiccating eggs or stranding fry. An agreement called the Vernita Bar Agreement was reached in 2004 and maintains a minimum outflow of 70,000 cfs to guarantee adequate spawning habitat for Chinook salmon below Priest Rapids Dam during spawning and incubation. To evaluate effects to spawning habitat, investigators calculated the frequency of meeting the Vernita Bar Agreement. Under the No Action Alternative, the agreement is met in all years.

Water quality is important for egg and fry incubation and development. Specifically, water temperatures over 68°F and TDG over 120 percent were selected as metrics to evaluate adverse effects to early life stages of Chinook salmon. The frequency of days that exceeded these values were used to evaluate effects. Under the No Action Alternative, no days were projected with values for temperature or TDG would exceed critical levels.

*Juvenile Migration/Survival*

Compared with yearling Chinook and steelhead, subyearling fall Chinook typically migrate deeper in the water column and are less likely to use surface spillway routes. An estimated 50 percent of juvenile upper Columbia summer/fall-run Chinook salmon are lost before they reach McNary Dam to birds or other predators (Harnish et al. 2014). Water temperature can affect juvenile salmon survival via predation. As temperatures increase, aquatic predators become more active and metabolic demands increase. Consequently, risk to predation for juvenile salmon increases. To analyze potential effects of MOs, an increase or decrease in water temperatures during migration was used as a surrogate for predation risk. To measure effects to predation risk, the number or percent of days, May through August, with mean temperatures over 20°C was used to compare MOs. Currently, water temperatures exceed 20°C approximately 42 percent of the time. These water temperatures would impact juvenile Chinook salmon survival through the mechanisms listed above; however, it is unknown what total number of these fish are lost to predation. The No Action Alternative is expected to continue the existing conditions.

Avian predation on juvenile salmon is another important factor impacting their surviving during outmigration. Snake River fall-run Chinook salmon predation rates from avian predators at East Sand Island ranged from 0.7 to 3.4 percent for Caspian terns and from 1.6 to 8.7 percent for Double Crested Cormorants (Evans et al. 2018). Similar rates of predation are expected for upper Columbia River summer/fall-run Chinook salmon. Nesting habitat for birds would remain the same under the No Action Alternative.

During juvenile outmigration, instances of higher turbidity can decrease predation rates because reduced clarity of water hides juveniles so their susceptibility to predation decreases. The No Action Alternative is expected to have no changes to timing and duration of higher turbidity.

*Adult Migration/Survival*

The frequency that water temperatures at McNary Dam exceeded 20°C July through November was used as a measure of potential migration delay for upper Columbia River summer/fall-run Chinook salmon. In the No Action Alternative, over 34 percent of days between July and November would be over 20°C. Most of these days occur in July and August. Adult summer run Chinook typically migrate from the start of June through early August, and the tail end of the run may continue to be affected by elevated temperatures in late July and August. The start of the fall Chinook migration typically starts in August when temperatures still exceed 20°C, and peaks in September when temperatures decline.

During upstream migration, a temperature difference of more than 2°C in the fish ladders compared to river water can delay adult migration. Water temperature differentials at the fish ladders are most concerning June through September when elevated temperatures are most likely to create differences that may lead to adult migration delays. At McNary Dam, less than 3 percent of days from June through September would have ladder differentials greater than 2°C. Under the No Action Alternative, these limited events are expected to continue.

Other water quality parameters include sediment levels measured in total suspended solids and DO concentrations. Both parameters are measured in milligrams per liter (mg/L). The average sediment concentrations in current conditions are approximately 2 mg/L and no change is anticipated in the No Action Alternative. The typical DO concentrations in the Snake River are between 9.5 and 11 mg/L, which poses no trouble for fish species. Under the No Action Alternative, no adverse effects are expected from the oxygen concentrations.

***Middle Columbia River Salmon and Steelhead***

<u>Middle Columbia River Spring Chinook Salmon</u>

See quantitative results from the Upper Columbia River Spring Chinook analysis as a surrogate for Middle Columbia River Spring Chinook Salmon.

*Summary of Key Effects*

Middle Columbia River spring Chinook salmon are not ESA-listed and limited migration/survival data exists. The primary challenges for middle Columbia River spring Chinook salmon are the conditions they encounter during upstream and downstream migrations. Downstream survival and migration for juveniles is dependent on water flow and routing at the dams. Higher flows and higher spills generally lead to higher survival. See Upper Columbia River spring Chinook salmon for estimated, surrogate measures of juvenile survival. Middle Columbia River spring Chinook salmon would experience similar survival rates, although they traverse a shorter distance than their upper Columbia River counterparts, they pass the same dams from McNary to Bonneville Dam and their juvenile and adult migration timing and survival would be similar.

<u>Middle Columbia River Steelhead</u>

Refer to upper Columbia River steelhead analysis as a surrogate for middle Columbia River steelhead.

*Summary of Key Effects*

Key effects for middle Columbia River steelhead include delays during upstream adult migration from elevated water temperature and reduced survival during downstream migration, similar to the results of surrogate species, upper Columbia River steelhead.

*Juvenile Migration/Survival*

Middle Columbia River steelhead would experience similar survival rates under the No Action Alternative. Although middle Columbia River steelhead traverse a shorter distance than their surrogate, upper Columbia River steelhead, they pass the same federal dams from McNary Dam to Bonneville Dam. Because effects to middle Columbia River steelhead were not modeled, upper Columbia River steelhead were used as a surrogate species to evaluate effects of MOs on middle Columbia

Predation on juvenile steelhead from the middle Columbia River has not been estimated in the interior Columbia plateau; however, predation rates would be similar to upper Columbia River steelhead under the No Action Alternative. Refer to the results of Upper Columbia Steelhead as a surrogate for Middle Columbia River Steelhead.

*Adult Migration/Survival*

No smolt to adult return rates were calculated for upper or middle Columbia River steelhead. Refer to the results of Upper Columbia Steelhead as a surrogate for Middle Columbia River Steelhead.

Each summer, when the mainstem Columbia River temperature increases to above 18°C, a large portion of middle Columbia River steelhead seek cool water temperature refuge in cooler tributaries such as the Little White Salmon, White Salmon, or Deschutes Rivers, or in deeper/cooler mainstem areas within the Columbia River. In July and August, during the peak of the middle Columbia River steelhead adult migration, the sun warms the water in the top portion of the reservoirs, which can lead to high temperatures and water temperature differences in the fish ladders. Ladder temperatures exceeding 20°C and water temperature differences greater than 1.8 degrees Fahrenheit have been demonstrated to cause delay in steelhead and can reduce their successful migration to the streams in which they were born (Caudill et al. 2013). Ladder temperatures commonly exceed 20°C and ladder differentials regularly exceed 1.8 degrees Fahrenheit while middle Columbia River steelhead are migrating (McCann 2018). During the most extreme summer days, ladder temperatures in CRS dams can exceed 75.0°F, and ladder differentials can exceed 4.5 degrees Fahrenheit (FPC 2019). This would continue under the No Action Alternative.

A proportion of middle Columbia River steelhead from the John Day major population group (MPG) do not enter the John Day River in the summer, likely because of elevated water temperatures. Based on PIT detections, many of these fish migrate past the John Day River in the summer and overshoot McNary Dam, presumably to find cooler water until the John Day River cools. A large portion of these fish do not attempt to migrate back downstream through McNary Dam until after prescribed spill has ended in August, and a smaller portion do not attempt downstream migration until after the juvenile bypass system has shut down in mid-November. Some of these fish overwinter in the McNary Reservoir or further upstream. This leaves the turbines as the only available passage route for many of these fish, which is the lowest survival route for adult steelhead. Research conducted since the implementation of the 2008 FCRPS Biological Opinion has demonstrated the spillway weir is the most effective and safe route to pass adult steelhead at McNary Dam. Normandeau et al. (2014) conducted an adult steelhead balloon tagging study at McNary Dam and found that 98.0 percent of the steelhead passing the temporary spillway weir survived and were injury-free. The fish passed through the turbine unit had significantly lower survival (91 percent) and more life-threatening injuries, presumably caused by blade strike and shear forces. Colotelo et al. (2013) also found that the survival of adult steelhead kelts through spillways and surface weirs was high (>95 percent), and survival through turbine units was lower (<80 percent), indicating that overshoots survive at a higher rate when spill protection is provided when they migrate back downstream.

Downstream migration of iteroparous steelhead (i.e. steelhead that spawn more than one time, also known as kelts) occurs from March through July (Keefer et. al, 2016). Kelt migration can be affected by the extreme energetic demands of spawning and iteroparity, harvest, and the Columbia River System (Colotelo et al. 2014) and non-federal dams. Normandeau et al. (2014) conducted an direct survival adult steelhead balloon tagging study at McNary Dam and found that mean survival of steelhead passing through the temporary spillway weirs was 98 percent and 91 percent through the turbine route, for overwintering adults presumed to be in good condition. As part of a two-year study, Colotelo et al. (2013) estimated that 67 percent survived from the McNary forebay to the Bonneville Dam face.

Predation effects to summer migrating adult middle Columbia River steelhead are likely relatively small because pinniped numbers are generally low in July and August, when most middle Columbia River steelhead pass Bonneville Dam, and the steelhead are mixed with relatively abundant fall-run Chinook salmon migrating in September and October.

#### ***Snake River Salmon and Steelhead***

<u>Snake River Spring/Summer-Run Chinook Salmon</u>

*Summary of Key Effects*

COMPASS and CSS modeling estimates of juvenile Snake River spring/summer-run Chinook salmon survival range from 50.4 to 57.6 percent, respectively, with substantially different estimates for the number of Snake River spring/summer-run Chinook salmon that would be transported. The two models also predict significantly different smolt-to-adult return rates.

*Juvenile Migration/Survival*

COMPASS and CSS cohort models both provide estimates of juvenile survival metrics (Table 3-67). Results below reflect combined natural and hatchery origin juvenile Snake River spring/summer Chinook salmon in-river survival. It is important to note that hatchery Snake River spring-run Chinook salmon have about 15 percent higher in-river survival rate than natural origin Snake River spring-run Chinook, but Snake River summer-run Chinook salmon for both hatchery and natural origin juveniles have similar in-river survival rates (Buchanan et al. 2010). The COMPASS and CSS cohort model estimates are reported as the average value based on the 80-year water record estimates for both hatchery and natural origin fish. The values are provided below, but these metrics are best used for relative comparison purposes between MOs.

**Table 3-67. Juvenile Model Metrics for Snake River Spring/Summer Chinook Salmon (Hatchery and Wild Fish combined) under the No Action Alternative.**

| Metric (Model) | NAA |
|---|---|
| Juvenile Survival (COMPASS) | 50.4% |
| Juvenile Survival (CSS) | 57.6% |
| Juvenile Travel Time (COMPASS) | 17.7 days |
| Juvenile Travel Time (CSS) | 15.8 days |
| Juveniles Transported (COMPASS) | 38.5% |
| Juveniles Transported (CSS) | 19.2% |
| Juvenile Transport: In-River Benefit Ratio (CSS) | 0.86 |
| Juvenile Powerhouse Passages (COMPASS) | 2.25 |
| Juvenile Powerhouse Passages (CSS) | 2.15 |
| TDG Average Exposure (TDG Tool) | 115.1% |

All Estimates are from Lower Granite Dam to Bonneville Dam.

For comparison with historic survival rates, Widener et al. (2018) estimated that juvenile Snake River spring-run/summer Chinook salmon survival rates (wild and hatchery combined) from Lower Granite to Bonneville Dam averaged 53 percent (ranging from 44 to 64 percent) for the same time period. These survival rates incorporate multiple sources of mortality such as passage mortality, natural mortality, and predation (NMFS 2019).

Juvenile fish transportation is also a factor in returning adult conversion rate as fish pass back up through the CRS years later, though other factors such as temperature, spill, and catch are more important to upstream system survival (Crozier et al. 2016). Overall, transported Snake River spring/summer-run Chinook salmon tend to have relatively low rates of straying (Gosselin et al. 2018).

Wild yearling Chinook salmon tend to have the lowest transport benefit, and hatchery yearling Chinook salmon and hatchery steelhead tend to have higher benefits from transport. In addition, fish transported later in the year generally show greater benefits from being transported late and to transporting hatchery fish. For the No Action Alternative, CSS cohort modeling predicts a season-wide Transport:In-River benefit ratio for natural origin yearling Chinook salmon of 0.86 for comparison with alternatives. However, season wide TIR ratios can be misleading as benefits of transport vary within season. For example, in most years, beginning in May, adult returns are higher for transported spring summer Chinook than for in river fish (Smith et al. 2013).

*Adult Migration/Survival*

See the Effects Common across Salmon and Steelhead section, Section 3.5.2.2, No Action Alternative, for an overview of adult migration/survival effects on salmon and steelhead under the No Action Alternative.

The 10-year average (2008 to 2017) minimum survival estimate for hatchery and natural origin Snake River spring/summer-run Chinook salmon from Bonneville to McNary Dam is 89 percent, with range of 83 to 100 percent, and from Bonneville to Lower Granite Dam is 84 percent, with range of 77 to 94 percent (NMFS 2019). These survival estimates account for total losses from the dams and reservoirs, as well as any losses in these reaches resulting from any flow effects, temperature, disease, or other natural causes (NMFS 2019).

Columbia Basin spring-run Chinook salmon stray rates have consistently been less than 5 percent, though some case studies have had estimates ranging to more than 20 percent (Keefer and Caudill 2012). Adult migration success is not expected to change over time due to these factors under the No Action Alternative.

For Snake River spring/summer-run Chinook salmon specifically, seal and sea lion presence in the Columbia River appears to coincide with salmon upstream migration timing (Tidwell et al. 2017). While pinniped injury to some degree adversely affects conversion to spawning tributaries, pinniped-caused injury rates decrease as annual run sizes increase, indicating density dependent or saturation effects in some years (Naughton et al. 2011). Pinniped predation rates are expected to continue to increase under the No Action Alternative.

Under the No Action Alternative, SARs for Snake River spring/summer-run Chinook salmon were estimated at 0.88 and 2.00 for NMFS and the Fish Passage Center models, respectively (Table 3-68). These numbers are similar to values observed in recent years for this species. Overall Lower Granite to Bonneville SARs for wild Snake River Chinook with jacks included have ranged from 0.30 to 4.13 (arithmetic mean of 1.32 percent) between 2000-2016 (Table B.2, 2018 Final CSS Report).

**Table 3-68. Model Metrics Related to Adult Survival and Abundance of Snake River Spring/Summer Chinook Salmon under the No Action Alternative**

| Metric (Model) | NAA |
|---|---|
| LGR-BON SARs (NWFSC LCM) | 0.88 |
| LGR-BON SARs (CSS) | 2.0 |
| NWFSC LCM abundance | 2,351 |
| Abundance (CSS)[1/] | 6,114 |

1/ CSS provided results for six populations in the Grande Ronde/Imnaha Major Population Group. The absolute values represent those populations only.

Snake River Steelhead

*Summary of Key Effects*

Modeled estimate of in-river survival is near the recent observed survival rates of juvenile Snake River steelhead between Lower Granite Dam and Bonneville Dam, which were estimated on average at 56 percent from 2008 to 2017. Over the same period, the average upstream survival for these adult fish from Bonneville Dam to McNary Dam was 94 percent, and survival from Bonneville Dam to Lower Granite Dam was 87 percent. Juvenile transport continues to show an overall benefit for Snake River steelhead. However, the degree of benefit has decreased as in-river survival has increased. Additionally, the proportion of fish being transported has steadily declined since 2008.

*Juvenile Migration/Survival*

Survival of juvenile Snake River steelhead from Lower Granite to Bonneville Dam is estimated at 42.7 and 57.1 percent for COMPASS and CSS modeling, respectively (Table 3-69). By comparison, Widener et al. (2018) estimated historic juvenile Snake River steelhead survival rates (wild and hatchery combined) from 2008 to 2017 for this same reach at 56 percent. These survival rates incorporate multiple sources of mortality, such as passage mortality, natural mortality, and predation (NMFS 2019).

**Table 3-69. Juvenile Model Metrics for Snake River Steelhead under the No Action Alternative**

| Metric (Model) | NAA |
|---|---|
| Juvenile Survival (COMPASS) | 42.7% |
| Juvenile Survival (CSS) | 57.1% |
| Juvenile Travel Time (COMPASS) | 16.4 days |
| Juvenile Travel Time (CSS) | 16.2 days |
| Transported (COMPASS) | 39.7% |
| Transported (CSS) | Unknown |
| Transport:In-River Benefit Ratio (CSS) | 1.41 |
| Powerhouse Passages (COMPASS) | 1.73 |
| Powerhouse Passages (CSS) | 1.96 |
| TDG Average Exposure (TDG Tool) | 115.1 % TDG |

The effectiveness of the juvenile fish transportation program is evaluated annually, and juvenile transport continues to show an overall benefit for Snake River steelhead. However, the degree of benefit has decreased as in-river survival has increased and the proportion of fish being transported has decreased subsequent to the increase in spill and the later transport collection dates that were implemented for juvenile yearling spring-run Chinook salmon and steelhead in 2006 (NMFS 2019). The experience of transportation as juveniles is a factor influencing conversion rate of returning adults as fish pass back up through the CRS years later, especially for natural origin steelhead (Keefer et al. 2008). Recent transport rates (2008 to 2017) have averaged 34 and 32 percent for wild and hatchery Snake River steelhead, respectively (NMFS 2019). For No Action Alternative modeling, the transportation start date was April 25 under the *Juvenile Fish Transportation in the Columbia and Snake Rivers* measure. CSS cohort modeling estimated the average season-wide transport to in-river SAR ratio (TIR) for Snake River steelhead at 1.41 for comparison to MOs, based on both hatchery and natural origin fish. However, season wide TIR values can be misleading as the benefits of transport vary within season, where fish transported later in the year generally show greater benefits from being transported.

*Adult Migration/Survival*

The historic 10-year average (2008 to 2017) minimum survival estimate for Snake River steelhead adults from Bonneville Dam to McNary Dam was 94 percent, with range of 90 to 100 percent, and the minimum survival estimate from Bonneville Dam to Lower Granite Dam was 87 percent, with range of 81 to 94 percent (NMFS 2019). Most estimates of steelhead straying in the Columbia River basin have been for Snake River summer-run populations. Median straying estimates for Snake River steelhead are typically between 3 to 10 percent, although some point estimates were considerably higher (Bumgarner and Dedloff 2011; Keefer and Caudill 2012). Adult migration success is not expected to change over time under the No Action Alternative, but Chapter 4 discusses anticipated effects of climate change.

For Snake River steelhead specifically, Steller sea lions in particular aggregate at the base of Bonneville Dam in the fall when Snake River steelhead are present. Adjusted consumption estimates for all steelhead at the tailrace of Bonneville Dam by pinnipeds is 1.5 percent (Tidwell et al. 2018). Based on the timing of the observations in the study, NMFS (2019) stated that 1.5 percent is a reasonable estimate for Snake River steelhead mortality due to pinnipeds.

Migration of iteroparous steelhead (kelts) occurs from March through July (Keefer et. al, 2016). Migration success rates from Lower Granite Dam to downstream of Bonneville Dam was estimated at 4.1 and 15.6 percent in 2001 and 2002, respectively (Wertheimer and Evans, 2005). These estimates represent total mortality to outmigrating kelts and were derived in a low flow year with very little spill (2001) and a more normal flow year with spill (2012). In 2013, Colotelo et al. (2014) estimated that 27 percent of kelt migrated successfully from Lower Granite Dam to below Bonneville Dam. The majority of kelts utilized spillways and surface flow outlets to pass dams when those routes were available. For example, Rayamajhi et al. (2013) estimated fish passage efficiency (passage routes other than turbines) at 91 and 84 percent in 2013 at The Dalles and Bonneville Dams, respectively. At both projects passage survival through spillways and surface flow outlets was estimated in the low 90s while turbine passage survival was estimated in the low70s. Normandeau et al. (2014) conducted an adult steelhead balloon tagging study at McNary Dam and found that 98 percent of the steelhead passing the temporary spillway weirs were injury-free. The fish released through the turbine unit had more life-threatening injuries, presumably caused by blade strike and shear forces. Colotelo et al. (2013) also found that the survival of adult steelhead kelts through spillways and surface weirs was high (greater than 95 percent) and survival through turbine units was lower (less than 80 percent), indicating that kelts and potentially steelhead overshoots survive at a higher rate when spill protection is provided when they migrate back downstream.

Table 3-70 displays the CSS model results for Snake River steelhead. NWFSC LCM modeling for Snake River steelhead was not available. Overall Lower Granite to Bonneville SARs for wild Snake River steelhead have ranged from 0.25 to 3.95 (arithmetic mean of 2.03 percent) between 2006-2015 (Table B.36, 2018 Final CSS Report).

**Table 3-70. Model Metrics Related to Adult Survival and Abundance of Snake River Steelhead under the No Action Alternative**

Snake River Coho Salmon

See Snake River spring/summer-run Chinook as a surrogate for juvenile Snake River coho salmon and Snake River fall-run Chinook as a surrogate for adult Snake River coho salmon.

*Summary of Key Effects*

The primary effects for Snake River coho salmon involve both downstream and upstream passage through eight Federal dams and their reservoirs. Changes in dam reservoir environments in the Snake River may affect the susceptibility of Snake River juvenile coho salmon to fish-eating predators (e.g., channel catfish, walleye, pikeminnow, and smallmouth bass), which become more active at warmer water temperatures.

Snake River Sockeye Salmon

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for Snake River sockeye salmon.

*Summary of Key Effects*

The primary issues for Snake River sockeye salmon are the conditions encountered during upstream and downstream migrations. Longer downstream juvenile migration passage and timing at projects put sockeye salmon at risk for effects associated with higher water temperatures, predation, or physical effects over a longer period than historically occurred. For adult sockeye salmon, the primary issue is high water temperatures.

*Juvenile Migration/Survival*

Data for Snake River spring/summer run Chinook salmon were used as a surrogate for Snake River sockeye salmon to analyze survival and travel time. Snake River sockeye salmon typically display faster travel times and migrate at a deeper depth than Chinook salmon, so they likely experience shorter travel times than those estimated by the surrogate species, under the No Action Alternative. Studies conducted by the middle Columbia River PUDs have also found juvenile sockeye to migrate at faster rates than yearling Chinook salmon (Timko et al. 2011; Blue Leaf 2012). Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for Snake River sockeye salmon in Section 3.5.3.2.

Spill affects juvenile migration routes through the projects under the *Spill Operations to Improve Juvenile Passage* measure of the No Action Alternative. Increased spill generally reduces travel time as fish find spill routes more readily than turbine routes. Additionally, more spill generally means fewer powerhouse encounters, which would increase survival by not going through turbines. Snake River sockeye salmon are assumed to have similar survival rates and powerhouse encounter rates as Snake River spring/summer run Chinook salmon under the No Action Alternative.

Under the No Action Alternative, approximately 65,000 (11 percent) Snake River sockeye salmon would be transported annually through the *Juvenile Fish Transportation in the Columbia and Snake Rivers* measure. Because there are relatively few studies that evaluate the benefits of transportation for Snake River sockeye salmon, there is less certainty regarding the effects of these operations.

TDG during the migration period can affect juvenile and adult Snake River sockeye salmon in the form of GBT. The parameter of concern is the number of days over 120 and 125 percent at Bonneville, McNary, and Lower Granite dams (Table 3-71). The No Action Alternative is expected to continue with similar rates to observed data.

**Table 3-71. Percent of Days with TDG above 120 Percent and 125 Percent in the No Action Alternative**

| Project | % of days above 120% TDG | % of days above 125% TDG |
|---|---|---|
| Bonneville Dam | 10.8 | 3.2 |
| McNary Dam | 6.8 | 2.1 |
| Lower Granite Dam | 2.7 | 1.3 |

Juvenile Snake River sockeye salmon are susceptible to predation by other larger fish during their downstream migration. Literature estimates indicate that smallmouth bass, walleye, and northern pikeminnow remove large numbers of sockeye salmon smolts. However, under the No Action Alternative, it is difficult to measure and quantify these effects to Snake River sockeye salmon. Temperature during outmigration is sometimes used as a surrogate for estimating risk of loss to predators. However, the mean water temperature from April 15 to May 31 at McNary Dam is only 12.03°C and is unlikely to increase the metabolic rates of predators that eat more migrating smolts due to increased food needs associated with the higher water temperatures. Changes in predation rates under the No Action Alternative are not expected.

Avian predation on juvenile salmon is another important factor of surviving their outmigration. Roby et al. (2017) estimated avian predation of Snake River sockeye salmon at 5.9 percent. These rates are not expected to change under the No Action Alternative.

*Adult Migration/Survival*

See the Effects Common across Salmon and Steelhead section, under Section 3.5.2.2, for an overview of adult migration/survival effects on salmon and steelhead under the No Action Alternative.

Historic returns for Snake River sockeye salmon are so variable that the analysis used Snake River spring/summer-run Chinook salmon as a surrogate for Snake River sockeye salmon. For analysis of life cycle models and a description of potential latent effects of the CRS, refer to the Snake River spring/summer-run Chinook salmon section of the No Action Alternative.

Recent Snake River sockeye adult survival rates (2013 to 2017) from Bonneville Dam to McNary Dam have averaged about 60 percent, and adult survival from Bonneville Dam to Lower Granite Dam has averaged about 50 percent (NMFS 2019). These survival estimates account for total losses from all sources, including from effects from the dams and reservoirs, flow, temperature, disease, or other natural causes. Estimated survival rates for PIT-tagged sockeye salmon from Lower Granite dam to Redfish Lake, the Sawtooth Hatchery weir, or other locations vary from just over 0 percent to greater than 70 percent depending on water conditions and migration timing of a given year (Johnson et al. 2017). In addition, earlier fish survive at higher rates and fish that pass Lower Granite Dam after the first week in July generally do not survive to reach the Sawtooth Valley (Crozier et al. 2014; NMFS 2019). Adult migration success is not expected to change over time due to these factors under the No Action Alternative.

To reach Redfish Lake and their home spawning areas, this population of fish swims upstream more than 900 miles with an elevation gain of over 6,500 feet. Along this route, Snake River sockeye salmon encounter eight dams. Adult Snake River sockeye salmon encounter upstream migration difficulties in the form of reduced homing ability if they were transported downstream as juveniles, as well as high water temperatures and TDG levels. The water temperature differential between river water and fish ladder water can often make sockeye salmon hesitate to enter and ascend the ladders.

Adult sockeye salmon that were transported downstream as juveniles exhibit a higher rate of fallback (i.e., salmon that pass two or more times the same project on the same day or on a later day), reduced homing ability, and longer migration time on their upstream migration compared to the fish that migrated in-river as juveniles. This causes a longer adult upstream migration time, which takes more energy and can reduce fitness for spawning once the destination is reached. Approximately 39 percent of juveniles are transported, and transported sockeye salmon are 2.9 times more likely to fall back and experience delay as adults (Crozier et al. 2015). This rate is expected to continue under the No Action Alternative.

Higher water temperatures correspond to lower adult survival. Adult survival rate has been less than 50 percent when water temperature is greater than 18°C measured at Bonneville Dam. High temperatures can also cause delays in upstream migration. Under the No Action Alternative, temperatures would exceed 18°C at Ice Harbor approximately 78 percent of all days during the sockeye salmon migration (June 21 to July 31).

During upstream migration, a temperature differential of more than 2°C in the fish ladders compared to river water can delay adult migration. During adult migration (June 21 to July 31), approximately 50.1 percent of all days have a temperature differential greater than 2°C. This would continue under the No Action Alternative.

Other water quality parameters include sediment levels measured in total suspended solids and DO concentrations. Both parameters are measured in mg/L. The average sediment concentrations in current conditions are approximately 2 mg/L and no change is anticipated in the No Action Alternative. The typical DO concentrations in the Snake River are between 9.5 and 11 mg/L, which poses no adverse effect for fish species. Under the No Action Alternative, no adverse effects are expected from the oxygen concentrations.

<u>Snake River Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

Unlike most other ESUs discussed, Snake River Fall Chinook salmon spawn within the mainstem of the Snake River; therefore, the area that would be directly impacted by the operation of CRS projects could impact larval development and juvenile rearing.

*Larval Development/Juvenile Rearing*

For eggs to develop properly in their gravel nests, called redds, the adult spawners must have access to acceptable sizes of spawning gravel; the appropriate gravel size allows for water to bring in oxygen and clear wastes from the embryos until they grow to fry size and emerge from the gravel. Suitable sediment sizes for spawning are between 1 and 6 inches (Geist and Dauble 1998). Within the lower Snake River, fall Chinook spawning habitats are limited to tailwater areas of each of the four lower Snake River dams and sections of the Clearwater and Snake River above Lower Granite Dam. Under the No Action Alternative, spawning sites are not expected to change.

Some juvenile Chinook salmon that originate in the Clearwater River use reservoirs as rearing habitat and overwinter in reservoirs before migrating downstream as yearlings. Under the No Action Alternative, all reservoirs that support this life history type would continue to provide juvenile rearing habitat.

*Juvenile Migration/Survival*

Temperature affects juvenile salmon survival via predation, increased energetic requirements, and susceptibility to disease (e.g., columnaris). During the juvenile outmigration period, concentrations of juvenile salmonids at dam structures make them more susceptible to predators that are larger fish (e.g., channel catfish, walleye, pikeminnow, and smallmouth bass), which become more active at warmer water temperatures. The threshold for higher risk is thought to be 20°C, but these predators become active at even cooler temperatures. To analyze potential effects to juvenile from predation, an increase or decrease in mainstem temperatures during migration is used as a surrogate for predation risk. Average temperature at Ice Harbor Dam between May and July is measured and the risk index is calculated as the percent of days over 20°C. The Snake River's mainstem water temperatures have a mean temperature of 16.5°C and 26.6 percent of days over 20°C. Current water temperatures have minor effects to juvenile Chinook salmon through the mechanisms listed above; however, it is unknown what total number of these fish are lost to predation. The No Action Alternative is expected to continue the existing conditions.

Bird predation on juvenile salmon is another factor that determines juvenile salmon surviving their outmigration. It is estimated that gulls, cormorants, terns, and pelicans consume 11.6 percent of Snake River fall-run Chinook salmon (Evans et al. 2018). Nesting habitat is used as a measure for predation risk from bird predators. These risks would remain the same under the No Action Alternative.

During juvenile outmigration, instances of higher turbidity can decrease predation rates because reduced clarity of water hides juveniles so their susceptibility to predation decreases. The No Action Alternative is expected to have no changes to timing and duration of higher turbidity.

Approximately 1.5 million Snake River Fall Chinook salmon would be transported under the No Action Alternative each year (39 percent). Recent studies indicate that there is an advantage to transporting Snake River Fall Chinook later in the season. Smith et al. (2017) suggested transporting these fish, beginning on July 1 each year, would maximize returns.

*Adult Migration/Survival*

Adults migrating upstream have been studied for effects of having been barged downstream as juveniles and were found to have increased straying rates relative to juveniles that completed in-river migration downstream to the estuary (Bond et al. 2017). The effect can be estimated from the proportion and timing of juveniles transported downstream from collector projects. Bond et al. (2017) found that adult fall-run Chinook salmon bound for the Snake River were more likely to stray into the upper Columbia River if they were barged as juveniles. Under the No Action Alternative, *Juvenile Fish Transportation in the Columbia and Snake Rivers* measure, fall-run Chinook transportation would continue at approximately 39 percent of the juvenile outmigrant population. While this action improves the total number of fish that return, it would continue the rate of straying to other tributaries and basins.

High water temperatures can cause migrating adult salmon to stop or delay their migration or can increase fallback after ascending a dam. When they exceed 20°C, water temperatures delay adult migration during summer/fall. To analyze potential effects, the frequency that water temperatures in the reach of Lower Granite to Bonneville Dam exceed 20°C August to September was used as measured at McNary and Ice Harbor Dams. At McNary Dam, 58.3 percent of all days are over 20°C, and at Ice Harbor, 54.3 percent of days are over 20°C. During August and September under the No Action Alternative, nearly 60 percent of all days at McNary and Ice Harbor Dams are expected to be over 20°C. Delays in adult migration are expected due to elevated temperatures during August. The effect becomes reduced downriver in this reach.

During the peak migration period through the dams (August and September), approximately 50.1 percent of all days have a temperature differential greater than 2°C.

In addition to finding appropriate gravel sizes, the depth of water is necessary for successful deposit of fertilized eggs into the gravel. Fall Chinook salmon vary in the depth of water they select; the range in the Snake River Basin was found to be from 3 to 26 feet deep (1.0 to 8.1 m;

Geist and Dauble 1995; Dauble et al. 1999). The No Action Alternative would not change current conditions in the CRS project area.

Other water quality parameters include sediment levels measured in total suspended solids and DO concentrations. Both parameters are measured in mg/L. The average sediment concentrations in current conditions are approximately 2 mg/L, and no change is anticipated in the No Action Alternative. The typical DO concentrations in the Snake River are between 9.5 and 11 mg/L, which poses no adverse effect for fish species. Under the No Action Alternative, no adverse effects are expected from the oxygen concentrations.

***Lower Columbia River Salmon and Steelhead***

Lower Columbia River Chinook Salmon

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for lower Columbia River Chinook salmon.

*Summary of Key Effects*

Lower Columbia River Chinook salmon are primarily affected by factors outside the scope of the operations and maintenance of the CRS, but to some extent Lower Columbia River Chinook salmon could be affected by passage conditions at Bonneville Dam, and to a lesser extent, The Dalles Dam. Only five of 32 populations in this ESU are affected by passage conditions at Bonneville Dam and, to a lesser extent, The Dalles Dam: upper Gorge Fall Run, White Salmon Fall Run, Hood River Fall Run, White Salmon Spring Run, and Hood River Spring Run Chinook salmon.

Spill and flows affect the migration survival and travel timing of juveniles. Adults are influenced from operation of the CRS under the No Action Alternative primarily by spill; as the percentage of spill increases, so does the likelihood of adult Lower Columbia River Chinook being pushed downstream (i.e., fallback) below Bonneville Dam. Water temperature and TDG are also considerations for adult and juvenile survival. These are influenced by the following measures under the No Action Alternative: *Spill Operations, Lower Columbia and Snake River Operations*, *Water Quality Plan for TDG and Water Temperature*, *Spill Operations to Improve Juvenile Passage,* and the *Fish Passage Plan*.

No Action Alternative results for metrics used to compare MOs for Lower Columbia River Chinook salmon include the following:

- Juvenile project survival, Bonneville reservoir and dam (using Snake River spring-run/summer-run Chinook salmon as a surrogate) estimated at 89.0 percent
- Bonneville Dam outflows, April to June
- Bonneville Dam outflows, August to September
- Spill proportion, Bonneville Dam

- Temperature, The Dalles Dam, days exceeding state standard = 71 days
- Temperature, Bonneville Dam, days exceeding state standard = 58 days
- TDG, The Dalles Dam, days exceeding state standard = 33 days
- TDG, Bonneville Dam, days exceeding state standard = 61 days

*Juvenile Migration/Survival*

The change in juvenile survival for the portion of the fish passing Bonneville Dam were assessed using Snake River spring-run/summer-run Chinook salmon as a surrogate. Interestingly, Bonneville Dam is the only CRS project where higher spill can result in lower juvenile survival and vice-versa (personal communication, Zabel). Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile migration and survival of lower Columbia River Chinook salmon.

Some lower Columbia River Chinook salmon juveniles migrate in the spring; their travel time can be affected by changes in spring (April through July) flows. Other Lower Columbia River Chinook salmon juveniles emigrate in late summer or early autumn and rely heavily on estuary habitats before moving on out to the ocean. These juveniles are also subject to effects from increased TDG to some extent. Under the No Action Alternative, TDG would exceed the state standard a total of 33 days in The Dalles Dam tailrace and 61 days in the Bonneville Dam tailrace.

*Adult Migration/Survival*

The area where Lower Columbia River Chinook salmon experience the effects of the CRS the most is near Bonneville Dam, and to lesser extent, The Dalles Dam. Based on PIT-tag detections of surrogate species Snake River spring-run/summer-run Chinook salmon, at Bonneville Dam and later redetected at upstream dams, observed estimates of upstream Chinook salmon survival rates were 98.6 percent (NMFS 2019). Under the No Action Alternative, adult lower Columbia River Chinook salmon are expected to have similarly high success rates in upstream passage at Bonneville Dam.

Adult Lower Columbia River Chinook salmon are vulnerable to predation throughout the lower Columbia River. This vulnerability is primarily for the nine spring-run populations that migrate during May and June, when pinniped abundance is highest.

<u>Lower Columbia River Steelhead</u>

Four of the 23 populations in the Lower Columbia River steelhead DPS pass Bonneville Dam: Wind summer-run steelhead, Hood summer-run steelhead, Hood winter-run steelhead, and upper Gorge winter-run steelhead.

Refer to Snake River steelhead analysis as a surrogate for lower Columbia River steelhead.

*Summary of Key Effects*

Observed data estimated a 96.9 percent passage survival for juvenile Lower Columbia River steelhead at Bonneville Dam and passage at Bonneville Dam would be similar under the No Action Alternative's *Lower Columbia and Snake River Operations*, *Spill Operations to Improve Juvenile Fish Passage*, and *Fish Passage Plan* measures.

No Action Alternative results for metrics used to compare MOs for lower Columbia River steelhead include the following:

- Juvenile project survival, Bonneville Reservoir and Dam (see Snake River steelhead as a surrogate) = 87.3 percent
- Bonneville Dam outflows, March to June (juvenile outmigration)
- Bonneville Dam outflows, adult migration time period year-round
- Spill proportion, Bonneville Dam
- Temperature, The Dalles Dam, days exceeding state standard = 71 days
- Temperature, Bonneville Dam, days exceeding state standard = 58 days
- TDG, The Dalles Dam, days exceeding state standard = 33 days
- TDG, Bonneville Dam, days exceeding state standard = 61 days

*Juvenile Migration/Survival*

Ploskey et al. (2012) found actual survival of juvenile steelhead through Bonneville Dam to be 96.9 percent. These results were based on a study that looked at survival through the spillway, Powerhouse 2 and Powerhouse 1. Snake River steelhead was used as a surrogate to provide an estimate of juvenile passage survival through Bonneville Dam for those populations located upstream of Bonneville Dam. Under the No Action Alternative, juvenile survival through Bonneville Reservoir and Dam would be 87.3 percent. Based on observed data (Ploskey et al. 2012) and modeled surrogate species information, juvenile survival through Bonneville Dam would be 87 to 97 percent. Refer to Snake River steelhead analysis as a surrogate for lower Columbia River steelhead for additional juvenile migration and survival information.

For all Lower Columbia steelhead, including those populations that do not pass Bonneville Dam, reduced flows April through June from CRS operation would increase travel times and reduce access to high-quality estuarine habitats (NMFS 2019). In addition, exposure to increased temperatures and elevated TDG during outmigration would further influence juvenile survival.

Researchers have not estimated predation rates for Lower Columbia River steelhead because these fish are not PIT-tagged.

*Adult Migration/Survival*

The area where Lower Columbia River steelhead experience the effects of the existence and operation of the CRS is predominantly near Bonneville Dam, and to lesser extent, The Dalles Dam. The most recent estimates of upstream survival (Rayamajhi et al. 2012) indicate Lower Columbia River steelhead survival of adults passing upstream of Bonneville Dam is 98.5 percent.

Summer-run steelhead migrate upstream from May to October, and winter-run steelhead migrate December to May, so changes in flows, spill, temperature, or TDG could affect adult migration and survival. Additionally, kelts moving downstream post-spawning could also be affected during and soon after these times. Migration of kelts occurs from March through July (Keefer et. al, 2016). Kelt migration can be affected by the extreme energetic demands of spawning and iteroparity, harvest, and the Columbia River System (Coletelo et al. 2014). Refer to Middle Columbia River Steelhead in Section 3.5.3.2 for additional information on kelts and system passage.

Adult Lower Columbia River steelhead are vulnerable to pinniped predation throughout the lower Columbia River. This vulnerability is primarily for spring-run adult populations that migrate during May and June, when pinniped abundance is highest.

<u>Lower Columbia River Coho Salmon</u>

The ESA-listed Lower Columbia River coho salmon ESU includes three geographical groupings (or strata): Coast, Cascade, and Gorge. Only Gorge coho salmon travel upstream far enough to pass Bonneville Dam.

See Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile Lower Columbia River coho salmon and Snake River fall-run Chinook salmon as a surrogate for adult Lower Columbia River coho salmon.

*Summary of Key Effects*

Survival rates of Lower Columbia River coho salmon transiting through the Bonneville pool and Bonneville Dam are expected to remain similar or increase somewhat under the No Action Alternative, due to the installation of the Bonneville Corner Collector and the *Lower Columbia and Snake River Operations, Spill Operations to Improve Juvenile Fish Passage*, and *Fish Passage Plan* measures. Modeled data includes historical records of fish passage before the Bonneville Corner Collector as constructed.

*Juvenile Migration/Survival*

Passage through the Bonneville Reservoir and Dam would continue to affect the survival of Lower Columbia River juvenile coho salmon under the No Action Alternative. Juvenile coho salmon outmigration timing generally overlaps with that of Snake River spring-run/summer-run Chinook salmon, and the size of these juvenile species are closely aligned; therefore, the Snake River spring-run/summer-run Chinook salmon were used as a surrogate for the Lower Columbia

River juvenile coho salmon. Juvenile Snake River spring-run/summer-run Chinook salmon are estimated to have a 95 to 96 percent survival rate at Bonneville Dam (Ploskey et al. 2012). Coho salmon smolts from tributaries in the Bonneville Reservoir are likely to have similar survival rates passing downstream through Bonneville Dam (NMFS 2019).

Refer to the Snake River Spring/Summer Chinook Salmon section (Section 3.5.2.2), No Action Alternative, for additional information on juvenile survival rate estimates under the No Action Alternative.

*Adult Migration/Survival*

Lower Columbia River adult coho salmon are assumed to have passage success rates similar to that of all coho salmon (including reintroduced upper river species) passing Bonneville Dam. Because there are no adult coho salmon-specific passage survival models available, it was necessary to rely on historic survival rates for a surrogate species to estimate and compare adult coho salmon passage rates under the No Action Alternative.

The timing of adult coho salmon upstream migration generally overlaps with that of Snake River fall-run Chinook salmon; although the fall-run Chinook salmon migration tends to start earlier in some years. For these reasons, Snake River fall-run Chinook salmon were used as a surrogate for Lower Columbia River coho salmon.

Based on Snake River fall-run Chinook adult PIT-tag detections at Bonneville Dam between 2013 and 2017, the average survival rate for Lower Columbia River adult coho salmon passing upstream of the dam is 97.6 percent (94.5 to 100 percent; 2019 CRS BiOp). This applies only to populations that migrate to natal streams within the Bonneville pool. Under the No Action Alternative, Lower Columbia River adult coho salmon survival rates are expected to continue in this range.

<u>Columbia River Chum Salmon</u>

One population in this ESU would be affected by operations at Bonneville Dam: Upper Gorge chum salmon.

Refer to Snake River spring/summer-run Chinook salmon analysis as a surrogate for Columbia River chum salmon.

*Summary of Key Effects*

Chum salmon rarely pass Bonneville Dam. For the period between 2008 and 2017, on average, 96 adults passed this dam each year. Chum spawning and incubation habitat is maintained through operations at Grand Coulee, which results in sufficient water passing through Bonneville Dam in 90 percent of years. Chum operations would continue at current levels under the No Action Alternative's *Chum Spawning Flow* measure.

*Larval Development/Juvenile Rearing*

Maintaining water saturation of 105 percent TDG or less from November 1 to April 30 appears to provide a sufficient level of protection to chum salmon eggs and sac fry incubating in the gravel downstream of Bonneville Dam. Under measures in the No Action Alternative, including *Spill Operations*, *Water Quality Plan for TDG and Water Temperature,* and *Spill Operations to Improve Juvenile Fish Passage*, chum sac fry would be exposed to TDG above 105 percent in 5 out of 80 years. Those exceedances all would occur in the mid- to late April timeframe when most of the chum have emerged from the gravel.

*Juvenile Migration/Survival*

There are no studies of downstream passage survival for juvenile Columbia River chum salmon. The survival of downstream migrants is likely to have improved in recent years and would be expected to continue under the No Action Alternative due to the construction of the Bonneville Corner Collector.

There is no direct estimate of Bonneville Dam and Reservoir passage specific to juvenile chum salmon, so juvenile Snake River spring-run/summer-run Chinook salmon were used as a surrogate to estimate effects to chum salmon. Juvenile Snake River spring-run/summer-run Chinook salmon are estimated to have a 95 to 96 percent survival rate at Bonneville Dam (Ploskey et al. 2012). 2012 Chum salmon smolts from tributaries in the Bonneville Reservoir are likely to have similar survival rates passing downstream through Bonneville Dam (NMFS 2019). Refer to Snake River spring/summer-run Chinook salmon analysis for additional surrogate information for Columbia River chum salmon. Grand Coulee is operated to balance the needs of multiple salmon species. The operations provide chum flows downstream of Bonneville Dam, along with Vernita Bar operations for fall-run Chinook salmon, and spring flow augmentation from the start of chum spawning in November through the end of chum emergence (approximately the end of April). The chum operation is intended to maintain sufficient water depth to protect chum spawning and incubation habitat at the Ives Island complex below Bonneville Dam. The Bonneville Dam tailwater elevation (measured at the Tanner Creek gage) affects chum access to the Ives/Pierce Islands spawning area. Tailwater elevations below 11.3 feet create connectivity issues to spawning channels and poorer conditions in the lower spawning elevation habitat. As tailwater elevations increase above 13.5 feet, some habitat in the lower elevations becomes unsuitable for chum due to higher water velocities. In addition, eggs spawned at higher elevations would be at higher risk of being dewatered later in the year if there is an insufficient water supply. Under the No Action Alternative, Bonneville Dam flows would be managed to prevent chum spawning at those higher elevations that are at greater risk of dewatering. How operations affect the ability of Grand Coulee to provide winter flows to protect chum redds and provide sufficient access to habitat was calculated using hydrology modeling. Under the No Action Alternative, chum flows would be met in 90 percent of years.

*Adult Migration/Survival*

Adult chum salmon counts at the ladders at Bonneville Dam have ranged from 17 in 2000 to 411 in 2003, averaging 107 adults passing Bonneville Dam per year. The most recent 10-year average (2008 to 2017) is 96 adults (McCann 2018), which is similar to the 107 adults mentioned above as the average number of adults moving upstream of Bonneville Dam between 2013 and 2017 based on dam counts. NMFS (2008a) estimated that the adult passage mortality rate for chum salmon at Bonneville Dam was similar to that of Snake River spring-run/summer-run Chinook salmon, which are present during the same time period (about 3.1 percent). Passage survival estimates incorporate passage under general operations and typical maintenance (e.g., screen blockages/cleaning) conditions, and previous survival estimates are anticipated to continue under the No Action Alternative.

Adult chum salmon are near the Bonneville Dam tailrace November to December each year, and therefore are not likely to be exposed to elevated levels of TDG. Eggs are present in the mainstem spawning area near the tailrace (the Ives/Pierce Island area) during winter, and fry are present in the bypass system at Bonneville Dam and the mainstem spawning area through May. The risk of GBT to these life stages is minimized by maintaining a Bonneville tailwater elevation of between 11.5 and 13 feet through spawning if reservoir elevations (indicative of available storage) and climate forecasts indicate this operation would be feasible (NMFS 2019). GBT risk is anticipated to remain at current levels under the No Action Alternative.

Pinniped predation on chum salmon is expected to increase based upon increasing numbers of pinnipeds. However, the magnitude of pinniped predation on chum salmon is likely lower than on spring-run Chinook salmon, due to fewer pinnipeds being present when chum salmon migrate.

**Other Anadromous Fish**

***Pacific Eulachon***

<u>Summary of Key Effects</u>

The time between the peak spawning runs, egg development, and larval emergence timed with the spring freshet to adequately disperse larvae to adequate food sources would continue to be highly variable, with an average of 168 days between spawning temperature triggers and peak flows (158 days in high-flow years, and 156 days in low-flow years). Freshwater flow rates can affect larval survival if reduced flow rates result in a mismatch of larvae and their planktonic food supply. Relatively low freshwater inputs into the nearshore environment would continue to moderately limit plankton food supply for larval eulachon in the April to July period. A hydrology analysis showed none of the MOs would appreciably affect the estuary/plume environment.

Bird predation risk can be influenced by flow rates. Higher flows are linked to higher predation rates on eulachon, whereas at lower flows, birds tend to switch to marine prey. Operation of the CRS system under the No Action Alternative would continue to result in lower peak turbidity levels in spring, but the relationship between turbidity and eulachon is not clear. Eulachon would continue to migrate into the Columbia River from November to March, with specific dates of migration and spawning based on a variety of environmental factors, including temperature, high tides, and ocean conditions (NMFS 2017). Modeled data for the No Action Alternative (based on the period of record for Bonneville tailwater temperatures) indicate that temperatures would typically be favorable for triggering upstream migration by mid to late November, with the spawning trigger (4°C) occurring in late December/early January of each run year. The location of spawning would continue to be dependent on the size of the run, as well as other environmental factors. Runs are expected occasionally as far up the Columbia River as Bonneville Dam. Bonneville Dam is near the upstream range of spawning, but it could continue to impede access further upstream in years of very large eulachon runs. Possible eulachon injury or mortality could continue if any eulachon pass through Bonneville Dam. Because Bonneville Dam is the near the upstream range of spawning, this would be a very minor impact. Tributary access to major spawning tributaries would remain unimpeded. Eulachon need pea-sized gravel and coarse sand for spawning. Substrate can be affected by flows, particularly during changes in peak flows. A portion of eulachon would continue mainstem spawning where appropriate substrate exists, and tributary spawning substrate would not be affected.

***Green Sturgeon***

<u>Summary of Key Effects</u>

Columbia River use by green sturgeon is limited to foraging habitat for adults. Key effects of the No Action Alternative are focused on how flows and temperatures influence the cues for entering the Columbia River as well as the availability and distribution of food sources.

Columbia River water temperatures (relative to ocean temperatures) cue the spring arrival and fall departure of green sturgeon. The date that water temperatures first reach 15°C in spring and the date that they drop below 15°C in the fall can be used as an indicator for arrival and departure in the estuary (Moser and Lindley 2007). Currently, green sturgeon arrive in June and leave in September or October. In some years, the arrival date can be as early as May and the departure date as late as December. Flows and water temperatures anticipated under the No Action Alternative are anticipated to result in green sturgeon migrating within a similar date range and are expected to continue supporting adequate rearing conditions.

Changes in Columbia River outflow can change the location of the saltwater/freshwater interface that is important for green sturgeon feeding. Under the No Action Alternative, the lower Columbia River would continue to provide good foraging habitat for green sturgeon.

### *Pacific Lamprey*

#### Ongoing Existing Mitigation Programs

There are numerous actions to benefit Pacific lamprey, including projects like the Pacific Lamprey Conservation Initiative and the Tribal Pacific Lamprey Restoration Plan. These plans improve understanding of Pacific Lamprey status and limiting factors, implement high-priority habitat restoration actions, increase populations through reintroduction and translocation efforts, and conduct artificial propagation research with plans to release hatchery juveniles in select areas pending an environmental assessment.

#### Summary of Key Effects

Unlike salmon and steelhead, larval lamprey spend several years rearing in the freshwater environment of the Columbia and Snake Rivers and tributaries. Factors important for lamprey relative to Columbia River System Operations include how they affect dam passage, flow and reservoir levels, water quality, predation, and habitat conditions. Key effects of the No Action Alternative on lamprey include continued effects to upstream migration of adults and downstream migration of juveniles in the form of passage delays, direct individual mortalities, and physical stress. The No Action Alternative also would continue effects on larval rearing via reservoir drawdowns and project maintenance dredging. Not enough years of dam passage efficiency data are available to determine whether recent passage improvements have had effects at the population scale and if the improvements would continue under the No Action Alternative.

#### Larval Development/Juvenile Rearing

System operations affect juvenile rearing in shallow waters when water elevation fluctuations dewater larvae that reside in soft substrates in the shoreline. Flow reduction rates that drop the amount of shoreline covered by water (shoreline inundation) at less than 4 inches per hour occur naturally; however, dam operations can cause a faster rate of water receding from the shore. Under the No Action Alternative, the effects of these more rapid fluctuations include changes to distribution of rearing habitat, direct mortality, and increased predation exposure[4].

[4] The evidence for these effects comes from a series of preliminary studies:

- Jolley et al. (2014, 2016) conducted surveys in mainstem areas of Columbia and lower Snake Rivers to determine presence/absence of rearing larvae potentially vulnerable to dewatering. Lamprey larvae were found at various depths in the mainstem Columbia and Snake Rivers and were commonly found near tributary deltas, in areas vulnerable to changes (seasonal or otherwise) in surface elevation.
- Mueller et al. (2015) used existing bathymetry and operations information to model relative risk of dewatering.
- Liedtke et al. (2015) conducted laboratory experiments with larvae, simulating dewatering events and monitoring lamprey response to dewatering of their habitat.

<u>Juvenile Migration/Survival</u>

Water temperatures and physical structures affect juvenile lamprey during their outmigration. Juvenile outmigration typically occurs in late fall through the spring into early summer. High-flow freshet events typically trigger outmigration events. The evidence of this is the timing of when juvenile fish are found in the tributary screw traps; this timing occurs with freshet events in winter and aligns with annual summary hydrographs (Mesa et al. 2015). However, warmer temperatures affect juvenile outmigration as well, and they are compelled to move out of the higher elevations of the system faster in warmer water temperatures due to physiological stress. Temperature data modeled from three of the Lower Snake River Dams show the number of days the water temperature exceeds state standards, which is expected to continue in the No Action Alternative:

- Lower Granite Dam: 4.4 days
- Little Goose Dam: 37.0 days
- Lower Monumental Dam: 47.2 days

Juvenile lamprey pass the CRS projects through all downstream passage routes and can potentially be harmed in any of the project components. Relative distribution across passage routes is not well understood, so the magnitude of all the injury and mortality effects on juvenile lamprey is unknown. As juveniles migrate downstream from their rearing areas, they must pass as many as eight projects of the Lower Snake and Columbia Rivers.

The majority of juvenile lamprey swim low in the water column below the depth of screens and pass the CRS projects via turbines. Fyke net evaluations of run-of-river fish at John Day Dam, McNary Dam, Bonneville Dam, and other dams found the majority (more than 70 percent) of juvenile lamprey appeared to move downstream low in the water column, below the turbine intake bypass screens installed for salmonids (BioAnalysts Inc. 2000; Moursund et al. 2003; Monk et al. 2004). Results of these fyke net studies provide an estimate of relative use of turbines at approximately 70 percent versus juvenile bypass systems at about 30 percent.

Lampreys that survive these passage routes can become injured or disoriented, putting them at greater risk of predation. Direct observations of predation on juvenile lamprey in powerhouse tailraces suggest passage via this route is substantial.

Turbine cooling water strainers can entrain juvenile lampreys in the turbine scroll case located upstream of turbines, which results in mortality. The evidence of this harmful mechanism is through mortality counts from routine cooling water strainer inspections at CRS projects. The Corps has developed a design for exclusion of juvenile lamprey and other fish from cooling water strainer intakes. The design would be tested at Ice Harbor as turbines are replaced with Improved Fish Passage turbines (IFPs) (under the No Action Alternative's *Ice Harbor Projects Turbines 1 to 3 Replacement and Generator Rewind* measure).

Juveniles that do not directly enter the turbines can be harmed and killed by impingement (being pushed up against the screens); this occurs mostly in the extended length submersible bar screens at McNary, Little Goose, and Lower Granite Dams. The Corps has observed the direct mortality of juveniles and a high number of entangled fish (Moursund et al. 2001, 2003). Bar screen installations at McNary Dam have been delayed until mid-April each year since 2009 to reduce this effect based on timing of lamprey migration. At other locations, lamprey timing is concurrent so bar-screen installation for the protection of salmon is not delayed. Woven mesh screen reduces impingements, but this has not been installed due to cost. Note that some dams and powerhouses have no turbine intake bypass screens and that other dams have what appear to be relatively benign Submersed Traveling Screens that use woven mesh.

Juvenile lamprey that migrate higher in the water column can pass via spillways, which may cause injury or indirect effects. It is unknown what proportion of lamprey use this route, and therefore the magnitude of effects to the population is unknown. The evidence for use of this passage route is direct observation of tailrace predation by gulls; lamprey become disoriented at spillways and become more susceptible to predation (Zorich et al. 2010, 2011, 2012).

Routine maintenance dredging occurs every 3 to 5 years for navigation in the lower Snake River in a channel 14 feet deep and 250 feet wide associated with the four lower Snake River Dams. The Corps also periodically dredges at Bonneville forebay locations, including immediately upstream of Bradford Island Fish Ladder exit, and upstream of Washington-shore fish turbine units. Dredging is necessary to remove debris and ensure that fish passage facilities are operating as designed. Juvenile lampreys are susceptible to entrainment in dredging equipment, but the number of fish harmed or killed is unknown. Juvenile lamprey have highest densities in fine particle, high organic matter substrates rather than the coarse mineral sand found in the channel. Sampling during dredging at Bonneville reservoir found no lamprey present. Although juvenile lamprey may be present in areas targeted for dredging, densities are thought to be site specific and most likely seasonal. Direct effects of the dredging action on juvenile lamprey is not well understood. Under the No Action Alternative, navigation channel maintenance would continue to occur periodically. Maintenance dredging at Bonneville would be expected to continue as needed.

<u>Adult Migration/Survival</u>

Dams inhibit upstream migration of adult lamprey to spawning areas, causing direct mortality or physical stress. Each dam that must be ascended poses risk of mortality or contributes to stress that reduces fitness for spawning. There is a poor understanding of magnitude of the impact to populations.

Only a portion of lampreys that attempt to move upstream in the Columbia River can pass the dams and move into desired spawning areas. Dams create barriers despite having fish ladders, which were designed for adult salmon. Dams can cause direct mortality or physical stress among adult lamprey that use conventional fishways. The ladders (designed for salmon) have too high of velocities, difficult shapes of ladder steps, and right-angled corners that cause difficulty for ascending lamprey. Lamprey adult upstream passage has been low at Columbia

River dams (Bonneville, John Day, and The Dalles Dams) with 65 percent or lower passage efficiency (Moser et al. 2002a, 2002b; Keefer et al. 2012). McNary Dam adult passage efficiencies have ranged from 65 to 75 percent (Keefer et al. 2013). Upstream passage efficiency at Snake River dams has been higher than at Lower Columbia River dams (Stevens et al. 2016); recent fish passage improvements at Snake River dams have increased adult passage survival from 70 to 75 percent (Stevens et al. 2016).

Mainstem dams can cause direct mortality or physical stress among adult lamprey that use lamprey passage structures or are otherwise diverted into collection structures or traps. Corps biologists and Corps-funded researchers periodically find dead lamprey in lamprey passage structures or in holding tanks. Other than equipment failures, mortality causes are often unknown. High temperatures or other water quality issues may cause physical stress or mortality of individuals, particularly as lamprey are kept in holding tanks during extended periods of high temperatures. Other unknown factors are causing lamprey to turn around and descend the ladders when they are expected to be migrating upstream.

Dam passage efficiency is the number of tagged lampreys that passed a dam divided by the number of lampreys that approached a fishway. Median dam passage efficiencies across all study years (1997 to 2010) ranged from 44 percent at Bonneville Dam, up to 68 percent at The Dalles Dam (Keefer et al. 2012). A study in 2014 found dam passage efficiency was at 49 to 52 percent at Bonneville Dam, 47 percent at The Dalles Dam, 83 percent at John Day Dam, and 100 percent at McNary Dam (Clabough et al. 2015). The Lower Snake River Dams have similar dam passage efficiencies at 41 to 68 percent (Stevens et al. 2016).

What these low success rates for ladder ascension mean is that attrition through the system leads to fewer and fewer lampreys that are able to make it further upstream into the system and reduces access to desired spawning locations. Reduced distribution and abundance reduces the effect of pheromone attraction cues, which would occur when adults detect the pheromone outputs of rearing juveniles. After many years of this reduced recruitment of lamprey to their desired spawning reaches in the watershed, the system has seen degraded ecosystem and food web effects because lampreys transfer nutrients upstream, so fewer lampreys mean fewer nutrients.

Under the No Action Alternative, there would be a neutral to decreasing trend in mortality and an increase in passage efficiency over time as the Corps continues to investigate and address known lamprey passage impediments. Adult lamprey passage metrics are expected to remain consistent in the near future and improve incrementally as conventional fishway structures and operations are modified and lamprey passage structures are installed.

The relationships of other parameters, such as outflows, spill rates, and water temperatures, with lamprey migration and survival are not well understood. Outflows and water temperatures are monitored at all of the CRS projects. Lampreys generally migrate faster later in the summer through most reaches, coinciding with increasing river temperatures and decreasing river discharge (Keefer et al. 2012). Temperatures greater than 72°F cause stress to adult lamprey and can reduce migration success, although this is a rare occurrence at Bonneville. High flows and lower water temperatures correlate to poorer passage success and slower migration speed, but little is known about the migration cues used by adult lamprey and how these and migration timing interact. Keefer et al. (2012) speculated that higher flows associated with higher tailwater elevations at Bonneville might compromise attraction to fishway entrances, collection channels, and transition pools of ladders. These factors can affect distribution of lamprey throughout the basin. Lamprey appear to have a relatively flexible migration strategy, and in some conditions, can overwinter up to 2 years before spawning, although temperature conditions in the project facilities are unlikely to support this strategy. Effects of different mainstem flow and temperature conditions on spawning success remain unclear. Total attrition due to all these factors affects the whole population. All these parameters and effects are expected to remain constant under the No Action Alternative.

Other stressors, such as predation and contaminants, are known to affect lampreys. Predation on adults by sea lions at Bonneville Dam is well documented (Corps Annual Reports) and by white sturgeon is likely to occur. This predation risk can be exacerbated by the delay in adult migrations at the dams and interactions of the predators and prey within the project structures. Birds and mammals may also take the opportunity to capture lamprey in structures. All life stages of Pacific lamprey can be affected by contaminants (CRITFC 2011). Contaminants such as methyl mercury are bioaccumulated in larval lamprey and can have ecosystem effects on predators that prey on them (Bettaso and Goodman 2008). These effects would continue under the No Action Alternative.

***American Shad***

<u>Summary of Key Effects</u>

Shad are generalists that tolerate a wide range of conditions and thrive in reservoir habitats; populations are increasing in trend and distribution. Changes in project operations are not likely to influence their populations, but their distribution and migrations could be affected by changes in flow, temperatures, or food supply. Both adults and juveniles would continue to thrive with the abundance of reservoir conditions in the Snake and Columbia Rivers that tend to favor them over other native fish. They consume up to 30 percent of the zooplankton present in the rivers and are expected to continue to eat at least that same amount under the No Action Alternative. Upstream migrating adults would continue to crowd fish ladders in the basin but also provide a recreational fishing opportunity.

<u>Juvenile Migration/Survival</u>

Juvenile shad thrive in aquatic vegetation found in off-channel habitats provided by reservoir shorelines (Petersen et al. 2003; Gadomski and Barfoot 1998), and they feed on zooplankton from June to September. Under the No Action Alternative, the reservoirs associated with the CRS would continue to provide vegetated shoreline habitat and adequate zooplankton at the levels that support a robust juvenile shad population. Juvenile shad would continue to experience high survival in these conditions.

Adult Migration/Survival

Adult shad return to the Columbia River system to spawn when temperatures reach about 16°C, which would occur between June and August under the No Action Alternative. Though they migrate upstream successfully in all conditions, Hinrichsen et al. (2013) found shad migrate further upstream under lower dam discharges. Under the No Action Alternative, shad would continue to thrive and potentially crowd fish ladders that could interfere with salmon and steelhead migrations.

**RESIDENT FISH**

Resident fish were analyzed as fish communities generally at the scale at which they are managed and as related to CRS Projects. These communities in Region A include Hungry Horse/Flathead/Clark Fork (Hungry Horse Dam); Lake Pend Oreille (Albeni Falls Dam) and Pend Oreille River; and the Kootenai River, including Lake Koocanusa (Libby Dam).

**Region A**

Ongoing Existing Mitigation Programs

There are numerous ongoing actions to benefit resident fish. CKST and MFWP's Hungry Horse Mitigation projects address habitat loss in the Flathead basin from construction and operation of Hungry Horse Dam, and the inundation of 72 miles (125.8 km) of the South Fork Flathead River and its tributaries. Project work assesses population level effects of dam operations on native fishes, implements habitat improvement, habitat conservation, and fish passage actions, and quantifies and reduces the effects of non-native aquatic species on native fishes.

Part of the mitigation work for Hungry Horse Dam involves fish production at two small hatcheries in northern Montana. Bonneville funds Creston National Hatchery's production of 200,000 juvenile westslope cutthroat trout and 200,000 juvenile rainbow trout for stocking in Montana waters. Stocking occurs according to the fisheries management strategy of MFWP and CSKT. Bonneville also funded the construction of Sekokini Springs Isolation Facility for spawning, rearing, isolation, and release of genetically unique westslope cutthroat trout stocks originating from wild parent stocks.

Mitigation actions for the fish impacts of Libby Dam are coordinated with adjacent tribal, state, and provincial governments. Programs like the Libby Dam Fisheries Mitigation and Implementation Plan (Montana Fish Wildlife and Parks et al. 1998) seek to enhance fish stocks affected by the Columbia River System in the Montana portion of the Kootenai Watershed consistent with white sturgeon, bull trout, westslope cutthroat trout and redband trout conservation needs and requirements. This program implements and evaluates habitat enhancement to alleviate limiting factors to native species including projects to protect or enhance spawning, rearing, and over-wintering habitats. Additionally, since 2010, Bonneville has funded the Kootenai Tribe of Idaho (KTOI) to manage and implement habitat restoration measures within the Kootenai River downstream of Libby Dam. These habitat restoration actions have increased active floodplain, increased river pool depths, reduced erosion, and provided increased complexity and velocities to aid in the survival and potential reproduction of Kootenai River white sturgeon and potential benefit for the native salmonid populations as well. Bonneville also funds IDFG for ongoing burbot monitoring actions, including evaluating population demographics, spawning activity and natural recruitment, and other actions. In addition to their habitat work, KTOI operates the Kootenai Tribal sturgeon hatchery and the Tribal Twin Rivers sturgeon and burbot hatchery facility, which was constructed in 2014. These facilities have preserved sturgeon genetic and demographic diversity and have pioneered culture techniques for burbot.

Bonneville's F&W Program also provides funding to the Kalispel Tribe to develop and implement a resident fish mitigation program for the impacts from Albeni Falls Dam. This work includes improving bull trout habitat within the basin. Additional priorities are to restore habitats for westslope cutthroat trout and maintain the suppression effort on non-native predator and competitive fish species within the Pend Oreille Basin. Finally, through the 2018 Northern Idaho Wildlife Agreement, Bonneville and the State of Idaho work to protect and enhance 1,378 acres to fully address operational impacts of Albeni Falls Dam on wildlife. Much of this work will focus on the Clark Fork Delta and restoration of riparian habitat and the reestablishment of wetland plant communities, which will also benefit resident fish species.

#### ***Kootenai River Basin***

<u>Summary of Key Effects</u>

Currently, water releases from Libby Dam can have detrimental effects to fish species in the Kootenai River downstream of Libby Dam related to altered flow and temperature. Under the No Action Alternative, spring flows would continue to increase at a rate less than normalized rates. The diminished spring flows would continue to reduce aquatic food sources associated with inundated river habitats between Libby Dam and Kootenay Lake in British Columbia. Burbot populations would be expected to continue to grow in abundance with continuation of the burbot restoration efforts.

Under the No Action Alternative, fluctuations in discharge from Libby Dam in the winter would continue to adversely affect benthic organisms. Cottonwood seedlings would continue to have variable survival depending on timing, stage, and duration of spring flows, along with the winter stage during the ensuing winter. In addition, the discharge regime from Libby Dam would continue to not provide for successful burbot recruitment, and spring water temperatures would be too cold to allow for proper larval development.

<u>Habitat Effects Common to This Fish Community</u>

Important operational relationships affecting species in this basin are related to river flows due to the construction and operation of Libby Dam. Prolonged periods of reduced early spring flow from the dam has changed the river ecosystem from mid-March through mid-May. During this period, it is critical for river flow and stage to rise and inundate riparian and side channel habitat to promote productivity. Under the No Action Alternative, the rate of increase in spring flows would be about one-third of a more normalized hydrograph needed to establish productivity.

Bull Trout

Important operational relationships affecting bull trout habitat in this basin include reservoir elevations in Lake Koocanusa and the impact of these elevations on reservoir productivity, how reservoir temperatures influence discharge temperatures, and how discharges from Libby Dam affect downstream habitat inundation. Higher reservoir elevations in the warm summer months results in a thicker water layer in which primary production and zooplankton production (i.e., euphotic zone) occurs in Lake Koocanusa. High reservoir elevations during winter (which have a large quantity of cold water) reduce the ability to provide warm/normative discharge temperature during spring and early summer in the Kootenai River. Bull trout forage in the reservoir and rely on this production in the river for food the following winter. Lake productivity under the No Action Alternative would continue to beneficially affect bull trout (both ESA-listed in the U.S. and non-listed individuals in Canada) growth and/or survival in Lake Koocanusa (Marotz et al. 1996; Marotz et al. 1999). However, lower flows and colder temperatures in spring and summer would likely suppress primary and secondary production in the river downstream of Libby Dam.

The minimum elevation of Lake Koocanusa each year influences insect larvae production the following year. The minimum elevation of the reservoir is typically in mid-April. The higher this minimum elevation is each year, the greater the insect larvae production and the more food available for juvenile bull trout (Marotz et al. 1996; Marotz et al. 1999; Chisholm et al. 1989). Under the No Action Alternative, the minimum reservoir elevation would be 2,366 feet during median years.

The maximum elevation of Lake Koocanusa is related to volume and surface area and to the proximity of the reservoir surface to terrestrial insect deposition, a food source for bull trout. The reservoir typically reaches maximum elevation in early August (Marotz et al. 1996; Sylvester et al. 2019). Under the No Action Alternative, the median maximum reservoir elevation would be 2453.1 feet, which is 5.9 feet below full pool.

Water temperature in Lake Koocanusa influences bull trout habitat suitability in the reservoir. Reservoir surface elevation and volume also influence the thermal structure of the pool. Reservoir temperature (Dunnigan, unpublished) is determined by several variables, the most indicative of which are volume of the reservoir through the winter (as measured by minimum pool elevation in April), inflow, and air temperature. Fish seek preferred temperatures, and the volume and temperature ranges influence the amount of preferred habitat. For bull trout, optimal growth occurs at 13.2°C, while the upper lethal temperature for bull trout is 20.9°C (Selong et al. 2001). Under the No Action Alternative, the mean monthly reservoir temperature from January to August (analysis was not performed September to December) would range from 3.5°C in March to 11.3°C in August. Reservoir water temperatures would be suitable for bull trout under the No Action Alternative.

Water temperatures in the reservoir also influence temperatures in the Kootenai River downstream of Libby Dam. Libby Dam discharge water temperature is manageable seasonally when the reservoir stratifies. During this time, a selective withdrawal system is used to release water from the reservoir forebay that is closer in temperature to what would have been the normal water temperature before the dam was constructed (Corps unpublished). Under the No Action Alternative, the mean monthly temperature of the discharge water from Libby Dam from January to August was assumed to be the same as for the water temperature in Lake Koocanusa. Bull trout temperature objectives would be met under the No Action Alternative from June to December via operation of the selective withdrawal system, though optimal growth temperature is met only intermittently via use of the selective withdrawal system. However, the No Action Alternative does not provide the ability to meet temperature objectives during late winter through late spring because the reservoir is no longer stratified. In addition, the amount of heat that the water in the reservoir can hold at the over-winter elevation would dictate the Libby Dam discharge temperature.

Discharges from Libby Dam would affect habitats for bull trout in the Kootenai River below the dam. Maximum high flows greater than or equal to 20 kcfs are needed seasonally during the spring freshet period of May 15 through June 15 to flush and sort fine sediments and gravels. These flows promote macroinvertebrate production and inundate productive varial zone habitats (i.e., the edges of the reservoir that alternate between being wet and dry depending on the reservoir water levels; see the Macroinvertebrates section below). Under the No Action Alternative through the *Kootenai River Operations for Bull Trout* measure, Libby Dam would provide a discharge of 20 kcfs or greater for 11 to 16 days (25th to 75th percentile) during the spring freshet. The mean flow rate would be 18.2 to 20.8 kcfs, with a peak discharge of 23.1 to 26.9 kcfs. This would support seasonal flow objectives for flushing and sorting sediments and gravels. However, these higher flows are insufficient to reshape tributary deltas that have been formed by excessive tributary bedload and insufficient river discharge. These deltas can prevent bull trout access during the fall (low river flow) spawning season (Marotz et al. 1996; Hauer et al. 2016).

Food availability for bull trout, off-channel inundation, and connectivity would be optimized with discharges of 9 to 12 kcfs from Libby Dam during the minimum flow requirement period for bull trout of May 15 to September 30 (Hoffman et al. 2002; Marotz et al. 1996; USFWS 2006). The No Action Alternative would provide a median discharge of 10.7 to 15.1 kcfs during this period; therefore, this alternative would support varial zone and off-channel inundation and productivity objectives for bull trout.

<u>Kootenai River White Sturgeon</u>

Important operational relationships affecting Kootenai River white sturgeon in this basin are related to how discharge and temperature affect spawning behavior and location, as well as egg development. The more prolonged the peak discharge is between mid-May and mid-July, the greater the probability of adult Kootenai sturgeon moving to spawning areas and successfully spawning (USFWS 2006; IDFG unpublished data; Ross et al. 2018). The number of consecutive days of high/prolonged discharge of 30 kcfs or greater at Bonners Ferry was used to determine the ability of the alternative to provide desirable conditions for Kootenai sturgeon spawning. The No Action Alternative would provide an average of 19 consecutive days of peak discharge greater than or equal to 30 kcfs at Bonners Ferry between May 15 and July 15 under the *Sturgeon Operations at Libby Project* measure.

Water temperatures downstream of Libby Dam are influenced by the water temperatures in Lake Koocanusa and are important in inducing sturgeon spawning. Higher pool elevations through the winter associated with system flood risk management protocols can result in colder water that warms more slowly than optimal during spring and early summer, which in turn results in cooler and more variable discharge temperatures (personal communication, Hoffman 2019). Lower pool elevation in the winter can result in faster springtime warming of the forebay, and warmer, less variable discharge temperatures during spring and early summer. Warmer water (8.5°C to 12°C) is needed in late-May through late-June for sturgeon spawning (Paragamian and Wakkinen 2011). Egg deposition generally occurs at temperatures greater than 8°C with a peak at about 9.5°C (Paragamian and Wakkinen 2011). Under the No Action Alternative, the median mean reservoir water temperature for spring and early summer at Lake Koocanusa are 3.5°C in March, 3.79°C in April, 6.22°C in May, 9.17°C in June, and 10.78°C in July. The mean water temperature discharged from Libby Dam under the No Action Alternative meets temperature objectives in June but is still too cold in May. In addition, this alternative would not meet the pre-spawning temperature objectives for productivity because over-winter reservoir volumes influence reservoir temperature (see previous temperature discussion).

In a similar way, water temperatures further downstream at Bonners Ferry are also important in determining the potential for Kootenai sturgeon spawning. The same water temperatures are required for successful spawning and egg deposition. Under the No Action Alternative, the mean monthly temperatures at Bonners Ferry are approximately 2°C warmer than below Libby Dam (8.3°C in May, 11.1°C in June, and 13.5°C in July) and would be more conducive to successful sturgeon spawning at this site.

Water temperature affects incubation and larval development. Pre-dam temperatures in the Kootenai River were consistently cold November to March, and then rose sharply in April and May. Higher water temperatures reduce incubation time (Paragamian and Wakkinen 2011). Water temperatures of about 6°C in mid-March that increase to about 14°C by the end of June are needed for proper development of sturgeon (Hardy and Young, unpublished). Under the No Action Alternative, the mean monthly water temperature at Bonners Ferry would be below those temperatures, ranging from 3.8°C in March to 11.1°C in mid-June. This would not support development of post-hatch larval and juvenile sturgeon.

Bonners Ferry peak flows and the duration of high flows can provide connectivity to backwater and slough habitats that are important for Kootenai sturgeon larval and juvenile rearing. These flows provide warmer water over inundated, productive floodplains that provide better conditions for sturgeon development and growth. Any increase in access to side channel and floodplain habitats would be beneficial to sturgeon. The number of days that water levels were above 1,758 feet at Bonners Ferry was used to evaluate the extent of inundation under each alternative. The greater the number of days that water levels are above this elevation, the greater the extent of inundation. Under the No Action Alternative, the river would be above elevation 1,758 feet at Bonners Ferry for an average of 17 days during the sturgeon spawning period. The No Action Alternative would provide for some unknown level of larval and juvenile sturgeon rearing habitat.

<u>Other Fish</u>

Entrainment of young-of-year and adult kokanee through Libby Dam results in adverse effects to kokanee populations. Peak entrainment densities can occur from early spring into mid-summer, and during fall through early winter (Skaar et al. 1996), depending on kokanee density and distribution in the forebay. Higher discharges are correlated with higher entrainment. Fish entrainment rates increase with higher discharge rates.

Many effects to habitat conditions for rainbow/redband trout and westslope cutthroat trout under the No Action Alternative would be similar to those for bull trout. As with bull trout, important operational relationships affecting rainbow/redband trout and westslope cutthroat trout habitat in this basin are related to how reservoir elevations in Lake Koocanusa affect productivity and food organisms in the reservoir, how reservoir temperatures influence discharge temperature, and how discharge shape and volume influence habitat suitability in the river downstream of Libby Dam.

Higher reservoir elevations in the warm summer months would provide a larger euphotic zone where primary production and zooplankton production would occur in Lake Koocanusa. As with bull trout, the westslope cutthroat trout food base relies on this production for food the following winter. The expected increase in productivity from a larger body of warm water would likely have a beneficial effect on westslope cutthroat trout growth and/or survival (Marotz et al. 1996).

The effect of the minimum elevation of Lake Koocanusa under the No Action Alternative would be the same for rainbow/redband trout and westslope cutthroat trout as for bull trout. The higher the minimum elevation, the greater the insect larvae production and the more food available for juvenile westslope cutthroat trout (Marotz et al. 1996; Chisholm et al. 1989). The median minimum reservoir elevation under the No Action Alternative would be 2,366 feet.

The effect of the maximum elevation of Lake Koocanusa as related to volume, surface area, and proximity of the reservoir surface to terrestrial insect deposition would be the same for rainbow/redband trout and westslope cutthroat trout under the No Action Alternative as for bull trout. Under the No Action Alternative, this elevation would typically be 2453.1 in early August during median years.

Rainbow/redband trout and westslope cutthroat trout optimal growth occurs at 13.1°C and 13.6°C, respectively (Bear et al. 2007). Under the No Action Alternative, the mean monthly (water column mean) reservoir temperature from January to August (September to December were not analyzed) would range from 3.5°C in March to 11.3°C in August. This indicates the No

Action Alternative does provide the ability to meet temperature objectives for rainbow/redband trout and westslope cutthroat trout in the reservoir, as fish would be able to find the preferred temperatures they seek.

Libby Dam discharge water temperature is manageable seasonally (when the reservoir stratifies) using the selective withdrawal system to release water from the reservoir forebay that is closer to pre-dam river temperatures. The No Action Alternative would continue to provide the ability to meet temperature objectives for rainbow/redband trout and westslope cutthroat trout during early summer through early winter (June to December) via operation of the selective withdrawal system. However, the No Action Alternative does not provide the ability to meet temperature objectives during late winter through late spring, as the reservoir would be isothermic.

Discharges from Libby Dam would have the same effect on habitat for rainbow/redband and westslope cutthroat trout as for bull trout in the Kootenai River downstream from the dam. Maximum high discharges greater than or equal to 20 kcfs are needed annually during the spring freshet period to flush and sort fine sediments and gravels. Higher discharges (up to 25+ kcfs) of longer duration (up to 30+ days) are desired. Under the No Action Alternative, Libby Dam would provide discharges of 20 kcfs or greater for 11 to 16 days (25th to 75th percentile) during the spring freshet. This would support seasonal flow objectives for flushing and sorting sediments and gravels in the river below Libby Dam

Dewatering the varial zone of the Kootenai River during the productive season (June to September) reduces the density of the benthic invertebrate community. Benthic organisms die in less than 5 days in the dewatered zone, and it takes over a month and a half for them to recover after the substrate becomes re-wetted (Oasis Environmental 2011; Marotz and Althen 2005).

Under the No Action Alternative, winter operations at Libby Dam would continue to have winter ramping rates that are less protective than spring and summer rates, allowing for varial zone desiccation, re-inundation, and freezing. This may affect species bioenergetics and increase their metabolic activity and would be deleterious to benthic ecology, which would affect food organisms for rainbow/redband and westslope cutthroat trout. As mentioned under bull trout, no data are available to assess the within-day variability of the flows, and therefore this effect was not evaluated for any of the MOs.

Off-channel habitats are important for larval and juvenile burbot in the lower Kootenai River. These habitats provide warmer water, cover, and important forage. Similar to Kootenai River white sturgeon, the number of days that water levels were above 1,758 feet at Bonners Ferry was used to evaluate inundation under each alternative. The No Action Alternative would provide a median of 17 days above this elevation during the larval emergence and development stages of burbot, providing access to warmer and more productive rearing habitats for these days. This alternative would provide some floodplain connectivity for burbot; however, larval and juvenile burbot would benefit from an even longer duration of inundation.

Pre-dam flows and temperatures in the Kootenai River from November to March were low, stable, and cold. Burbot required these conditions for successful spawning and migration. Stable flows around of about 4 kcfs result in spawning congregations (based on empirical catch rates; IDFG cite), while daily load shaping and weekly load following result in high and variable flows and interrupted spawning migrations of adult burbot (Paragamian et al. 2005; Ross et al. 2018; Ashton et al. in press).

The modeled mean, maximum, and minimum flow at Bonners Ferry between January 1 and April 30 was used to represent the flow variability under each alternative. Under the No Action Alternative, the mean flow would be 13.4 kcfs, with an average maximum and an average minimum flow of 29.4 kcfs and 5.5 kcfs, respectively. Under the No Action Alternative, flows would not provide the appropriate discharge regime for successful burbot recruitment.

Water temperature is important for burbot egg incubation and larval development. Pre-dam temperatures in the Kootenai River were consistently cold November through March, and then rose sharply in April and May. Because discharge temperatures are too cold, and access to sufficient floodplain areas is limited, larval development is slowed and mortality increased.

Burbot need water temperatures of about 2°C in mid-February for spawning, egg incubation, and survival. Following spawning and early incubation, these fish need water temperatures to increase at a rate of over 2°C each month until they reach about 14°C by the end of June for normal development. Under the No Action Alternative, the mean monthly water temperature at Bonners Ferry would be below those temperatures, ranging from 3.88°F in March 11.1°C in mid-June. These temperatures would not provide appropriate mean monthly temperatures at Bonners Ferry for development of burbot. Early winter temperature would often be too warm for spawning and egg development and too cold for proper body development, growth, and survival.

A potential adverse effect on burbot is the entrainment of eggs and larval burbot through Libby Dam during March and early April. Although not explicitly quantified, the lower the discharge, the fewer the number of eggs and larvae would be entrained (Skaar et al. 1996). Modeling results show the median Libby Dam discharge between March 1 and April 15 would be 4 to 11 kcfs under the No Action Alternative; the effects of this discharge are not quantifiable.

#### ***Hungry Horse/Flathead/Clark Fork Fish Communities***

<u>Summary of Key Effects</u>

Hungry Horse Reservoir is a naturally cold, nutrient-poor reservoir; as such it has poor algae and zooplankton production but typically good water quality. Successful reproduction drives fish populations, but food availability is very important. Many of the important relationships between operations and fish in the reservoir focus on primary and secondary food production and the entrainment of both fish and zooplankton out of Hungry Horse Reservoir. In addition to these effects, reservoir elevations also influence the ability of migrating fish to access tributaries to spawn, and lower lake elevations increase the risk of predation and angling exploitation fishing on these fish in the varial zone. In the river below Hungry Horse, changes in temperatures and flows due to dam operations influence habitat suitability, and these effects continue downstream to the mainstem Flathead River and into Flathead Lake, then beyond into the lower Flathead River and Clark Fork River.

Habitat Effects Common to This Fish Community

Hungry Horse operations influence food web production in several ways:

- Lake elevations in the warm summer months influence the volume of warm, productive water for primary production and zooplankton production. This primary production in the summer provides food for the zooplankton that become an important food source for fish the following fall and winter (Fraley and Graham 1982, Fraley and Shepard 1989).
- The magnitude and rate of reservoir drawdown influences the production of benthic insects on the reservoir bottom from the water's edge down as far as light can penetrate. Insects need five to seven weeks of wetted substrate with light penetration in order to be productive. If areas are dewatered before this process is complete, there is no production. Higher reservoir levels also provide for inundation of the large flat shallow areas at the upper end of the reservoir to be productive with aquatic insects. These are an important food source in the spring (May et al. 1988).
- Reservoir elevations influence the availability of terrestrial insects for fish. This is an important summer food source. Lower lake elevations equate to less surface area for these insects to land on the water and be eaten by fish. Further, two of the four orders of insects that are this food source (flies, bees, and wasps) are able to fly so they readily transport to the water surface, but the other two (beetles and leafhoppers) do not fly, so as the water recedes away from the terrestrial vegetation, these food items become less available as they simply drop to the ground rather than dropping in the water (May et al. 1988).
- Outflows, elevations, and the location of water withdrawal affect the loss of zooplankton through entrainment out of the dam and into the South Fork Flathead River (Cavigli et al. 1998).

Lake elevations also influence the ability of fish to access tributaries for spawning, as most species migrate upstream into these inflowing streams to spawn. At elevations near the top of the normal pool, there is generally good access into the tributaries directly from the lake. As elevations drop, fish must traverse a length of tributary flowing through the varial zone, or where previous inundation has resulted in sedimentation and lack of vegetation. In these areas, fish are more susceptible to predation, angling pressure, and reduced access to tributaries.

Lake elevation in the warm summer months determines the volume of reservoir that would be available to produce plankton (euphotic zone). Note as the summer goes on, this productive zone gets thicker. This was estimated by determining the modeled reservoir elevation at the end of each month, converting it to reservoir volume, then subtracting the volume of the reservoir lower zone that would not produce plankton. See Appendix F for additional detail.

Drawdowns through the summer affect this production as well as the production of insects that live on the bottom of the reservoir. As reservoir elevations drop, insects in this zone can become dewatered. The insect eggs would have been deposited within the euphotic zone described above. If reservoir levels drop, that zone remains the same thickness and drops with the surface level, but there would be no insects deposited at the lower elevation that is now the euphotic zone, so steeper drops in the elevation relate to less benthic insect production. In addition, the large bays at the upper end of the reservoir become dewatered with dropping levels over the summer. This would continue to result in the loss of some benthic insect production but would continue to be enough to support a healthy native fish community. Additionally, there are three lobes of the reservoir with different shapes that would tend to become dewatered at different rates; they are known as Emery (the main lobe towards the dam), Murray, and Sullivan.

The reservoir elevation determines the surface area available for terrestrial insects to land on the water and be available for fish food, as well as influencing the proximity of the water's edge to terrestrial vegetation and therefore the ability of the two non-flying orders of important insects to be available to fish by passively landing in the water. To evaluate the No Action Alternative, the end-of-month elevation was converted to surface area using bathymetric data (USBR unpublished data). See Appendix F for end-of-month surface area calculations.

Zooplankton would continue to be entrained into the South Fork Flathead River from Hungry Horse Reservoir. The zooplankton enhances food supply in the South Fork Flathead River and along the near bank of the Flathead River but decreases food supply for fish in Hungry Horse Reservoir. Outflows, and therefore entrainment rates, are lower in the winter when the zooplankton are most important for fish.

Outflow patterns can also affect how fish are entrained into the South Fork Flathead River and the habitat conditions, such as river elevation (stage), velocities, and temperatures in the river. These effects continue downstream to affect the main Flathead River in the same patterns, but are somewhat attenuated by the flows in the mainstem Flathead River. Temperatures in summer are regulated with a selective withdrawal structure that is operated to release water at a temperature that favors native fish.

In the Flathead River down to Flathead Lake, habitat suitability is a key issue due to unnaturally high flows in the summer and winter. Under the No Action Alternative, summer flows would continue to be higher than natural, resulting in velocities that can be difficult for bull trout and other native fish, but the river would continue to provide habitat to support them. Higher-than-normal winter flows would continue to limit establishment of riparian vegetation important to fish. Spring peaks, although lower than natural, would continue to occasionally provide flushing of sediments from gravel to enhance production of benthic food sources.

Temperatures in the Flathead River would continue to be influenced by the contribution of the South Fork Flathead River with normalized temperatures in summer, when the selective withdrawal system operates. In the winter, the selective withdrawal structure is not operated so no longer useful to release targeted temperatures, but, in the winter, the reservoir is warmer than mainstem Flathead and so releases during this period are warmer than what would be normal. TDG in the Flathead River would continue to fluctuate with spill at Hungry Horse Dam but generally would not exceed 117 percent, which is within a safe zone for fish, under the *Operations to Limit TDG Production at the Hungry Horse Project* measure.

The influence of project operations on Seli'š Ksanka Qlispe' Dam and outflows Flathead Lake elevations is minor but could influence fish in the lower Flathead River and the Clark Fork River. Winter base flows out of Seli'š Ksanka Qlispe' Dam would typically be stable at about 7,700 cfs in January under the No Action Alternative, and summer flows are also artificially high.

Bull Trout

Hungry Horse Reservoir and its associated upstream tributaries support one of the healthiest populations of bull trout in their range. The productivity conditions described above as the No Action Alternative would continue to support this food web and bull trout. Reservoir elevations influence the access to spawning tributaries and the degree of varial zone effects, such as predation risk and exposure to angling exploitation that fish experience. Bull trout spawn in the fall. Changes in reservoir operations implemented in 2009 have reduced water level fluctuation during the summer and fall, which overlaps with the primary period when bull trout are migrating to spawning and overwintering habitats in tributaries (Reclamation 2009). In most years, tributary access and predation exposure and angling pressure in the varial zone are typically not an issue. The No Action Alternative would continue to provide access to spawning tributaries and limit varial zone effects. This could become a problem in low water years.

Bull trout entrainment through the dam is known to occur but the extent of entrainment has not been studied and the overall effect to populations is not known. It would be expected to continue at similar levels that do not impact overall populations. Bull trout are known to be present at depths greater than 100 feet near the dam and would be susceptible to being swept through the dam (i.e., entrainment), especially as the lake stratifies in the summer.

Bull trout in the South Fork Flathead River below Hungry Horse Reservoir are typically limited to either individuals entrained out of Hungry Horse or transitional use by individuals from the mainstem Flathead River, typically in October to July. There is not a spawning population in this stretch from Hungry Horse dam to the confluence with the Flathead River, and it is not designated critical habitat (FR 63898). As in the reservoir, food web relationships are important. The No Action Alternative would continue to allow for this transitory use by bull trout and other native fish with adequate food. Established minimum flows would continue to protect habitat, and ramping rate restrictions limit fluctuations.

The mainstem Flathead River would continue to provide conditions suitable for bull trout, with somewhat normalized temperatures, higher summer flows limiting slow-velocity habitat in summer, and higher winter flows limiting production of riparian vegetation.

Seli'š Ksanka Qlispe' Dam (Flathead Lake) operations would continue to potentially influence bull trout by occasional erosion events, causing water quality effects and favoring non-native fish such as northern pike in the bays and sloughs at the top of Flathead Lake. Bull trout use of

Flathead Lake would continue, and there could be some entrainment of bull trout at Seli'š Ksanka Qlispe' Dam into the lower Flathead River, particularly in cooler months when the temperatures would not exclude them from the large lobe of the lake near the outlet, though the extent is not known. Finally, the operations would continue to provide the flow regime to Seli'š Ksanka Qlispe' to operations downstream that support small, highly fragmented bull trout populations limited by dams and reservoirs influence on temperatures, flows, and non-native species on downstream in the Clark Fork River.

<u>Other Fish</u>

Hungry Horse Reservoir, as described in Section 3.5.1.4, favors a native-fish-dominated fish community. Juvenile bull trout and adult whitefish, northern pikeminnow, sculpins, and westslope cutthroat trout feed on zooplankton, aquatic insects, and terrestrial insects, and adult bull trout prey on mountain whitefish, suckers, and minnows. The food web effects described above would also apply to these species of fish in Hungry Horse Reservoir.

Westslope cutthroat trout and other native fish spawn in the spring (April to June), so the effects on adults migrating into tributaries to spawn would differ from bull trout. Spring spawning fish migrate when reservoir levels are lower and tend to experience longer varial zones with increased predation exposure, but access to tributaries is not typically problematic in most years.

Entrainment from the reservoir would also continue at current, unquantified levels, though westslope cutthroat trout would not be expected to be as susceptible as bull trout because they are not found at the depths of outlets like bull trout. Operations rules (VarQ), ramping rate restrictions, and minimum flows would continue to support the observed increasing trends of native fish and limit invasion by lake trout and brook trout.

A selective withdrawal structure and VarQ rules would continue to regulate temperatures to support a more natural thermal regime that is beneficial to native fish and minimize invasion by non-native fish such as lake trout from Flathead Lake. Westslope cutthroat trout in the Flathead River would continue to move up into the South Fork Flathead River when the temperature control structures operate. In Flathead Lake, northern pike are nearly beyond the time when their eggs would still be viable by the time the lake levels rise far enough for them to access spawning areas in bays, and further delay in refill could reduce their spawning success. Some entrainment out of Flathead Lake likely occurs but is unquantified.

Below Seli'š Ksanka Qlispe' Dam in the lower Flathead River and Clark Fork River, the altered hydrograph would favor non-native species; the fish community is dominated by non-natives but some bull trout and westslope cutthroat trout are also present. High winter flows limit riparian cover, and higher summer flows increase habitat for non-native fish such as walleye and smallmouth bass.

***Lake Pend Oreille (Albeni Falls Reservoir)/Pend Oreille River***

Summary of Key Effects

The No Action Alternative would not change the way bull trout are currently utilizing Lake Pend Oreille or the Pend Oreille River downstream of Albeni Falls Dam. Bull trout would continue to use Lake Pend Oreille from November to June when water temperatures are cooler, then move into tributaries in the summer. Sub-adult bull trout and non-spawning adults may remain and rear in the lake year-round. An unknown number of bull trout would be entrained at Albeni Falls Dam. These fish would likely perish in the summer when water temperatures in the river downstream of the dam reach lethal levels, although a small number (between 1-12 per year) may be recovered by temporary efforts to collect fish from the tailrace. A permanent trap and haul fishway may be completed during the period of analysis for the EIS. Kokanee would continue to be able to spawn, but their populations would be influenced by competition with opossum shrimp for food (zooplankton) coupled with predation by lake trout and other predatory fish species. Westslope cutthroat trout would continue to use Lake Pend Oreille, and an unknown number would be entrained at Albeni Falls Dam. Like bull trout, they would likely experience high mortality rates in the summer when water temperatures in the river downstream of the dam reach lethal levels. Some may be recovered by trap and haul efforts. Key effects for warmwater game fish such as pike, walleye, and smallmouth bass include stable spring water levels for spawning and rearing, winter drawdowns that interrupt juvenile rearing, adequate forage for large predators, and potential entrainment.

Habitat Effects Common to This Fish Community

As discussed in Appendix D, *Water Quality*, 7-3, *Albeni Falls*, temperature data collected in the lake in 2004 to 2006 showed surface water temperatures typically exceed 19°C by the end of June and reach a maximum of 24°C at the end of July. At depths below 14 m, temperatures are within the preferred range of bull trout during summer (less than 15°C). Colder water of 5°C and below is found throughout the summer in some locations. These water temperature patterns would be expected to continue under the No Action Alternative. The river section of Lake Pend Oreille does not provide cool water refugia. This is because the shallow low-water channel near Sandpoint, Idaho, acts as a heat source for downstream flows and blocks the movement of much colder subsurface water from Lake Pend Oreille into the river section. Large woody debris is not currently allowed to enter Lake Pend Oreille as it poses a safety hazard to boating. A log boom currently diverts debris coming into the lake.

Outflows from Albeni Falls Dam would affect rates of entrainment of fish from Lake Pend Oreille. Mean flows under the No Action Alternative in May and June would be about 50,700 and 55,600 cfs, respectively. Under the No Action Alternative, median flows are 23,700 cfs in October to draft Lake Pend Oreille. In the winter, median discharge is 14,500 cfs to 16,600 cfs. River temperatures below Albeni Falls Dam are expected to be similar to those in the river part of Lake Pend Oreille above the dam. These temperatures reach 15°C in June and lethal temperatures for cold water fish in July (Corps 2018). Under the No Action Alternative, these high summer water temperatures are expected to continue.

Bull Trout

Access to tributaries is important for bull trout in Lake Pend Oreille, as that is where they spawn. Under the No Action Alternative, bull trout would continue to have access to tributaries to Lake Pend Oreille during the spring and summer. Bull trout move into the tributaries when lake levels are high during May and June. Because Albeni Falls Dam operations affect sedimentation and erosion from the lake shorelines, this could indirectly affect bull trout access to tributary mouths due to sedimentation. During the upstream migration of bull trout in May to September, the pool elevation is rising or at the full pool elevation of 2,062 feet under the *Lake Pend Oreille Elevations for Kokanee and Bull Trout* measure. Gold and Granite Creeks may be affected more as fish move into these tributaries later in the year. However, current operations rarely affect tributary access during spring and summer (Corps 2018). Operations under the No Action Alternative would continue to provide access to most tributaries for bull trout.

Historically, bull trout from Lake Pend Oreille would migrate up the Clark Fork and spawn. The construction of Cabinet Gorge Dam on the Clark Fork in 1953 blocked those runs, and the genetics for that population may have been lost. In 2001, a trap-and-haul operation was implemented to capture adult bull trout at Cabinet Gorge Dam and transport them to sites upstream. On average approximately 35 adult bull trout are transported at this site each year. The design for an updated permanent fish trap at Cabinet Gorge Dam was finalized in 2018 (Avista 2017). Under the No Action Alternative, bull trout from the lake would continue to have passage to their historic habitat above Cabinet Gorge Dam, either from the trap-and-haul program or the new permanent fish trap.

An unknown number of bull trout are entrained through Albeni Falls Dam each year and are lost to the system, as there currently is no trap-and-haul program at Albeni Falls Dam to return them to the lake. However, a permanent trap and haul fishway may be completed during the period of analysis for the EIS that would allow these fish to return upstream. Entrainment is most common from March to June when flows are high (Corps 2018). Most populations of bull trout within Lake Pend Oreille are large enough that there are not likely to be major effects from entrainment. Entrainment is likely to continue under the No Action Alternative, with trap and haul reducing the number of fish lost in the future.

Under the No Action Alternative, water temperatures in Lake Pend Oreille would continue to be suitable for bull trout year-round in at least part of the lake. Bull trout prefer cold water with temperatures below 15°C (Barrows et al. 2016). In November through June when bull trout are present in the lake, surface temperatures range from about 4°C to 15°C, while temperatures in deeper water greater than about 65.6 feet (20 m) rarely exceed 15°C. In June to October, surface water temperatures would likely be too warm for bull trout (greater than 18°C), but deeper parts of the lake below the thermocline 45 ft. (14 m) or greater, would still provide cold water habitat (less than 15°C) suitable for bull trout. Temperature profiles from Appendix D show that water temperatures between June and October are likely too hot for bull trout in the river section of Lake Pend Oreille. This is because a shallow low-water channel near Sandpoint, Idaho, acts as a heat source for downstream flows and blocks the movement of much colder subsurface water from Lake Pend Oreille into the river section. This is likely to continue under the No Action Alternative.

The continuing loss of large woody debris along the shoreline is not likely to adversely affect bull trout; historically this debris settled out in shallow water habitat that has warmer surface water and is not likely to be used by bull trout.

Lake Pend Oreille would continue to provide adequate forage for bull trout under the No Action Alternative. Bull trout need robust kokanee populations for adequate forage as kokanee are the principal prey for adult bull trout (Hansen et al. 2019). Under current conditions, kokanee would continue to provide a good forage base for adult bull trout. Kokanee have increased from about 40 adult fish per acre (100 adult fish per hectare) in 2008 to about 152 adults per acre (377 adults per hectare) in 2016 (Hansen et al. 2019). Winter fluctuations are likely to increase erosion of the lakebed at lower elevations of about 2,051 to 2,056 feet and may affect forage fish production (Corps and Bonneville 2011).

Under the No Action Alternative, bull trout may experience greater predation and competition for food from walleye, northern pike, and lake trout. Walleye populations have been at a low level but are now expanding rapidly. From 2011 to 2017, relative abundance has doubled every 3 years (reference to be added prior to final). There is recruitment of walleye in Lake Pend Oreille as well as entrainment from upriver. Operations of Albeni Falls Dam and the lake may favor walleye and other warmwater fish during the time that bull trout subadults are migrating downstream into Lake Pend Oreille through the river/lake interface. Under current conditions, walleye populations are expected to expand and prey on sub-adult bull trout. Walleye also forage on kokanee, and therefore would compete with adult bull trout for this important food source.

Northern pike would also prey upon and compete with bull trout, but the actual effect under the No Action Alternative is undetermined. Studies in Montana show that northern pike eat bull trout (Muhlfield et al. 2008). Bull trout and westslope cutthroat trout make up about 5 percent of the diet of northern pike in upriver sites. Northern pike also prey on kokanee. While northern pike enter Lake Pend Oreille from upstream entrainment and in-lake recruitment, their numbers are still low and their future populations are undetermined.

Lake trout compete with bull trout for kokanee in Lake Pend Oreille. A lake trout suppression program in effect from 2006 to 2016 was successful in removing many lake trout from the lake and, consequently, kokanee populations have increased (Hansen et al. 2019). However, bull trout populations remained low and bull trout redd counts are down. Under the No Action Alternative, competition from lake trout is expected to continue at low levels in the lake.

There is a potential indirect effect to bull trout from hybridizing with brook trout populations. However, brook trout populations are primarily found in the tributaries, and only limited populations are found in the mainstem habitats.

Downstream of Albeni Falls Dam, non-native Northern pike and walleye have expanded their populations and may consume bull trout there. Northern pike are the apex predator in this system and are experiencing exponential population growth (reference to be added prior to final). Suppression efforts started in 2012 in Box Canyon reservoir, the first reservoir downstream of Albeni Falls Dam, have resulted in a 90 percent reduction in northern pike (reference to be added prior to final). Suppression efforts have also started at Boundary Dam, which is downstream of Box Canyon Dam. However, suppression efforts would not eliminate northern pike from the river, and the remaining fish could prey on entrained bull trout. This predation would not affect bull trout populations as any entrained bull trout would not be able to return upstream of the dam to spawn and would not survive the high water temperatures in the summer. Walleye have also expanded their populations in both Box Canyon and Boundary Reservoirs, but their numbers are still relatively low. Predation by walleye would have the same effect on bull trout as for northern pike under the No Action Alternative.

<u>Other Fish</u>

Under the No Action Alternative, kokanee would continue to be able to spawn, but their populations would be influenced by competition with opossum shrimp for food (zooplankton) coupled with predation by lake trout and other predatory fish species. The operation to manage winter lake elevations behind Albeni Falls Dam is, in part designed to support kokanee spawning and egg incubation in Lake Pend Oreille under the *Lake Pend Oreille Elevations for Kokanee and Bull Trout* measure. The intent is to lower the lake to its winter elevation before kokanee start spawning along the shoreline in November and December and hold it there through March to prevent dewatering of the redds during egg incubation. Flexible winter power operations (power peaking) result in changing lake elevations in the winter and may increase erosion of kokanee spawning habitat. While the modeling used for evaluating reservoir elevations cannot show power peaking operations, the current lake operations do not appear to adversely affect kokanee spawning or egg incubation. Relatively low numbers of kokanee would continue to be entrained through Albeni Falls Dam under the No Action Alternative. Entrainment most likely occurs during high flows but is not likely a large source of loss to the population of kokanee in Lake Pend Oreille (Bellgraph et al. 2015). Sampling by the Kalispel Tribe shows a limited number of kokanee downstream of Albeni Falls Dam. Kokanee have also been seen in the reservoirs behind Box Canyon Dam and Boundary Dam following high-flow events (personal communication, Bill Baker, WDFW).

Under the No Action Alternative, kokanee populations in Lake Pend Oreille would continue to be influenced by competition with opossum shrimp and predation by lake trout and other predators (e.g., Gerard rainbow trout, walleye, bull trout) (Corsi et al. 2019). Both opossum shrimp and kokanee feed on zooplankton, and high shrimp numbers reduce the amount of forage available to kokanee. At the same time, kokanee are also prey for lake trout, walleye, and bull trout. To maintain kokanee populations, predator suppression has been used to keep lake trout numbers down at Lake Pend Oreille, but walleye continue to increase. Opossum shrimp regulate kokanee population potential while predator populations appear to be the primary driver for kokanee populations within that potential in Lake Pend Oreille. Kokanee populations under the No Action Alternative are expected to continue remain at current levels in the foreseeable future assuming opossum shrimp populations remain low and predator management continues to be successful. Kokanee are expected to continue to provide forage for predators, including bull trout, in future years.

As with bull trout, the construction of Cabinet Gorge Dam blocked access to tributaries for westslope cutthroat trout in Lake Pend Oreille. This blockage resulted in a loss of genetics and habitat for the species. In 2016, trap-and-haul operations were implemented to capture adult westslope cutthroat trout at Cabinet Gorge Dam and transport them to upstream sites. As discussed above for bull trout, the design for a permanent fish trap at the dam was finalized in 2018 (Avista 2017). Under the No Action Alternative, westslope cutthroat trout from the lake would continue to have passage to their historic habitat above Cabinet Gorge Dam, either from the trap and haul program or the new permanent fish trap.

Similar to bull trout, an unknown number of westslope cutthroat trout are entrained through Albeni Falls Dam each year. Cutthroat are found relatively often below the dam and are isolated from their habitat as there currently is no trap and haul program at the dam to capture fish and return them to the lake. Cutthroat are cued to spawn when water temperatures reach about 10°C (Liknes and Graham 1988), or about May in Lake Pend Oreille. Entrainment is highest in May and June during the spring high spill season (Corps 2018) and coincides with when the fish are moving to spawning areas. Entrainment at Albeni Falls Dam is likely to continue and affect an unknown number of fish under the No Action Alternative.

As discussed above for bull trout, water temperatures between June and October are likely too hot for westslope cutthroat trout in the river section of Lake Pend Oreille as well as the river downstream of Albeni Falls Dam. Bear et al. (2007) found that water temperatures over 18°C are limiting for westslope cutthroat trout and the upper lethal temperature is about 20°C. Westslope cutthroat trout in the Pend Oreille River would also continue to be susceptible to predation from walleye and northern pike.

Walleye in Lake Pend Oreille spawn in the spring over cobble and gravel substrates when water temperatures reach at least 4°C (reference to be added prior to final). Under the No Action Alternative, water temperatures in Lake Pend Oreille would range from 3°C in February to 12°C in May (Appendix D). These temperatures and substrates would continue to support walleye spawning at Lake Pend Oreille under the No Action Alternative.

Stable water levels are also critical for walleye spawning success, as drawdowns during spawning would leave eggs and larvae dry. Walleye spawn when Lake Pend Oreille is filling, so the eggs and larvae would likely remain submerged under the No Action Alternative. Winter operations can fluctuate as much as 5 feet during early March and may affect a small portion of the walleye spawn. The effect on walleye spawning under the No Action Alternative is unknown, but elevated stable water levels may improve summer habitat for walleye.

Walleye fry (young fish that are capable of feeding themselves) are pelagic (living in open water) and feed on zooplankton. Reduce plankton numbers lead to reduced fry survival. Lake

Pend Oreille is classified as oligotrophic to mesotrophic (low to moderate productivity), and a moderate number of zooplankton were sampled, with increases in the last 8 years (reference to be added prior to final). Recent increases in walleye populations is evidence of lack of limitations to fry survival. Currently plankton numbers do not appear to be limiting for walleye. This would be expected to continue under the No Action Alternative.

Smallmouth bass spawning in Lake Pend Oreille is initiated when water temperatures reach about 13°C (Edwards et al. 1983). Under the No Action Alternative, water in Lake Pend Oreille would reach this temperature in mid-May. Egg development for smallmouth bass requires temperatures of 13°C to 25°C for normal growth. Surface water temperatures in Lake Pend Oreille currently reach 13°C in May and rise to over 20°C in July. This indicates the lake currently provides water temperatures that support smallmouth bass embryo development. This would continue under the No Action Alternative.

Pool elevation affects spawning, egg development, and fingerling survival for smallmouth bass. Water fluctuations during spawning and egg incubation (mid-May through June) can reduce recruitment if the water levels drop and dry up the nests. However, water elevations in Lake Pend Oreille generally increase from 2,057 to 2,062 feet during this period and therefore do not adversely affect smallmouth bass spawning or recruitment. This effect would continue under the No Action Alternative.

Pool elevations in Lake Pend Oreille from May through October may affect smallmouth bass fingerling survival. Water levels are generally raised from May to June, held constant until September, and dropped rapidly until mid-November. Under the No Action Alternative, this pattern of water level management in the lake may adversely affect smallmouth bass fry or fingerlings at the end of the rearing period in September and October by forcing the fish to leave nesting and rearing areas.

Pool elevations at Lake Pend Oreille can affect northern pike habitat availability. When the lake is at full pool, inlet and slough habitats that are optimum habitats for northern pike are inundated. When water levels drop, these habitats are no longer available. Pool elevations in Lake Pend Oreille are generally raised from May to July, held constant until September, and dropped rapidly through October. This operation would continue under the No Action Alternative and would result in lake levels that would support limited spring spawning and summer rearing habitat for northern pike.

High flows could affect entrainment at upstream reservoirs and move invasive northern pike from these reservoirs into Lake Pend Oreille. Flows from Cabinet Gorge Dam during the spring freshet (May and June) can be used as a surrogate for the risk of northern pike entrainment into Lake Pend Oreille with higher flows resulting in increased risk of entrainment. Median flows under then No Action Alternative for May and June would be 50,700 cfs and 55,600 cfs respectively. Under these flows, continued entrainment of northern pike into Lake Pend Oreille would be expected.

Mountain whitefish spawn in the Pend Oreille River below Albeni Falls Dam in October. Eggs and fry require sufficient stable winter flows to prevent desiccation and freezing. Under the No Action Alternative, median flows are 23,700 cfs in October to draft Lake Pend Oreille. In the winter, median discharge is 14,500 cfs to 16,600 cfs. As a result, an unknown number of whitefish eggs and fry are lost during this operation. Under the No Action Alternative, these losses would continue.

When non-native plants invade littoral zone habitats, changes in biotic and abiotic interactions often occur (Madsen 1998). Lake Pend Oreille has approximately 20,700 acres of littoral zone habitat for aquatic plant growth, or about 27 percent of the lake area. Eurasian watermilfoil is an invasive species that often grows in dense beds that can be responsible for reductions in DO, increases in water temperature, internal nutrient loading, reduced native plant richness, and reduced macroinvertebrate abundance and fish growth (Madsen 1998). Currently, milfoil beds are treated chemically to reduce their abundance and distribution. These treatments have resulted in a 90 percent reduction in the distribution of this invasive plant. Under the No Action Alternative, these treatments would continue and milfoil distribution is not expected to expand.

Game fish, particularly warmwater game fish, require stable water levels during spawning and rearing to prevent the desiccation of eggs or fry. The No Action Alternative operation would result in lake levels that would generally support spring spawning and summer rearing for warmwater game fish. Early winter drawdowns of Lake Pend Oreille can interrupt juvenile rearing and may reduce numbers of non-native game fish species like largemouth bass, pumpkinseed, and black crappie. Currently, water levels are dropped at Lake Pend Oreille in early September through November under the *Lake Pend Oreille Elevations for Kokanee and Bull Trout* measure. This drop would likely interrupt juvenile rearing and reduce successful recruitment in some years.

Gerrard or Kamloops rainbow trout are an important trophy fishery at Lake Pend Oreille. These fish grow to large sizes and require robust kokanee populations for adequate forage, as kokanee are the principal prey for adult rainbow trout. Under the current conditions, kokanee would continue to provide a forage base for large predators in this system. Kokanee have increased from about 40 adult fish per acre (100 adult fish per hectare) in 2008 to about 152 adults per acre (377 adults per hectare) in 2016 (Hansen et al. 2019).

In the river below Albeni Falls Dam, summer water temperatures are limiting to cool and cold water fish species. Salmonid species in particular often experience lethal temperatures in this reach of river. Only brown trout, the most temperature tolerant of salmonids, survive in Box Canyon and Boundary Reservoirs, but even they are still limited in their distribution. Currently, water temperatures reach approximately 22°C in late July. Under the No Action Alternative, temperatures would continue to reach lethal levels for most cold water fish in late July.

**Region B**

***Ongoing Existing Mitigation Programs***

In Region B, Bonneville F&W-funded hatchery programs include programs for white sturgeon, burbot, kokanee salmon, westslope cutthroat trout, and rainbow trout. For example, the Spokane Tribe, the Confederated Tribes of the Colville Reservation, and WDFW are collaborating to implement white sturgeon monitoring and conservation aquaculture in Lake Roosevelt. Spokane Tribe, Colville Tribe, and WDFW also implement projects to support resident redband trout and kokanee. With the use of Bonneville funds, the co-managers of Lake Roosevelt (Colville Confederated Tribes, Spokane Tribe of Indians and Washington Department of Fish and Wildlife) are working to address invasive fish. For example, they have removed 2,000 Northern Pike from the middle and upper sections of Lake Roosevelt since February 2018. Funding for these efforts have been provided by several other entities, including the Confederated Tribes of the Colville Reservation, Chelan Public Utility District, and Grant Public Utility District.

***Lake Roosevelt/Columbia River from U.S.-Canada Border to Chief Joseph Dam***

<u>Summary of Key Effects</u>

Flow, elevations, and water quality impact the quality of habitat for various resident fish species above, in, and downstream of Lake Roosevelt. For example, the Columbia River from the U.S.-Canada border would continue to support a white sturgeon population that spawns successfully but primarily relies on fish manager intervention. Sufficient flows and riverine length that allow for natural recruitment are experienced in only very few years. In Lake Roosevelt, retention time is a key metric for most fish species in Lake Roosevelt, driving the food web that supports the fish as well as influencing how many are entrained. Current levels of entrainment would continue. Lake elevations would continue to allow impaired tributary habitat access needed for spawning for redband rainbow trout and the portion of kokanee that spawn in tributaries, and reservoir operations would continue to result in some level of egg desiccation of the burbot spawn and the portion of kokanee that spawn on lake shorelines. The No Action Alternative would continue to support both wild and hatchery-raised kokanee, redband rainbow trout, and hatchery rainbow trout, as well as non-native warm water game species such as walleye, smallmouth bass, and northern pike. Under the No Action Alternative, adfluvial species are expected to continue to experience impeded migration to and from tributaries associated with varial zone effects.

Northern pike would likely continue to increase and invade downstream, with that rate of invasion slowed somewhat by suppression efforts. Rufus Woods Lake would continue to provide habitat for fish entrained from Lake Roosevelt and from limited production of shoreline spawning by some species, all influenced by high TDG levels.

Habitat Effects Common to This Fish Community

Peak outflows typically occur in late May to mid-June during the spring freshet. Higher winter flows can happen from winter rain events or drafting for larger spring water supplies. These peak outflows can influence the rate of entrainment from Lake Roosevelt into Rufus Woods Lake. TDG concentration in the Grand Coulee tailwater is also a concern for fish in Rufus Woods Lake. Under the No Action Alternative, daily average TDG would continue to exceed the state water quality standard of 110 percent saturation from early May through mid-August, and occasionally exceed 120 percent to 125 percent saturation in some years.

Retention time of water through the reservoir is a driving metric for the food web in Lake Roosevelt and influences the populations of several fish species as retention time is strongly correlated with entrainment (LeCaire 2000). Under the No Action Alternative, median retention time would range from about 40 to 50 days in the winter and early spring, dropping to as low as 21 days by June, then gradually increase over the summer to about 45 days at the end of August. September and October would have high retention times, with a median of 60 to 80 days. Entrainment of key species would continue, while habitat conditions would still support various life histories of these species in an impaired capacity.

Kokanee, redband rainbow trout, juvenile burbot, larval sturgeon, and many prey species rely directly on the food source provided by the zooplankton production, and higher-level predators such as bull trout prey on these fish. Zooplankton are more widespread, more plentiful, and larger in body size when retention times are higher, and tend to be smaller bodied, swept out of the reservoir faster, and more concentrated near Grand Coulee Dam with a lower retention time. In this scenario, not only is there less food available to fish, but they also tend to follow the food source and crowd down toward the dam, becoming more susceptible to entrainment.

Bull Trout

Bull trout are rare in Lake Roosevelt and individuals are likely occasional strays from populations in river systems north of the U.S.-Canada border isolated from their spawning habitat (USFWS 2015). Bull trout are temperature-sensitive and would continue to use this reach for foraging, migration, and overwintering habitat until temperatures reach stressful levels at about 18°C (BioAnalysts 1998). Bull trout in Lake Roosevelt, although considered rare (USFWS 2015), are believed to exhibit adfluvial behavior, overwintering in the reservoir then moving into cooler tributaries as water temperatures in the mainstem increase. The timing of temperatures reaching levels that trigger bull trout migration would be similar to that in the past. High-flow years would continue to influence bull trout distribution through flushing more of them from the river near the U.S.-Canada border down into Lake Roosevelt, similar to the high flows of 1997, after which fish managers noticed an increase in bull trout in Lake Roosevelt (unpublished data). High flows also can cause entrainment out of Lake Roosevelt and into Rufus Woods Lake, as evidenced by past surveys that have captured occasional bull trout (Lecaire 2000).

Bull trout prey base would continue to fluctuate, as the fish they eat are sensitive to changes in productivity and location of zooplankton in Lake Roosevelt that is influenced by how long water stays in the reservoir. Bull trout are also sensitive to contaminants that are found in this region and would continue to bioaccumulate contaminants as a top predator (See Section 3.4, *Water Quality*).

Other Fish

In the Columbia River reach from the U.S.-Canada border to Lake Roosevelt, white sturgeon are typically able to spawn, but they rarely experience successful survival from larvae to juvenile life stages, and only in extremely high-water years. Successful recruitment appears to be dependent on a combination of flows exceeding 200 kcfs and water temperatures of about 14°C for 3 to 4 weeks in late June/early July (Howell and McLellan 2011 and Howell and McLellan 2014). The timing of these flows coinciding with lower reservoir levels can also increase sturgeon reproduction with the longer river habitat provided by a lower reservoir level. Other factors that would continue to influence sturgeon include: predation by fish that are favored by reservoir conditions if larvae are flushed into the Lake Roosevelt, and the uptake of contaminants such as copper closer to the U.S.-Canada border that can be flushed downstream into the reservoir by high flows. These higher flows would also continue to move larval sturgeon out of the area of higher copper concentrations. Under the No Action Alternative, recruitment of white sturgeon would continue to be a rare event supplemented by hatchery propagation, as larval sturgeon are captured and raised in hatcheries until they are past the time window where recruitment has been shown to fail at a high rate. Once these juveniles are released back into the reservoir, they continue to grow and survive well. The reservoir would continue to provide good conditions for growth and survival of these fish.

Wild production of native fish such as burbot, kokanee, and redband rainbow trout would continue to provide valuable resources in Lake Roosevelt. As described in the common habitat effects, these fish are the most sensitive to the effects of changing retention times. LeCaire (2000) estimated an average of over 400,000 fish annually are entrained, 30 to 50 percent of which were kokanee, primarily of wild origin. Rainbow trout were the second most entrained species. Entrainment of key species would continue at similar rates, while habitat conditions would still support various life histories of key species in an impaired capacity.

For tributary spawning species such as redband rainbow trout and a portion of the wild production of kokanee, tributary access at the right time of year is important. Reservoir drawdown in the spring creates barren tributary reaches through the varial zone, which would impede access to tributaries and the reservoir. Redband rainbow trout and the fluvial (that migrate up tributaries to spawn) portion of the kokanee population would continue to have impaired access.

Species such as kokanee and burbot that spawn on shorelines are susceptible to egg desiccation if reservoir levels drop while eggs are still in the gravel. Kokanee spawn on shoreline gravels September 15 to October 15, and eggs incubate through February. Burbot tend to spawn successfully in depths provided by the No Action Alternative in the Columbia River and in Lake Roosevelt on shorelines near the Colville River in winter, with eggs incubating through the end of March (Bonar et al. 2000). Under the No Action Alternative, reservoir elevations begin to draft from near the full pool in January, with steeper drafts starting February through April, with larger water supply forecasts requiring deeper drafts. The portion of kokanee that spawn near the fall surface elevation would be more at risk, with a lesser effect on early spawners such that the fry emerge earlier in February. Fry sometimes also stay in the gravel and could become stranded as well. Burbot spawn later in the fall so would be less affected in dry years, with only about 3 feet of reservoir drop while eggs are in gravel, but they remain in gravel until the end of March when the median reservoir elevation is more than 30 feet deeper than the fall. Burbot spawn in the Columbia River above Lake Roosevelt and in the reservoir toward the upper end. These areas would be affected as the reservoir is drafted.

Kokanee are sensitive to water temperature, and during summer they are found at depths below 120 m to find suitably cool water. Under the No Action Alternative, Lake Roosevelt is very weakly stratified but does have suitably cool water at this depth along with suitable levels of DO. Lake whitefish and mountain whitefish also likely use this cool water in the summer.

Non-native warmwater gamefish, such as walleye, northern pike, smallmouth bass, sunfish, crappie, and others, as well as the prey fish that they eat (such as shiners, dace, and sculpins) all tolerate a wide range of environmental conditions and would continue to contribute to the fish community under the No Action Alternative, and continue to adversely impact native species via predation. The invasion downstream by northern pike is of concern because they are aggressive predators that threaten native fish, including anadromous salmonids. The Lake Roosevelt Co-Managers are actively suppressing pike populations using gillnets set by boats as soon as they can get on the water in the spring until the boat ramp becomes unusable at an elevation of 1,235 feet. Under the No Action Alternative, this occurs on April 15 in wet years, and would not occur at all in dry and average years. Additionally, outflows and retention time would continue to influence the entrainment and downstream invasion of non-native gamefish below Chief Joseph Dam where ESA-listed anadromous salmonids would be susceptible to predation by them.

Sterile rainbow trout are raised in net pens to provide additional recreational fishery as mitigation for the construction and operation of Grand Coulee dam. Once released, the net pen fish that supplement the rainbow trout fishery in Lake Roosevelt would experience similar effects as their native counterparts except for spawning and early rearing effects. In addition, the net pen locations are situated where the water quality can be affected by changes in reservoir elevations; these fish are sensitive to temperature and TDG, and their eventual recruitment to the fishery can be affected by retention time coupled with reservoir elevation at the time of their release (McLellan et al. 2008), which is typically in May. Under the No Action Alternative, the water quality at these locations from May 15 to June 15 would typically be suitable for rearing, with temperatures ranging from 10°C to 18°C and TDG from 101 percent to 125 percent, depending on water year conditions. The upper ends of these parameters under the No Action Alternative may cause some stress to net pen fish prior to their release. The average retention time would be about 13 to 33 days during this time, and the reservoir elevation would be highly variable, depending on the water year type driving reservoir operations. The operators strive to release these fish to coincide with the initiation of reservoir refill when outflows are reduced, which under the No Action Alternative is in early to mid-May, in order to reduce the risk of newly released fish being entrained out of the reservoir. Under the No Action Alternative, this typically would result in fish being released before water quality conditions become stressful in the net pens.

The fish in Rufus Woods Lake would continue to be supplemented by entrained fish out of Lake Roosevelt to a large extent, with fish mostly entrained during the spring freshet and winter drawdown periods. This lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. High flows during late spring and early summer would continue to flush eggs and larvae from protected rearing areas. Peak outflows typically occur in late May to Mid-June during the spring freshet. TDG in the Grand Coulee tailwater is a concern for fish in Rufus Woods Lake. Under the No Action Alternative's *Spill Operations* and *Water Quality Plan for TDG and Water Temperature* measures, daily average TDG concentrations would continue to exceed the state water quality standard of 110 percent from early May through mid-August, and occasionally exceed 120 percent to 125 percent in some years. There are also net pens in Rufus Woods Lake, and TDG levels would continue to influence when and where these fish could be released.

***Chief Joseph to McNary Dam***

<u>Summary of Key Effects</u>

Key effects under the No Action Alternative for this reach of the Columbia River include elevated summer water temperatures; elevated TDG; hydropower dams that pose migration barriers, cause passage delays, or increase fish mortality; reductions in spawning and rearing habitats; and changes in flow patterns and temperatures that reduce spawning and recruitment success.

<u>Habitat Effects Common to All Fish</u>

Reservoirs in this reach of the Columbia River are a series of run-of-river impoundments that create slow-moving, river-like habitats. The reservoirs are mesotrophic (contain a moderate amount of dissolved nutrients) and provide ample zooplankton and aquatic invertebrates as forage for a variety of fish. This reservoir environment tends to favor non-native fish such as walleye, smallmouth bass, bluegill, perch, and crappie. Some native suckers also do well in these habitats, including bridgelip and largescale suckers. The temperatures would continue to be favorable for these cool and warmwater species. The substrate of these reservoirs is primarily silt and sand with some gravel and cobble habitats at dam tailraces. Large sections of the shoreline have been armored with riprap, providing suitable spawning habitat for many of these fish.

Water quality in the reservoirs would continue to be favorable for the current fish communities, with temperatures well within the tolerance of cool and warmwater fish. High flow events in the watershed can temporarily increase the amount of suspended sediment in the reservoirs.

However, under the No Action Alternative, most of the time suspended sediment levels would be less than 10 mg/L (see Section 3.4, *Water Quality*).

<u>Bull Trout</u>

Bull trout prefer water temperatures below 15°C, but adults can use temperatures up to 18 C. Although juvenile bull trout are not found in the mainstem in this river reach, temperatures above 15°C can limit their distribution (Selong et al. 2001; BioAnalysts 1998). Few bull trout are found in areas from the Chief Joseph Dam tailrace to the Okanagan River as the nearest spawning tributary is the Methow River 20 miles downstream. Adult and sub-adults exit the mainstem by early July returned to their spawning tributaries (Barrow et al. 2016; Nelson et al. 2012). Under the No Action Alternative, bull trout would continue to spawn in the tributaries, and both adults and subadults would continue to use the mainstem Columbia River and reservoirs for foraging, migration, and overwintering.

Effects to sub-adult and adult bull trout during passage at Mid-Columbia River dams include passage delays and mortality. Bull trout moving past Wells Dam may be delayed by about 5 days and may typically experience survival rates over 95 percent (Robichaud and Gingerich 2017). Under the No Action Alternative, bull trout would continue to pass all the dams in this reach except Chief Joseph and would be expected to continue to experience high survival rates.

TDG levels from spill under the No Action Alternative, including through the *Spill Operations* and *Water Quality Plan for TDG and Water Temperature* measure, may adversely affect an unknown number of bull trout in the reservoirs. As discussed in Appendix D, *Water Quality*, TDG exceeds 110 percent on 11.3 percent of all days from October through July at Chief Joseph Dam and 26 percent of all days during this time at McNary Dam. Under the No Action Alternative, there continues to be a minor risk for adverse effects from TDG on bull trout May through July in this reach of the river.

<u>White Sturgeon</u>

White sturgeon spawning habitats are limited to fast water areas below run-of-river dams and the Hanford Reach. Under the No Action Alternative, an unknown number of juvenile white sturgeon would continue to be entrained from this river reach.

White sturgeon generally initiate spawning in the late spring when water temperatures reach 10°C to 12°C during the peak or descending limb of the hydrograph. Higher flow years have better spawning and recruitment success. Currently, white sturgeon recruitment is rare. The lack of spawning habitat and high lows to induce spawning are cited as the cause for this lack of recruitment (Hildebrand et al. 2016).

Currently, an unknown number of white sturgeon succeed in passing downstream of dams on the Columbia River. Sturgeon populations in upper basins currently act as source populations for downstream recruitment. Under the No Action Alternative, these fish would continue to be limited to downstream dam passage.

Elevated water temperatures can have adverse effects on white sturgeon. Temperatures over 20°C can limit egg survival (Wang et al. 1985), and in some years, a combination of low flows, elevated summer temperatures, and low DO levels have led to white sturgeon mortality (IDFG 2008). During 2015, elevated water temperatures interacted with large sockeye runs to increase white sturgeon mortality. Sturgeon gorged on decomposing sockeye while water temperatures were near 22°C and were unable to metabolize these fish. Under current conditions, mean high temperatures greater than 21°C would occur nearly 10 percent of the year at McNary Dam and only about 1 percent of the year at Priest Rapids Dam. Under the No Action Alternative, extreme low-flow or high-temperature years would continue to result in white sturgeon mortality events.

Elevated gas or TDG can have adverse effects on white sturgeon. Larval sturgeon may experience GBT with an elevated TDG of nearly 120 percent and may have up to 50 percent mortality at a TDG of 130 percent and greater (Counihan et al. 2000). The magnitude of effects from an elevated TDG may be offset if fish are able to compensate by moving to greater depths where TDG saturation is reduced. Currently, TDG values over 118 percent occur on less than 1 percent of all days in this reach of the river. Under the No Action Alternative, TDG is not expected to adversely impact white sturgeon.

<u>Other Fish</u>

Walleye require cold water over clean gravel or cobble substrates for successful spawning. Currently, water temperatures in the Columbia River are suitable for walleye spawning from early to mid-spring, and there is no shortage of suitable substrates for spawning in the mid-Columbia River reach.

In addition, walleye fry require stable backwater habitats for rearing until they are able to swim proficiently. Operations that fluctuate water levels can entrain walleye fry from the safety of these critical backwater habitats. Current operations create a flow and temperature regime that would continue to support walleye growth and recruitment in these habitats on approximately 65 percent of days in the rearing period. Under the No Action Alternative, walleye would continue to have adequate spawning and rearing habitats.

Smallmouth bass require stable or rising water levels and temperatures to induce successful spawning and rearing. Water temperatures between 12°C and 15°C trigger spawning activity, while stable water levels prevent the desiccation of eggs and fry. In addition, an influx of cold water, once spawning has begun, can cause males to abandon nests, resulting in recruitment failure. Current operations provide stable water levels and temperatures in most years. Modeling suggests spawning temperature of 12°C would be reached on May 3 in an average year.

Cold water temperatures reduce smallmouth bass activity. In fact, when water temperatures drop below 10°C, smallmouth bass become inactive and seek shelter (Edwards 1983). If temperatures remain below this level for too long, adult fish would not survive. Currently, at McNary Reservoir, smallmouth bass would be inactive for approximately 161 days. Under the

No Action Alternative, water temperatures would continue to provide adequate growth and survival for smallmouth bass populations.

Smallmouth bass are visual predators, and increased turbidity can limit growth and feeding success (Sontag 2013). In addition, highly turbid waters can displace smallmouth bass fry and limit recruitment (Edwards 1983). Currently, elevated turbidity is limited to spring runoff and large rain events. The remainder of the year, water clarity is good with a suspended sediment measure of about 2 ppm. Under the No Action Alternative smallmouth bass foraging would be limited in high spring runoff and large rain events. Turbidity is not expected to limit recruitment for this alternative.

Passage success for most fish at CRS projects in this reach of the Columbia River is unknown. Currently, upstream passage would be difficult for some species, while downstream passage would be associated with some unknown level of survival. Under the No Action Alternative, passage success is not expected to change. Some unknown portion of each species would continue be entrained or would pass upstream through fish ladders.

Elevated summer water temperatures limit the distribution of fish species. Currently, upstream reservoirs have cooler water temperatures relative to dams lower in the reach by about 2 degrees Celsius on average. This slight difference in water temperatures can affect important changes in the fish community. Under the No Action Alternative, upstream reservoirs near Chief Joseph Dam would continue to reduce growth and productivity of warmwater fish species relative to McNary Dam and the Hanford Reach.

The Hanford Reach is the last remaining free-flowing reach of the Columbia River in the United States above Bonneville Dam. However, current operations above the Hanford Reach can have detrimental effects to resident fish communities. Water flows can change such that river elevations in the Hanford Reach can fluctuate by as much as 3 m in 6 hours, which has the potential to dewater aquatic habitats and reduce productivity in this reach of river. Under the No Action Alternative, the Hanford Reach would continue to be an important refuge for native resident fish species but would experience water level fluctuations that may limit productivity of this reach.

**Region C**

Region C consists of the Snake River Basin. Resident fish analyses in this region are discussed in one section, including the mainstem Snake River, Clearwater River, and Dworshak Reservoir.

***Ongoing Existing Mitigation Programs***

In Region C, Bonneville F&W-funded projects with the Nez Perce Tribe in the Lochsa watershed are working to improve habitat for resident fish. Idaho Department of Fish and Game are also improving habitat for Yellowstone cutthroat trout. Riparian, wetland, and instream habitat restoration in Region C that targets anadromous fish or wildlife species also can improve habitat conditions for resident fish species. Through its F&W Program, Bonneville funds many habitat restoration actions that benefit multiple species. For example, the Shoshone-Bannock Tribes of the Fort Hall Reservation have enhanced over five miles of the Yankee Fork Salmon River to promote anadromous and resident fish habitat.

Another example is the Dworshak Dam Resident Fish Mitigation, which boosts Kokanee Salmon abundance, thereby providing forage resources (eggs, fry, sub-adults) for bull trout, cutthroat trout, and other resident fish species in the blocked area of the North Fork Clearwater River.

***Snake River Basin***

Summary of Key Effects

Kokanee would continue to use Dworshak Reservoir during most of their life history and return to the tributaries to spawn. Reservoir elevations in the fall would provide access to about 90 percent of their spawning areas. The chance of kokanee being entrained through the dam would be low, with the highest risk in late February and all of March. Dworshak Reservoir would also continue to provide habitat for smallmouth bass.

Under the No Action Alternative, the Snake River Dams would continue to fragment white sturgeon habitat by limiting passage upstream and downstream. Populations of white sturgeon in the Ice Harbor, Lower Monumental, and Little Goose Reservoirs would be expected to continue to decline from lack of recruitment (young fish surviving past the larval stage and up to 1 year of age). Habitat conditions for white sturgeon would continue to be of limited adequacy in the reservoirs under the No Action Alternative. Water temperature would be within the range needed for spawning and rearing. Flows and substrate in the tailraces of the four Snake River Dams would provide suitable habitat for spawning and rearing. Water quality would be sufficient to support white sturgeon.

The No Action Alternative would continue to provide reservoir conditions that favor non-native fish such as walleye and smallmouth bass. No change in resident fish populations or their use of the Snake River Basin would be expected, except for walleye. Walleye have been expanding their range upriver in the reservoirs and are now found as far upstream as Little Goose reservoir. Two crustaceans, Siberian prawns and opossum shrimp, are increasing their populations in the lower Snake River Reservoirs and may provide an additional food source for resident fish. This population trend may continue under the No Action Alternative.

Habitat Effects Common to this Fish Community

The Snake River Reservoirs are a series of run-of-river impoundments that create a long run of reservoir and slow-moving river habitat. This reservoir environment tends to favor non-native fish such as northern pikeminnow, walleye, smallmouth bass, bluegill, perch, and crappie. Some native suckers also do well in these habitats, including bridgelip and largescale suckers. Generally, the temperatures would continue to be favorable for these warmwater species to be abundant and some may increase in population and distribution. Much of the substrate in the reservoirs is sand or cobble, and large amounts of shoreline have been armored with riprap, providing suitable spawning habitat for these fish.

Water quality in the reservoirs would continue to be favorable, with temperatures well within the tolerance of warmwater fish, and consistently favorable levels of DO. High-flow events in the watershed can temporarily increase the amount of suspended sediment in the reservoirs. However, under the No Action Alternative, most of the time, suspended sediment levels would be less than 10 mg/L (Appendix D).

<u>Bull Trout</u>

Under the No Action Alternative, low numbers of bull trout would continue to use the mainstem of the Snake River for foraging, migration, and overwintering and some movement between populations would continue. Bull trout migrate foraging, migration, and overwintering habitat in November and December, then return to tributaries in March through May. Lower Monumental and Ice Harbor Reservoirs provide a connection between the Tucannon and Walla Walla Subbasins, with some Tucannon fish moving downstream through the Snake River to the Columbia River, then up the Walla Walla River. Larger bull trout that do use the Snake River are the drivers of the population as they are generally more productive. Potentially, the loss of the larger, fluvial fish (fish that spawn and rear in tributaries, then migrate to a lake) from the upstream community could drive a change in that community structure.

Bull trout movement through the basin would continue to be primarily downstream rather than upstream under the No Action Alternative. Low numbers of fish would continue to be entrained at the Snake River Dams and passed downstream either through the turbines or through the juvenile salmon bypass systems. This movement at the dams is primarily between April and June when the fish are moving out of the reservoir system to avoid higher water temperatures. Even though the fish ladders at the dams were not designed to pass bull trout (Barrows et al. 2016), low numbers of bull trout would be expected to continue to use the fish ladders to move upstream to other reservoirs and the upper basin. Bull trout movement through the fish ladders on the lower Snake River Dams would continue to be temporarily halted when the ladders are closed for maintenance in January and/or February.

Under the No Action Alternative, migration of bull trout to the North Fork Clearwater River Subbasin from the rest of the Clearwater Basin would continue to be blocked by Dworshak Dam, as the dam has no fish ladders or other means of passing fish upstream. However, bull trout in Dworshak reservoir would continue to have access to most spawning areas in tributaries above the dam. The reservoir drawdown does not eliminate the ability of fish to access the free-flowing reach of the North Fork Clearwater above the reservoir. The timing of reservoir refill coincides with the time in May and June that adult bull trout begin their upstream migration (Hanson et al. 2006) and would continue to provide connectivity between the reservoir, tributaries, and the rest of the North Fork Clearwater Basin under the No Action Alternative.

Water temperature would remain cold enough for low numbers of bull trout to continue to use the Snake River Reservoirs and the Snake and Clearwater Rivers during much of the time they are most likely to be present, primarily November through May (Barrows et al. 2016). Under the No Action Alternative, the water quality modeling shows water temperatures in the lower Snake Reservoirs are expected to exceed 15°C 0.3 percent of the time from November through May, resulting in a negligible effect on bull trout.

Elevated TDG levels from spill may adversely affect an unknown number of bull trout in the reservoirs by degrading habitat in the mainstem Snake River and causing habitat loss. Bull trout effects from an elevated TDG during spill was determined using the number of days that TDG would be over 110 percent between November and June, the months bull trout are most likely to be in the Snake River reservoirs. Under the No Action Alternative, 37.3 percent of days November through June would exceed 110 percent TDG through the *Spill Operations* measure. Suspended sediment and DO would continue to be within tolerance levels for bull trout.

Forage for migrating bull trout in the Snake River would continue to be adequate in the lower Snake River under the No Action Alternative. The Snake/Clearwater River system supports healthy populations of forage fish.

The potential for predation on bull trout in the rivers and reservoirs would also be reduced under the No Action Alternative because bull trout use these areas in the winter when the water is generally cold. Warmer water temperatures generally are associated with higher risk of predation. Predators such as catfish, northern pikeminnow, walleye, and smallmouth bass are more active when water temperatures are relatively warm (greater than 15°C).

<u>White Sturgeon</u>

Spawning behavior by white sturgeon in the Snake River Basin is not expected to change under the No Action Alternative. Spawning behavior is cued by high water velocities during the period just after peak runoff and by adequate temperatures (Hildebrand et al. 2016). Spawning is currently limited in most areas of the Snake River Reservoirs because water velocities are not adequate to cue spawning. However, some spawning occurs near the dams in the tailraces where velocities are higher. The mean water velocity to support spawning needs to be greater than or equal to 2.6 feet/second, but the average velocity for the year under the No Action Alternative would be about 0.4 feet/second.

Water temperatures in the lower Snake River would be suitable for sturgeon spawning under the No Action Alternative. Spawning in the Snake River occurs between April and July and when water temperatures are between 12°C and 18°C (Hildebrand et al. 2016). Modeling results for the April 15 and June 30 spawning period under the No Action Alternative indicate water temperatures would be above 18°C for 8.2 percent of the time. This indicates water temperatures would be within the acceptable range for most of the spawning period.

Water temperatures in the lower Snake River would also be suitable for egg incubation under the No Action Alternative. Water temperature is critical for white sturgeon egg incubation. Temperatures outside of the 8°C to 18°C range show reduced egg survival, with mortality occurring when temperatures are greater than 20°C (Lepla and Chandler 2001). Modeling results for the spawning period between April 15 and June 30 indicated water temperatures would be below 8°C for 0.3 percent of time, and above 18°C for 8.2 percent of the time).

Modeling results also showed water temperatures above 20°C for 2.7 percent (168 out of 6,160 days) during the spawning period. This indicates water temperatures would be within the acceptable range for egg incubation during the spawning period.

The Snake River would continue to provide limited rearing habitat for the yolk sac larvae under the No Action Alternative. The preferred habitat for these larvae is gravel and cobble substrates with interstitial spaces in which to hide (Hildebrand et al. 2016; McAdam 2012). This type of substrate is limited in most areas of the reservoirs. However, previous surveys of the Snake River Reservoir substrate have shown that gravel and cobble habitat occurs primarily in the tailraces of each of the Snake River Dams. These tailrace areas would continue to provide potential habitat for the yolk sac larvae under the No Action Alternative.

Snake River Reservoir trophic production would continue to provide adequate forage for larval (less than 1 year of age), juvenile (1 to 7 years of age), and adult white sturgeon under the No Action Alternative. All of food organisms for each life stage are found in adequate quantities in the reservoirs and would not limit the sturgeon population. The increasing number of Siberian prawns and opossum shrimp in the reservoirs would provide an additional food source for sturgeon.

Migration of white sturgeon through the lower Snake River would continue to be hindered by the dams due to the limited to no passage at the dams (though a few have been observed moving downstream). Sturgeon do move between Lower Granite Reservoir and the free-flowing section of the river above the reservoir. There appears to be a gradient of reduced abundance of juvenile sturgeon with increased distance from Lower Granite Dam. This suggests that many of the white sturgeon in the lower Snake Reservoirs could have been entrained through the dams (Hildebrand 2016; Devore 1999). It is also possible that juvenile sturgeon move downstream seeking food sources.

Under the No Action Alternative with its *Spill Operations* measure, TDG levels at the dams would have an adverse effect on white sturgeon for about 10 days, primarily in June and July. Young white sturgeon are sensitive to TDG levels (McGrath 2006; Weitkamp 2008; Hildebrand 2016; Counihan et al. 1998). TDG levels of 118 percent alters buoyancy in larval white sturgeon, which make them more prone to predation. TDG levels of 130 percent cause about 50 percent mortality. Modeling shows that under the No Action Alternative, TDG levels would be greater than 120 percent for 809 of 9,760 days from April 1 through July 31, or 8.3 percent of that period, with a high of 136 percent TDG. Suspended sediment and DO levels would remain favorable for sturgeon.

In-river contaminants are not likely to affect white sturgeon populations under the No Action Alternative. Sturgeon are highly sensitive to in-river contaminants such as selenium and methylmercury, which can have sublethal effects (Coffey 2014; Little 2014 Wan Ming 2014). Through the portion of the Snake River downstream of the confluence of the Snake and Clearwater Rivers, these contaminants are not expected to be found in the sediments in concentrations that would affect sturgeon.

Predation and harvest would have little effect on white sturgeon under the No Action Alternative. There are no known adult predators of sturgeon in this subbasin (several fish species prey on sturgeon eggs and juveniles, including walleye, smallmouth bass, and sculpin). Harvest is not allowed on the lower Snake River except below Ice Harbor Dam, but catch-and-release recreational fishing on sturgeon is allowed. The estimated mortality of this fishing is about 3 percent, which may have a minor effect on white sturgeon populations (Robichaud et al. 2006).

<u>Other Fish</u>

Dworshak Reservoir and the Clearwater are inhabited predominantly by cold water species such as kokanee bull trout, westslope cutthroat trout, redband rainbow trout, as well as the cool-water-favoring smallmouth bass. Westslope cutthroat occur in Dworshak Reservoir and the Clearwater Basin, but would not likely be affected by the MOs. They are not addressed further.

Redband rainbow trout are divided into two subgroups. Trout that are anadromous are considered to be steelhead. Those that are residents of the interior Pacific Northwest are redband or resident rainbow trout (Muhlfeld et al. 2015). Within the Snake River Basin, redband rainbow trout that interact with the projects are classified as steelhead and are addressed in the four steelhead sections (Upper Columbia River, Snake River, middle Columbia River, and Lower Columbia River steelhead), under Anadromous Fish, under Section 3.5.2.2, No Action Alternative. Those redband rainbow trout that are in the tributaries are not likely to be affected by actions at the projects and are not addressed further.

In the Snake River Subbasin reservoirs, kokanee are found only in Dworshak Reservoir, where they were introduced in 1972. Since their introduction, kokanee have become the primary fishery in the reservoir. Kokanee spawning normally occurs in the fall and would continue along the tributaries to Dworshak reservoir under the No Action Alternative. Spawning areas are inaccessible when the reservoir level is below elevation 1,450 feet during September and October. However, under the No Action Alternative the mean water elevation in the reservoir in September and October would be at elevation 1,521, therefore kokanee would have access to about 90 percent of their spawning areas in most years.

Entrainment of kokanee at Dworshak Dam would continue to be of concern under the No Action Alternative if the Corps needs to release large volumes of water in the winter or spring. Entrainment occurs when water is released from the dam and fish in the forebay are pulled through the dam along with the water. Entrainment at Dworshak Dam is mostly a problem in the winter when kokanee congregate near the dam, making them susceptible to high discharge, as opposed to other times of the year when they are using the upper parts of the reservoir near the spawning areas. Kokanee entrainment is positively related to discharge during January through March (Bennett 1996). However, the use of lower gates to release water away from kokanee populations has likely reduced the effect. Historically, the Corps has released water in the fall and winter to make room for flood storage. Large numbers of kokanee have been removed from the reservoir during high winter releases, which can result in lower populations that can take several years to rebuild. Entrainment has been reduced in recent years now that the Corps starts releasing water in the summer for flow augmentation and cooling of the lower Snake River and does not wait until winter to start to release water (personal communication, Paul Pence, April 29, 2019). Modeling results for the No Action Alternative show median discharges from Dworshak would remain low for January through March, with a maximum flow typically near powerhouse capacity. The highest risk would be in late February and the entire month of March. High water years have a greater risk of entrainment. Median years have risk in late March.

Smallmouth bass also inhabit Dworshak Reservoir. Dworshak Reservoir provides smallmouth bass spawning habitat along the shoreline, but the timing of the reservoir operations could interrupt the spawning/rearing cycle under the No Action Alternative. Smallmouth bass spawn in the spring (Webster 1954, as cited in Wile 2014). Males move into spawning areas when the water temperature reaches about 16°C (Wile 2014). The optimum temperature range for spawning is 12.8°C to 21°C (Edwards et al. 1983). Dworshak reservoir start to refill in April or early May, usually reaching full pool elevation of 1,600 feet by July 4. After July 4, water releases from the reservoir for flow augmentation and cooling water lower the reservoir to elevation 1,520 by September. Water temperatures under the No Action Alternative would not reach 16°C, the temperature at which smallmouth bass spawn, until about May 7. In most years, smallmouth bass would be able to spawn, and the fry should be able to leave the nesting area before the drawdown would desiccate the nest. In Dworshak reservoir, smallmouth bass feed on several fish species, including kokanee. The abundance of kokanee contributes to the growth of smallmouth bass in the reservoir (IDFG 2018).

In the lower Snake River Reservoirs and river reaches, several non-native fish would continue to dominate the resident fish community. Native mountain whitefish would continue to be found in the tributaries. Downstream passage past the dams would be possible. The Corps has found mountain whitefish in the juvenile bypass system in varying numbers at Lower Monumental Dam. The Corps recorded 521 fish in the bypass in 2017 and 235 fish in 2018.

Northern pikeminnow prefer slow-moving water in lakes and rivers with gravel or soft sand substrates (Gadomski et al. 2001), that would continue to be provided by the lower Snake River. Northern pikeminnow prefer temperatures of 16-22°C but are found in warmer waters (Brown and Moyle 1981). Temperature modeling for the No Action Alternative predicted that water temperatures in the tailrace of Ice Harbor Dam would reach 14°C around June 5 and would be above 15°C for 88.7 percent of the modeled days (10,826 days) from June through October. Therefore, water temperatures would continue to support successful spawning and rearing by Northern pikeminnow. No Action Alternative conditions would continue to provide adequate food sources for larval and juvenile Northern pikeminnow. Because Northern pikeminnow rear in the gravels in the tailraces of the dams where the water is shallower and the TDG levels are higher, there is the potential for the juveniles to be adversely affected. Water quality modeling indicated TDG levels would be above 120 percent for 809 out of 9,760 modeled days (8.3 percent of the time) in April through July at Ice Harbor with a high of 136 percent TDG. The water quality plots show the majority of the days would be in June and July.

Under the No Action Alternative and its *Spill Operations* measure, elevated TDG would have an elevated adverse effect on northern pikeminnow for about 10 days, primarily in June and July. Occasional high-flow sediment events may occasionally affect northern pikeminnow, but most of the time would be low. DO and suspended sediment would be within tolerances for northern pikeminnow.

Walleye are abundant in Ice Harbor and Lower Monumental Reservoirs and are increasingly found in Little Goose reservoir. Adults have been found in Lower Granite Reservoir. Under the No Action Alternative, the reservoirs would continue to provide adequate spawning habitat and forage that would support large numbers of walleye. The lower Snake River Reservoirs would also continue to provide adequate conditions for walleye spawning. Temperature modeling for the No Action Alternative shows that water temperatures in the lower Snake River Reservoirs would be suitable for walleye spawning from mid-February to mid-April, which is within the period when walleye spawn. The lower Snake River Reservoirs would continue to provide adequate water temperature conditions for rearing walleye fry under the No Action Alternative for at least part of the year. Water temperatures would be too cold for optimum growth of fry when they first hatch, but conditions would improve and best growth would occur after mid-June. High or variable water velocities in rearing areas during April and May can transport juveniles to unsuitable habitats (reference to be added prior to final). Modeling for the No Action Alternative shows median flows in the lower Snake River during this time would be relatively high. Successful rearing would occur at limited sites with adequate shelter from high flows. Adequate resting and feeding habitat for adult walleye is currently provided by the lower Snake River reservoirs. Adults prefer deeper water offshore habitat during daylight hours, then move into shallow water feeding sites along the shoreline at night (reference to be added prior to final). These types of habitat are not limited in the lower Snake River and would continue to be available under the No Action Alternative.

Smallmouth bass would also continue to flourish. Much of the substrate in the reservoirs is sand or cobble, and large amounts of shoreline have been armored with riprap (large rock), which would continue to provide cover for nests. Water temperatures in the lower Snake River would continue to be conducive for embryo development under the No Action Alternative. Smallmouth bass prefer temperatures ranging from 12 to 31°C (Ferguson 1958; Barans and Tubb 1973; Reutter and Herdendorf 1974), and lower temperatures would be less favorable for smallmouth bass. Water flows and temperatures would be suitable for smallmouth bass fry in the lower Snake River in mid to late summer under the No Action Alternative. Conditions would be best for fry in July and August as there would be low flows and relatively high water temperatures. Temperatures in the lower Snake River, as represented by Little Goose Reservoir, would exceed 21°C, and thereby provide ideal growth conditions, for only about 52 days per year (14.3 percent of all days). However, the high numbers of smallmouth bass in the reservoirs show this is not currently limiting the population. Smallmouth bass growth would continue to increase in May to June. Water temperatures in the lower Snake River Reservoirs would affect the activity level of adult smallmouth bass under the No Action Alternative. Under the No Action Alternative, water temperatures in the lower Snake River Reservoirs, as represented by Little Goose Reservoir, would reach 10°C starting about April 25 and stay above that temperature until about November 12. Temperatures would be below 10°C for about 168 days out of the year, or 46.0 percent of the year. This would result in adults being inactive during the late fall through early spring, and then becoming active starting in May.

DO, turbidity, and suspended sediment levels in the lower Snake River under the No Action Alternative would be within acceptable limits for smallmouth bass growth and survival most of the time. High turbidity can limit growth and feeding success of adult smallmouth bass as they are sight feeders and turbidity can limit their ability to locate prey. Sontag (2013) found a drop in smallmouth bass predation during flows with high turbidity. Turbidity in the lower Snake River is usually less than five Nephelometric Turbidity Units and rarely exceeds 200 Nephelometric Turbidity Units but could limit feeding success of smallmouth bass during early runoff in some years under the No Action Alternative.

**Region D**

***Ongoing Existing Mitigation Programs***

Bonneville's F&W Program in Region D includes projects that focus on bull trout and sturgeon. Bonneville has worked with the Confederated Tribes of the Warm Springs to monitor the status of bull trout in the Lower Deschutes basin. ODFW, WDFW, and CRITFC have been conducting long-term monitoring of white sturgeon populations on the Lower Columbia. Floodplain, wetland, and instream habitat improvement that targets anadromous fish or wildlife also improves habitat conditions for resident fish species.

***McNary Dam to the Columbia River Estuary***

<u>Summary of Key Effects</u>

Bull trout would continue to migrate upstream and downstream through the Columbia River System in limited numbers and seek thermal refugia (i.e., cold water habitat) available at the mouths of tributaries. White sturgeon would continue to successfully reproduce in years with adequate flow and temperature conditions.

<u>Habitat Effects Common to this Fish Community</u>

Outflows from McNary Dam Reservoir would influence some of the fish relationships described in this section. Peak spring flows affect habitat maintenance for some species. Modeled mean monthly outflows for the No Action Alternative are as follows:

- April: 191,600 cfs
- May: 260,300 cfs
- June: 285,020 cfs
- July: 197,900 cfs

Other flow parameters referred to in this section refer to outflows of McNary Dam that are indicative of flows downstream through the other projects.

Bull Trout

Bull trout are known to use the mainstem Columbia River to move between tributaries and have been observed at Bonneville Dam and McNary Dam in the spring and summer (Barrows et al. 2016). Water temperature is the most important habitat factor for bull trout in the mainstem Columbia River. Fluctuations in the Bonneville Dam pool could suppress vegetation on the delta at the mouth of the Klickitat and Hood Rivers, making bull trout more susceptible to predation when trying to access tributaries or use the mouth of the tributary for thermal refugia (personal communication, Bill Sharpe, Yakama Nation, 2019). Under the No Action Alternative, bull trout would continue to use the mainstem Columbia for migration between tributaries, as well as tributary mouths for passage and thermal refugia.

Adult bull trout move downstream during fall and overwinter in reservoirs (October to February; Barrows et al. 2016). Although bull trout successfully move between areas on the mainstem, their migration can be delayed at the dams. Passage through turbines can cause injury or mortality.

Bull trout are subject to bird predation, as evidenced by recovery of PIT tags on bird colonies (Barrows et al. 2015). Predation on bull trout would continue to occur under the No Action Alternative.

White Sturgeon

White sturgeon occur throughout the lower Columbia River from McNary Dam to the estuary, but abundance is highest below Bonneville Dam and decreases further upstream (ODFW 2019). Factors important for white sturgeon relative to the operations of the CRS include flow rates, water quality (temperature and TDG), predation, and habitat conditions. To compare habitat characteristics important for white sturgeon to the MOs, the modeled median monthly outflows and modeled temperatures at Bonneville Dam (based on the period of record) were examined for the relevant time periods and documented. The Bonneville Dam tailrace was used as an indicator, because the highest abundance numbers for white sturgeon occur from Bonneville Reservoir downstream to the estuary. Under the No Action Alternative, the Bonneville Dam tailrace would provide suitable spawning and incubation temperatures from mid-April to mid-July. Model results indicate suitable spawning temperatures occurring from a range of 48 days (2015) to 74 days (2012). The number of days with optimal embryo incubation (12°C to 14°C) would range from 8 days (2013) to 27 days (2011). In years of low-flow conditions, water temperatures could increase beyond the suitable range by early June, resulting in little or no recruitment.

Flows for successful sturgeon spawning and recruitment were analyzed based on the McNary Dam tailrace. Since lower Columbia River Dams are run-of-river, the outflow at McNary Dam correlates with the outflows at John Day, The Dalles, and Bonneville Dams. Flows of at least 250 kcfs from April 1 to July 31, coupled with suitable temperatures, provide favorable spawning and rearing conditions. Flows would continue to be adequate for sturgeon spawning and recruitment in most of the April to June timeframe in high-flow years, but only about half of the time in average flow conditions. Low-flow years would likely not provide sufficient time with suitable flows for recruitment to occur. In years of extreme low flows and warm water, higher-than-typical adult mortalities have been documented (personal communication, O. Langness 2019).

White sturgeon spawning generally occurs in areas with fast-flowing waters over coarse substrates (Parsley et al. 1993). McCabe and Tracy (1994) concluded that spawning in the Bonneville Dam tailrace occurred on days with mean discharges from Bonneville Dam, ranging from 120 kcfs to 371 kcfs. Model results for the current analysis indicate that flows are always higher than 120 kcfs from April through July.

Lack of effective upstream white sturgeon passage for all age classes decreases the connectivity of the population (Parsley et al. 2007). Under the No Action Alternative, disconnection in populations would continue. White sturgeon are known to pass through the dams, although this only occurs in the downstream direction (Warren and Beckman 1989). The spillway is the most likely source of downstream passage.

Turbine units at Bonneville Dam can cause injury and mortality in juvenile and adult sturgeon due to blade strikes. This has been reduced by the slow-roll procedure for starting up turbines. Under the No Action Alternative, a small amount of injuries or mortalities could occur, but the incidence would be greatly reduced by continuing to implement the slow-roll start-up procedure.

White sturgeon larvae are adversely affected by TDG. Studies have shown high rates of altered buoyancy at 118 percent TDG, and 50 percent mortality at 131 percent TDG (Counihan et al. 1998).

Changes in a pool or tailrace elevation can affect juvenile white sturgeon through stranding in shallow water. Under the No Action Alternative, pool elevations in the reservoirs would remain consistent.

Pinnipeds, mainly Steller sea lions, are known to prey on white sturgeon in the Bonneville Dam tailrace. Stellar sea lions have increased their abundance and seasonal presence (Tidwell et al. 2019). Pinnipeds may have altered the spawning of white sturgeon in the Bonneville Dam tailrace as they attempt to avoid predation. ODFW has observed direct predation on sturgeon and harassment of spawning sturgeon by Steller sea lions, which can lead to stress and aborted spawning activity (personal communication, Chapman 2019). Resident fish such as sculpin, walleye, and smallmouth bass are predators of embryo and age-0 white sturgeon. Under the No Action Alternative, predation would continue to affect early life stages of white sturgeon.

Reservoirs in the lower Columbia have higher rates of sedimentation, and invasive aquatic plants could reduce habitat value for sturgeon through changes in predation, food availability, and suitability for invasive species. This trend would be expected to continue under the No Action Alternative.

<u>Other Fish</u>

Within this reach of the lower to middle Columbia River, at least 45 resident fish species occur, of which over half are native (NPPC 2001; Ward et al. 2001). In addition to white sturgeon and bull trout (discussed previously), Northern pikeminnow, walleye, smallmouth bass, native minnow species, and estuarine fish assemblages occur within this reach. Walleye, smallmouth bass, and other non-native gamefish are warmwater fish species, and channel catfish are present in the lower CRS.

Habitat components important for these resident fish communities include flow rates, water quality, and food availability. The mainstem dams are barriers to upstream movements by most resident fish. However, resident fish are known to pass through fishways at the dams. TDG levels could have adverse effects on any of the resident fish species. ODFW sampling during spring, when higher TDG rates occur, did not observe GBT in pikeminnow, smallmouth bass, or walleye.

Northern pikeminnow are a part of the resident fish community and are important in their role as predators of salmon and steelhead. Analysis of pikeminnow considered their life history and the potential for MOs to affect their predation rates. Northern pikeminnow have a plasticity to adapt to different environs, and there are different life histories between the free-flowing and impounded river sections. Pikeminnow abundance in the lower Columbia is highest from the estuary to The Dalles, with lower abundance further upstream. Spawning occurs in June through July when temperatures are above 18°C, over clean, rocky substrate in a range of depths (Lower Columbia River Province Plan 2004 to 2005 NWPCC). In reservoir areas, high flows followed by low flows could affect recruitment. Because they spawn at multiple depths, they are less sensitive to potential dewatering. Some tributaries have viable populations that seed downstream reservoirs with juveniles, so pool fluctuations are unlikely to have population-level effects. Survival of rearing juveniles appears highest in low flow years when shoreline water temperatures are higher (20°C) and there is abundant vegetation. Northern pikeminnow are site feeders and may decrease their feeding effectiveness during higher turbidity. Northern pikeminnow would be expected to maintain their current abundance levels under the No Action Alternative.

The adult optimum temperature for walleye is 20°C to 24°C, and growth stops below 12°C. Smallmouth bass have similar spawning timeframes and temperatures (mid-May to late June, when water temperatures reach 15.6°C to 18.3°C.) Female walleye gonad maturation requires winter temperatures less than 10°C, and optimum temperatures are 6°C to 9°C. When spring temperatures increase slowly (less than 0.18 degree Celsius per day), there is poor embryo survival. As the lower Columbia River system reservoirs operate as run-of-the-river, operations are unlikely to affect these conditions. Conditions that slow fry growth (low temperatures, low zooplankton abundance, and delayed hatching), increase overwinter mortality, because smaller fish tend to have lower survival rates. Under the No Action Alternative, food abundance is supportive of walleye growth rates. The John Day Reservoir has smaller walleye, which may be an effect of harvest (no angling limits on walleye, and harvest of larger fish leaves a population of smaller individuals). Smallmouth bass juveniles are affected more by discharge than by temperature during nursery season, because fry can be displaced from nests during high flow velocity (Larimore 2000; Simonson and Swenson 1990, as cited in Brown et al. 2009.) Smallmouth bass make and tend nests until hatching, and if a nest is disturbed or depth increases beyond 4 feet, they abandon the nest; this could be affected by reservoir pool elevations.

Smallmouth bass experience a winter starvation period when temperatures are below 7°C to 10°C (Shuter et al. 1980; Henderson and Foster 1956, as cited in Brown et al. 1990) Juveniles must grow enough during their first year to survive the winter period, and juvenile shad provide an important fall forage source for growth going into winter.

Similar to Northern pikeminnow, pool elevations dropping after Walleye spawning under the No Action Alternative can strand eggs or larvae, but this is not expected to cause population-level effects. The reservoirs have generally reduced variability in seasonal and daily flows. Newly hatched fry require food (plankton) at 3 days after hatching; fry are surface oriented and need low velocities. This life stage is population-limiting below Bonneville Dam (Lower Columbia River Province Plan 2004 to 2005 NWPCC). Higher velocities during the timeframe when fry are emerging could be a method to limit production.

Smallmouth bass shift to fish prey during their first year, due to caloric intake and growth needs (Brown et al. 2009). Their diet consists of sculpin, cyprinids, suckers, and sand rollers. Juvenile salmon are eaten during their migration (at sizes of less than 100 mm).

Conditions that promote lower water temperatures and higher spring flows tend to lower the survival rates of warmwater game fish, potentially lowering populations of salmon and steelhead predators. The No Action Alternative would be expected to continue supporting warmwater game fish at levels similar to current conditions.

## MACROINVERTEBRATES

Below is a discussion of the macroinvertebrates in Regions A, B, C, and D under the No Action Alternative. For more detailed information on the effects of the No Action Alternative on aquatic invertebrates and implications on food web interactions, see the Habitat Effects sections of these respective fish community analyses in the Resident Fish section under the applicable region.

### Region A

Aquatic invertebrate communities would continue to thrive in the aquatic environments provided by Hungry Horse Reservoir, South Fork Flathead River, Flathead River, Flathead Lake, lower Flathead River, Clark Fork River, Lake Pend Oreille, Pend Oreille River, Lake Koocanusa, and the Kootenai River.

The storage reservoirs (Hungry Horse, Lake Pend Oreille, and Lake Koocanusa) in Region A typically have low nutrients and good water quality. Reservoir elevations in the summer would continue to provide a large area for production of phytoplankton and zooplankton, with No Action Alternative operations typically filling to or nearly to full pool in most years and dropping relatively slowly through the summer. Outflows of these reservoirs would continue to carry a proportion of the zooplankton out of the reservoirs and into the rivers downstream. The varial zones of reservoirs would continue to provide habitat for production of benthic aquatic insects when inundated, and this benthic production would continue to be constrained by fluctuations in surface elevations. Larger, long-lived species would continue to dominate in the permanently wetted zones of the reservoir, and shorter-lived, smaller species would colonize the varial zone that is only inundated part of the year. These bottom-oriented aquatic insect life stages would continue to provide an important spring food source for fish. Flathead Lake and Lake Pend Oreille would also continue to support expanding populations of opossum shrimp. These shrimp would continue to compete with kokanee as both rely on zooplankton for food, but they also provide food sources for other species such as lake trout.

The riverine sections of Region A such as the Flathead River, Clark Fork River, Pend Oreille River, and Kootenai River would continue to produce benthic macroinvertebrates such as the larvae of stoneflies, caddis flies, and mayflies. The life cycle of these insects requires their habitat to stay inundated with water for 4 to 6 weeks, so their abundance and distribution would continue to be limited by fluctuations in river stage, especially in the Kootenai River where winter operations allow for varial zone desiccation, reinundation, and freezing.

**Region B**

The Columbia River from Canada to Lake Roosevelt would continue to produce benthic aquatic insects such as stonefly, caddisfly, and mayfly larvae. The river elevation in this reach is influenced by Lake Roosevelt operations and inflows, so it is somewhat variable, which would constrain benthic production to some degree. Under the No Action Alternative, median elevations near the U.S.-Canada border (RM 740) would fluctuate during certain times of the year. When water elevation rises in the September to January and April to June periods, water levels would allow the recolonization of benthic habitat as areas becomes inundated, but then any larvae left in the habitats as they dewater from January to April and July to August would be dried out. This likely limits the production of aquatic insects, especially the larger, longer-lived species. As the river flows downstream closer to Lake Roosevelt, the influence of reservoir operations becomes greater. The water levels would follow the same pattern as near the U.S.-Canada border, but with drops of 42 feet from January through April and 12 feet in July to August. Within Lake Roosevelt, the elevation changes modeled near Inchelium (RM 680) and further downstream near the Sanpoil River (RM 616) also followed the same pattern of filling and dewatering with similar magnitude (42 feet and 12 feet drops) as the stage at RM 720. This varial zone of the river and reservoir would likely be limited to short-lived, smaller aquatic insects that could fulfill their life cycle before being desiccated. Longer-lived species would be limited to the habitats below this annually dewatered zone. The amount of perpetually inundated habitat would increase as reservoir depth increases closer to Grand Coulee Dam.

In Lake Roosevelt, the production, distribution, and persistence of zooplankton are highly variable and sensitive to the amount of time the water is in the reservoir (retention time), which is a function of inflows, reservoir volume, and outflows. The longer water residence times allow greater abundance and larger-bodied zooplankton to be more widely distributed throughout the reservoir. Lower retention times result in fewer and smaller-bodied zooplankton that get concentrated near the dam, where they would be subject to high rates of entrainment. Zooplankton are the foundation of the food web in Lake Roosevelt, being the primary prey source for many of the key fish species at one life stage or another. Generally speaking, under the No Action Alternative, median retention time would range from about 40 to 50 days in the winter and early spring, dropping as low as 21 days by June, and then gradually increase over the summer to about 45 days at the end of August. September and October would have high retention times with a median of 60 to 80 days.

Downstream of Grand Coulee Dam, Rufus Woods Lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. Here the macroinvertebrate community consists of production of aquatic insects similar to upstream of Lake Roosevelt, as well as the zooplankton entrained out of Lake Roosevelt. Regarding aquatic insect production and desiccation, the stage at RM 594 in Rufus Woods Lake shows about a 4-foot drop in the month of March, and a double peak in June and July. This means the elevation would increase from April to early June, peaking at a median of 966 feet, then drop sharply in June to 961 feet, then up again in early July to 964 feet and drop again to 959 feet in early September. This hydrologic regime would allow for a fairly long insect growing season with stable or rising elevation for 6 months from September through February. However, two desiccation periods in the 5-foot range, one in June and another in July and August, would likely really limit the growth and production of larval insects in the summer.

Reservoirs and river stretches below Rufus Woods Lake are run-of-the-river and so would follow similar patterns, with a double-peak in elevation changes in June and July, but the magnitude of the drop would be attenuated downstream to about a foot or less for much of this reach. These variations in stage would somewhat limit production of aquatic insects but would continue to provide habitat for production similar to current levels.

**Region C**

Benthic production in the Dworshak Reservoir is low due to the extensive variation in water surface elevation, near-shore wave action that causes erosion, and the lack of aquatic plants along the shoreline (Corps 1992 and 2015). Dworshak Reservoir pool volume typically would reach full pool on July 1, and then decline rapidly over the summer, providing a limited euphotic zone for zooplankton production.

The benthic macroinvertebrate community of the lower Snake River has been investigated on several occasions since the reservoirs were created. The most common taxa observed in the soft substrate in the Lower Snake River reservoirs were oligochaetes, amphipods (primarily corophidae), nematodes, diptera (primarily chironomids), and pelecypoda (primarily mussels).

In the hard substrate, diptera (again primarily chironomids), tricoptera (primarily caddis flies), and amphipods (both bammaridae and corophidae), according to Bennett et al. (1997) as reported by the Corps (2014). A review of mollusk diversity (Corps 2014) noted that the current mollusk fauna is dominated by the Asian clam (*Corbicula fluminea*), which became established in the Columbia River in the 1940s. The California floater (*Anodonta californiensis*), a Washington State species of concern, was also found in the sampling. The shortface lanx (*Fisherola nuttallii*) as well as three other snails (western floater [*A. kennerlyi*], knobby rams horn [*Vorticifex effuse*], and creeping ancylid [*Ferrissia rivularis*]), and the bivalve western ridged mussel (*Gonidea angulata*) were also found in small numbers. Crayfish have also been found in the reservoirs (Curet 1993; Bennett et al. 1995a; Arntzen et al. 2012). The Lower Snake River reservoirs would continue to provide production of these aquatic macroinvertebrates with a low diversity of species. Crayfish would continue to thrive in the habitats provided by rock substrate and riprap. Riverine stretches elevations would vary seasonally but generally produce similar levels of macroinvertebrates as in current conditions.

**Region D**

Very little benthic macroinvertebrate information is available for the lower Columbia River. Of those studies completed, oligochaetes, the amphipod *Corophium*, ostracods (seed shrimp), chironomids (non-biting midge larvae), nematodes, pelecypods (bivalve mollusks), hydracarina (water mites), and nemerteans (proboscis worms) were identified. Samples collected in most months also contained relatively low densities of ephemeroptera (mayflies), trichoptera (caddisflies), ceratopogonidae (biting midges), mysids (opossum shrimp), gastropods, and turbellarians. For most major taxa, densities were relatively high in the spring, declined to seasonal lows during summer, then increased to relatively high levels in the fall. Taxa present at lower densities during the summer months included nemerteans, which were frequently most abundant in autumn, pelecypods, and ostracods. *Corophium* differed most notably from this seasonal trend in that higher *Corophium* densities were observed during the summer months than during fall. The run-of-river dams would continue to be operated at stable elevations that would continue production of these aquatic macroinvertebrates.

**SUMMARY OF EFFECTS**

**Anadromous Fish**

A variety of factors affect juvenile migration and survival at the Columbia and Snake River projects. These include project structures, dam passage modifications, natural mortality, and predation. Adult migration is affected by dam passage, predation, and temperature and flow conditions. The measures in the No Action Alternative are not expected to change these factors, although temperature and flow conditions may be impacted by climate change (See Chapter 4 Climate Change).

In addition, steelhead and salmon populations in the Columbia River basin are heavily influenced by many factors unrelated to the operations and configuration of the CRS and some that occur outside of the system. These factors include competition and interbreeding with hatchery stocks; commercial, recreational, and tribal fish harvest; habitat conditions including water quality in the tributaries and migratory river corridors and yearly and decadal changes in the ocean rearing environment. Factors outside of the CRS are described throughout this document, but in general are expected to continue to influence anadromous fish in addition to the impacts associated with CRS. The trend that each species has exhibited for the past 20 years, whether upward, downward, or steady, is expected to continue under the No Action Alternative.

**Resident Fish**

Key effects are likely to continue to resident fish under the No Action Alternative. These effects include elevated summer water temperatures; elevated TDG; federal and non-federal dams that pose migration barriers, cause passage delays, or increase fish mortality; reductions in spawning and rearing habitats and changes in flow patterns and temperatures that reduce spawning and recruitment success. Elevated water temperatures would have beneficial effects to warm water resident fish and minor adverse effects to bull trout. TDG would have minor adverse effects to resident species. Non-native fish would likely continue to increase with suitable water conditions. White sturgeon would continue to successfully reproduce in some water years with adequate flow and temperature conditions, and bull trout would continue to seek thermal refugia as they migrate through the Columbia River. Reservoir operations that cause fluctuations in water elevations would continue to limit productivity and reduce access to tributary habitats in storage reservoirs, while, non-native invasive species would likely continue to increase in number and area.

**Macroinvertebrates**

Macroinvertebrate communities would continue to thrive in the aquatic environments provided by CRS project reservoirs and riverine stretches. Abundance and distribution would continue to be limited by fluctuations in reservoir elevations and river stages.

### *3.5.3.4 Multiple Objective Alternative 1*

**ANADROMOUS FISH**

**Salmon and Steelhead**

Several different ESUs of salmon and DPS of steelhead share a similar life cycle and experience similar effects from the MOs, but also have ESU or DPS specific traits that specifically drive effects differently from one another. Common effects analyses across all salmon and steelhead are discussed first, and then those ESU or DPS specific effects are displayed. Unless otherwise noted, quantitative results from COMPASS or CSS models or the Life Cycle Model (LCM) are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results.

### *Effects Common Across Salmon and Steelhead*

<u>Summary of Key Effects</u>

MO1 includes several structural measures intended to improve juvenile migration, the block spill operations will generally increase the amount of spill at each of the lower Columbia River and lower Snake River projects for improved juvenile survival, and predator disruption operations at John Day would reduce juvenile predation by Caspian terns. During periods of increased spill, latent effects may be reduced for fish under those conditions, which could potentially increase ocean survival for those fish. Structural measures in MO1 would make small, incremental improvements in adult migration, but operational changes at Dworshak that were intended to improve thermal conditions for adult migrations in the lower Snake River actually would reduce adult migration success. Models predict that returns of salmon and steelhead would be similar or slightly higher compared to the No Action Alternative depending on species and on analytical model.

<u>Juvenile Fish Migration/Survival</u>

There are several structural measures in MO1 that may affect juvenile salmon and steelhead. Many of these structures are in one or more other MOs as well. The effects of these measures are described here and are briefly summarized where they appear in other MOs.

- *Additional Powerhouse Surface Passage* at McNary and Ice Harbor Projects.

  The percent of fish passing through turbine routes at a given project depends on flows and operations. Performance standard testing conducted at projects found the percent of fish that experienced turbine routes varied from 3 percent at the McNary Project to 12 percent at the Lower Granite Project. Because turbine routes generally have lower survival (87 to 95 percent), powerhouse surface passage routes were proposed to route additional fish to spillway or spillway like routes. For modeled species, the effects of powerhouse passage were incorporated into the COMPASS and CSS modeling directly. For COMPASS modeling, surface passage efficiencies for yearling Chinook salmon and steelhead of 40 and 50 percent respectively, were fed directly into model runs, while CSS modelers provided results with surface passage efficiencies of 10, 20, and 30 percent. From CSS modeling runs, for comparisons between MOs, a 30 percent passage efficiency was used. Even with the most optimistic 30 percent passage efficiency assumption in place, the effect of these powerhouse surface passage structures on in-river survival and subsequent adult returns was minor. These structures could potentially be more effective at influencing population level dynamics at lower spill levels than those included in MO1, but with the combination of up to 115%/120% TDG spill and performance standard spill, there were not enough fish passing via the powerhouse to have a meaningful impact.

  For those species that were not modeled, effects of powerhouse surface passage routes were described qualitatively. This would include improved juvenile survival. For dams with existing spillway surface weirs, forebay delay is insignificant under the No Action

Alternative so there is little expectation of large decreases in forebay travel times. The addition of powerhouse surface passage structures would route additional fish away from turbine passage routes to spillway or spillway-like routes where they generally have higher survival.

- Upgrade spillway weirs to ASWs at Lower Granite, Lower Monumental, Ice Harbor, McNary, and John Day Dams

The design of spillway weirs is different from existing spillways. Existing spillway gates open 50 feet below the water surface at the face of the dam and pass juvenile fish under high pressure and high velocities, while spillway weirs pass juvenile salmon and steelhead over a raised spillway crest near the water surface. Because juvenile salmon and steelhead migrate primarily in the upper 10 to 20 feet of the water column, spillway weirs are easier to find and are less stressful for fish passage. Weirs are effective in attracting about one-third of all juveniles passing the dams with survival rates over 98 percent at most projects.

ASWs are a newer generation of weir that increase the flexibility of managers to attract juvenile fish to the weir under a wider range of water flows. Effects are similar to temporary spillway weirs and removable spillway weirs. However, an ASW has a wider range of operation, flows can be increased in the spring to attract more fish and reduce flows in the summer to prolong operation. Effects of these weirs would include increased juvenile survival, reduced migration delays for juveniles, and increased operating range from high flows in spring and early summer to low flows in late summer and fall. In addition, these weirs allow for more flexibility in managing flows to improve tailrace conditions so that juvenile fish can pass quickly and avoid predation.

- *Improved Fish Passage Turbines* at John Day Project

Turbines at the John Day Project are scheduled for replacement after similar replacements have been completed at the Ice Harbor (up to three turbines) and McNary Projects (part of the No Action Alternative). As this measure will follow the Ice Harbor and McNary improvements, these improvements are currently scheduled to occur between 2025 and 2039. These new IFP turbines would have similar improvements in fish passage performance as the replacement turbines designed for install at the Ice Harbor Project. The Ice Harbor Project turbines were specifically designed for fish passage using a design process similar to what may be used for future runners at John Day Project. Turbine mortality was split into direct and indirect mortality. Direct turbine mortality includes injuries that occur during turbine passage, while indirect turbine mortality can include effects like predation that occur due to disorientation or poor egress following turbine passage. The primary sources of direct turbine mortality come from mechanical-, shear-, or pressure-related injuries.

Physical hydraulic models were used to evaluate the potential for mechanical and sheer related injuries, while potential for pressure related injuries were evaluated using sensor fish or computation fluid dynamic models. These analyses suggested that IFP turbines could reduce injury and mortality by as much as 68 percent for fixed-blade turbines and as much as 49 percent for adjustable blade turbines.

For modeling and analysis purposes, a value of 50 percent was used to evaluate reductions in injuries to juvenile salmon and steelhead that pass through turbine routes. COMPASS modeling incorporates these values directly into the model, and the results reflect the change in survival. For non-modeled species, qualitative analyses and surrogate species were used to evaluate effects of new IFP turbines. See appendix E for more information regarding these assumptions.

Several operational measures warrant discussion here individually, regarding effects to juvenile fish. Measures that would result in changes to spill, flows, passage routes, or temperatures were incorporated into the fish models. Others are not readily incorporated into modeling for effects analysis, or are modeled but may be difficult to separate from other factors, and so effects of these measures are discussed qualitatively.

- *Predator Disruption Operations*. Bird predators, including Caspian terns, ring-billed and California gulls have been shown to consume large numbers of juvenile salmon and steelhead during their downstream migration to the ocean. Blalock Islands are situated in the John Day Project pool and provide nesting habitat for colonies of Caspian terns and gulls. Under the No Action Alternative, approximately 500 breeding pairs of Caspian terns consume nearly 150,000 steelhead at these small islands annually. This measure calls for a change in operation to raise water levels in the John Day Project pool in April and May to elevations between 263.5 and 265 feet. Effects of this operation would greatly reduce potential nesting habitat for Caspian terns at the Blalock Islands. In fact, an increase in elevation of 1 foot, from 263.5 to 264.5 feet, would reduce habitat by approximately 90 percent. Recent studies show that regional efforts to dissuade Caspian tern nesting have led to a decline in Caspian tern population of approximately 44 percent (Roby 2019 presentation). Continued reductions in nesting habitat would likely be associated with continued reductions in nesting predators and increases in juvenile salmon and steelhead survival.
- *Block Spill Test (Base + 120/115%)*: A spring block spill test of alternating units of 115%/120% TDG spill (high spill block) and performance standard based spill (lower spill block). This operation would increase the proportion of spill at each of the lower Columbia River and lower Snake River projects. The high spill block would have the net effect of routing increased numbers of juvenile salmon and steelhead into spill routes and fewer through other routes, such as the juvenile fish bypasses and turbine routes. Spill levels, spill patterns, and turbine priorities also have significant effects on the survival rates of migrating juveniles via their influence on tailrace hydraulics and the formation of eddies. For juvenile salmon and steelhead, fish modeling was used when available to estimate the effects of these spill changes on fish. Increased spill could provide potential benefits to salmon and steelhead if delayed mortality is considered in relation to powerhouse encounters (see section 3.5.3.1 Comparison of CSS and COMPASS Models). The CSS predicts

that increased spill could substantially reduce latent mortality of juvenile yearling Chinook salmon moving downstream through the mainstem dams, and this outcome is reflected in the outputs of abundance in the CSS model. If this were to occur for other salmon and steelhead, SARs would also be improved. The spring block spill operation was specifically designed to test the impact of latent mortality due to passage through the CRS in a scientifically robust manner (see ISAB 2018-2).

Increasing the operating range by 6 inches at the lower Snake River Dams and at John Day Dam relative to the No Action Alternative would slightly increase juvenile fish travel times and exposure to predators. Travel time effects were included in the fish models.

The combination of all measures that affect flow patterns in the Lower Columbia River. These measures would result in changes in MO1 relative to the No Action Alternative, such as one to three percent decreases in monthly average flows March to July, a decrease of five to six percent in monthly average flow in August, and one to seven percent higher flows in December. In the lower Snake River, August flows would be 13 to 16 percent lower than the No Action Alternative, and 7 to 9 percent higher in September. Reductions in August flows were primarily driven by the measure to modify Dworshak flows to influence temperature but had the unintended and unexpected result of reducing flows while not affecting temperatures (see additional discussion in Adult Fish Migration/Survival below). Similar to the spill changes, fish modeling was used when available to estimate the effects of these flow changes on juvenile fish.

Adult Fish Migration/Survival

There are several structural measures in MO1 that may affect adult salmon and steelhead. Many of these structures are in one or more other MOs as well. The effects of these measures are described here and will be briefly summarized where they appear in other MOs.

- *Lower Granite Trap Modifications*.

  The adult fish trap at the Lower Granite Project is equipped with a weir gate that swings open in a turn pool above the trap. The gate diverts fish into the trap for data collection and trap and haul. The gate is difficult to operate and open. Consequently, the gate is rarely taken out of service and is generally closed, even when the trap is not in operation. This leads to delays in migration, occasional clogging from debris or dying shad, and blockage of downstream migrating fish. In addition, the design of the ladder creates delays in lamprey migration as they try to get over the bottom bar.

  Changing the gate to make it easier to operate would improve fish passage and reduce delays and clogging on days when the trap is not in operation. In addition, a redesign of the trap gate would allow for lamprey passage by leaving a slot in the bottom large enough for them to pass under it. These improvements would improve adult conversion and survival, reduce delays in migration, and aid in volitional downstream passage through the ladder.

- *Modify Bonneville Ladder Serpentine Weir*.

  At Bonneville Dam's Bradford Island and Washington Shore ladder flow control sections, the baffles that help slow velocities and control flows do not allow for direct line movement of fish passing the dam but requires fish to weave through the baffles. The modification of these baffles would include allowing for direct faster movement through the ladder by replacing them with ones that have in-line vertical slots and orifices.

  This measure has the potential to increase adult salmon and steelhead survival by reducing upstream travel times and higher conversion rates. A similar modification at John Day Dam, the only other CRS dam to use this type of ladder, resulted in major passage time reductions for salmon and steelhead. Similar improvements are expected for Bonneville Dam. In addition, these improvements would reduce migration delays and barriers for Pacific lamprey.

- *Lower Snake Ladder Pumps*.

  During hot summer months, warm surface water is often entrained into fish ladders at the Lower Monumental and Ice Harbor Projects, leading to a difference in temperatures between the water exiting the ladder in the tailrace and the main river within the tailrace. When these abrupt differences in temperature at ladder entrances exceed 2°C, they can lead to delays and even create barriers in fish migration as adults search for cooler passage routes.

  Installing pumps in the Lower Monumental and Ice Harbor Projects' forebays to supply water to the ladders from deeper and cooler sources would cool the ladders and reduce differences in temperature if colder water is available at deeper depths. These changes would reduce adult migration delays and barriers and would improve adult survival and conversion.

  The following measures are described in detail in the juvenile fish section above. In addition to juvenile benefits, they could have the following effects on adult migration and survival:

  - The Additional Powerhouse Surface Passage measure at McNary and Ice Harbor Projects could reduce forebay travel time and improve downstream migration of steelhead kelts.
  - Upgrading spillway weirs to AWSs at Lower Granite, Lower Monumental, Ice Harbor, McNary, and John Day Dams would reduce migration delays for steelhead kelts.
  - The Improved Fish Passage Turbines measure at the John Day Project would increase survival of salmon and steelhead that overshoot the John Day Project as well as steelhead kelts that pass back downstream through turbines.

Overall, MO1 contains structural measures at lower Columbia River and lower Snake River projects that may reduce delay for adult fish passing those projects; however, adult fallback rates may also increase under MO1 due to higher spill levels, which could increase adult fish delay (Boggs et al. 2004; Keefer et al. 2005). It is important to note that regional managers use in-season adaptive management to identify and remedy any excessive fallback.

Specific to adult salmon and steelhead passing through the lower Snake in July to September, the *Modified Dworshak Summer Draft* measure in MO1 was intended to provide cooler water during more targeted periods when the cooler water could make a difference for upstream migration conditions. However, the water quality effects analysis showed that this measure did not have the intended effect on cooling the lower Snake River corridor appreciably below 20°C during July and September in periods when water temperatures were otherwise above that threshold, and furthermore exacerbated warm water temperature issues in the August timeframe.

***Upper Columbia River Salmon and Steelhead***

Upstream of McNary Dam, upper Columbia salmon and steelhead migrate past as many as five non-federally owned dams and reservoirs, which also influence the survival and passage of these species. The federal agencies do not dictate generation or spill levels at the PUD projects so metrics such as powerhouse encounter rate are not directly affected but are influenced by river flow levels coming through the upper Basin. The timing and volume of flow levels affected by CRS operational decisions are reflected in model analysis. COMPASS and LCM estimates of powerhouse encounter rate and SARs include passage effects from a combination of federal and PUD dam passage (Rock Island Dam to Bonneville Dam). CSS model results are not available for upper Columbia stocks.

<u>Upper Columbia Spring-Run Chinook Salmon</u>

*Summary of Key Effects*

The COMPASS modeling results support the qualitative expectations that the MO1 survival rates from McNary Dam to Bonneville Dam would increase slightly and travel times would be reduced slightly. Predator disruption operations would further increase juvenile survival. Structural improvements and reduced flows would increase adult migration success, but higher spill blocks may cause additional fallback and delay compared to the No Action Alternative. Abundance would increase by 6 percent or more if latent mortality were reduced.

*Juvenile Fish Migration/Survival*

This ESU migrates through the Columbia River downstream past the four lower CRS projects and up to five PUD owned dams. Structural and operational measures in the Common Effects section that describe changes from the No Action Alternative at McNary, John Day, The Dalles, and Bonneville Projects would apply to these fish. COMPASS modeling estimates that MO1 is expected to result in a 0.5 percent increase in average juvenile survival for upper Columbia River spring, a 5 percent decrease in average juvenile travel time from McNary Dam to Bonneville Dam, and a 6 percent decrease in the number of powerhouse passage events. Predator disruption operations, also described in Common Effects, would further increase juvenile survival by reducing predation on outmigrating smolts. TDG exposure would be the same as the No Action Alternative for these fish. CSS cohort modeling for upper Columbia River spring-run Chinook salmon was not available for this analysis.

Table 3-72 summarizes COMPASS and TDG Tool model results for upper Columbia River spring-run Chinook salmon under MO1.

**Table 3-72. Multiple Objective Alternative 1 Juvenile Model Metrics for Upper Columbia River Spring-Run Chinook Salmon**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) McNary to Bonneville | 69.5% | 70.0% | +0.5% | N/A |
| Juvenile Travel Time (COMPASS) McNary to Bonneville | 6.1 days | 5.8 days | -0.3 days | -5% |
| % Transported (COMPASS) | No transport of upper Columbia Chinook | | | |
| Powerhouse Passages (COMPASS) Rock Island to Bonneville | 3.29 | 3.08 | -0.21 | -6% |
| TDG Average Exposure (TDG Tool) | 115.9% TDG | 116% TDG | -0.1 % TDG | N/A |

*Adult Fish Migration/Survival*

The *Modify Bonneville Ladder Serpentine Weir* measure, described in the Common Effects section, could decrease delay of upstream migrations, although higher spill periods of block spill could increase fallback rates. Adult exposure to TDG would be similar to the No Action Alternative.

The NWFSC LCM estimated SARS and abundance of the Wenatchee population. NWFSC LCM results predict abundance of the Wenatchee population, indicative of this ESU, could result in a slight increase of about 1 percent relative to the No Action Alternative (0.96 percent compared to 0.95 percent), assuming latent mortality was the same as in the No Action Alternative. Abundance estimates produced by the NWFSC Life Cycle model were also considered with a range of potential outcomes based on hypothetical increases in production that could be associated with reductions in latent mortality effects. While CSS modeling was not available for this population, the relationships in CSS modeling that indicate fewer powerhouse encounters would reduce latent mortality may apply to this population as well. If the 23 percent lower powerhouse encounter rate were to lower latent mortality that would subsequently increase ocean survival, abundance could increase more than 6 percent (Table 3-73).

**Table 3-73. Multiple Objective Alternative 1 Model Metrics for Adult Upper Columbia River Spring Chinook Salmon**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Rock Island to Bonneville SARs (NWFSC LCM) | 0.94% | 0.95% | +0.01% | +1% |
| NWFSC LCM abundance range with decreased latent mortality[1] (number of adults) | 498 | 526 (0%)<br>570 (10%)<br>690 (25%)<br>822 (50%) | +28 (0%)<br>+72(10%)<br>+192 (25%)<br>+324 (50%) | +6% (0%)<br>+14% (10%)<br>+39% (25%)<br>+65% (50%) |

[1] NWFSC LCM does not factor latent mortality due to the Columbia River System into the SARS or abundance output. For discussion purposes, potential decreases in latent mortality of 10 percent, 25 percent, and 50 percent are shown. The value for 0 percent is the actual model output, the 10 percent, 25 percent, and 50 percent values represent scenarios of what SARs, or abundance hypothetically could be under the increased ocean survival if changes in the alternative were to decrease latent mortality by that much.

<u>Upper Columbia River Steelhead</u>

*Summary of Key Effects*

There are no life cycle models for upper Columbia steelhead to estimate adult returns, only COMPASS model estimates of juvenile downstream survival. Functionally, upper Columbia River steelhead juvenile migration would be about the same as the No Action Alternative. Modeled survival shows a 0.2 percent decrease, but travel time would be the same as the No Action Alternative, and powerhouse encounters would be lower. Predator disruption operations would further increase juvenile survival. Structural improvements and reduced flows could increase adult migration success. Structural measures and higher spill blocks described in the Common Effects section, including the Additional Powerhouse Surface Passage and Improved Fish Passage Turbines measures, may increase kelt survival by reducing the proportion that go through turbine routes.

*Juvenile Fish Migration/Survival*

Juveniles from this DPS migrate through the Columbia River downstream past the four lower CRS projects and up to five PUD owned dams in the mid-Columbia. Operations at upstream reservoirs that affect seasonal flow patterns downstream influence travel time and survival at the PUD owned projects. Structural and operational measures described in the Common Effects section, including the *Additional Powerhouse Surface Passage* measure at the McNary and John Day Projects, and the *Upgrade to Adjustable Spillway Weirs* measure at the McNary and John Day Projects, would decrease powerhouse passage events, as indicated in the modeling. Overall, however, COMPASS modeling estimates that MO1 is expected to result in a 0.2 percent decrease in average juvenile survival for upper Columbia steelhead, travel time would be the same as the No Action Alternative, and powerhouse passage events would decrease 5 percent. The *Predator Disruption Operations* measure, also described in Common Effects, would further increase juvenile survival by reducing predation on outmigrating smolts. TDG exposure and the resulting effect on juvenile survival would be similar to the No Action Alternative for these fish.

Table 3-74 summarizes COMPASS and TDG Tool model results for upper Columbia River steelhead under MO1. CSS cohort modeling for upper Columbia spring-run Chinook was not available for this analysis.

**Table 3-74. Multiple Objective Alternative 1 Model Metrics for Juvenile Upper Columbia Steelhead**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) McNary to Bonneville | 65.8% | 65.6% | -0.2% | -0% |
| Juvenile Travel Time (COMPASS) McNary to Bonneville | 6.6 days | 6.7 days | +0.1 days | 0% |
| % Transported (COMPASS) | No transport of upper Columbia steelhead | | | |
| Powerhouse Passages (COMPASS) Rock Island to Bonneville | 2.72 | 2.59 | -0.13 | -5% |
| TDG Average Exposure (TDG Tool) McNary to Bonneville | 116% TDG | 116.1% TDG | -0.1% TDG | N/A |

*Adult Fish Migration/Survival*

The *Modify Bonneville Ladder Serpentine Weir* measure, described in the Common Effects section, would decrease delay of upstream migrations. Structural measures designed to increase juvenile survival (*Additional Powerhouse Surface Passage at McNary and John Day*, and *Upgrade to Adjustable Spillway Weirs at McNary and John Day Projects*) would also benefit kelt survival by increasing the proportion of downstream migrating kelts going through turbine routes. Higher spill periods of block spill could increase survival of kelts by increasing non-turbine routes. Adults migrate in late summer and early fall, so 5 to 6 percent lower outflows in the lower Columbia River in August could increase upstream migration success. Adult exposure to TDG would be similar to the No Action Alternative, as the total number of days TDG would exceed the water quality standard would be lower than the No Action Alternative at McNary, John Day, and The Dalles Dams; at Bonneville Dam, there would be 1 more day than the No Action Alternative. Temperatures would also be very similar to No Action Alternative. The number of days exceeding state temperature standards at the four lower river projects would be less than 1 percent higher than the No Action Alternative.

<u>Upper Columbia River Coho Salmon</u>

See upper Columbia spring-run Chinook salmon analysis as a surrogate for juvenile upper Columbia coho salmon and upper Columbia fall Chinook salmon analysis as a surrogate for adult upper Columbia coho salmon.

*Summary of Key Effects*

The primary challenges for upper Columbia River coho salmon are the conditions they encounter during upstream and downstream migrations. Downstream survival and migration for juveniles is dependent on water flow and routing at the dams. Higher flows and higher spills generally lead to higher survival. Juvenile coho survival would be similar to upper Columbia River spring-run Chinook salmon, with structural measures and spill increases potentially increasing juvenile survival and additional increases in survival due to lower avian predation in the John Day area. Adult coho salmon migration timing is similar to upper Columbia River fall Chinook salmon so that species is used as a surrogate for upstream migration effects.

*Juvenile Fish Migration/Survival*

See upper Columbia River spring-run Chinook salmon results as a surrogate for juvenile upper Columbia River coho salmon.

*Adult Fish Migration/Survival*

Adult migration conditions would be similar to upper Columbia Fall Chinook, which were analyzed in a workshop using water quality and hydrology information. MO1 water quality modeling showed no change in the frequency of water temperatures exceeding 20°C relative to the No Action Alternative, but a higher incidence of adult ladder temperature differentials above 2°C, which could delay upstream migration. Upper Columbia coho salmon migrate upstream as adults in August/September (early run) and October/November (late run), so migration success of a portion of the early run may be affected with 5 to 6 percent lower flows in August. See upper Columbia Fall Chinook salmon results as a surrogate for adult upper Columbia coho salmon.

<u>Upper Columbia River Sockeye Salmon</u>

Refer to the upper Columbia River Chinook salmon analysis as a surrogate for Upper Columbia River sockeye salmon.

*Summary of Key Effects*

MO1 would result in similar or minor improvements in juvenile migration over the No Action Alternative. Survival would be similar to upper Columbia River spring-run Chinook salmon, with structural measures and spill increases resulting in potentially minor increases in juvenile survival, and additional increases in survival due to lower predation by birds in the John Day area. Adult migration would be similar to the No Action Alternative.

*Juvenile Fish Migration/Survival*

Juvenile survival of upper Columbia River sockeye salmon is estimated using COMPASS juvenile modeling results for upper Columbia River spring-run Chinook salmon as a surrogate.

MO1 would have negligible increases in survival rates for juvenile sockeye passing downstream through the lower Columbia River compared to the No Action Alternative; travel time and powerhouse encounters would exhibit minor decreases. Structural measures, such as the *Additional Powerhouse Surface Passage* measure at the McNary and John Day Projects and the *Upgrade to Adjustable Spillway Weirs* measure at the McNary and John Day Projects, as well as the *Predator Disruption Operations* measure described in Common Effects would increase survival by increasing proportions of fish to pass through the spillways. This is in addition to increased survival of sockeye juveniles passing through John Day Dam turbines.

Refer to the upper Columbia River Chinook salmon analysis, as a surrogate for Upper Columbia River sockeye salmon, for additional information in modeled juvenile fish migration and survival metrics.

*Adult Fish Migration/Survival*

The summer water temperatures in the river during the upstream migration would be similar to the No Action Alternative, with thermal issues continuing to reduce adult survival in warm years, and TDG exposure would be similar to the No Action Alternative. Structural improvement of the *Modify Bonneville Ladder Serpentine Weir*, described in Common Effects at the Bonneville Project, could reduce migration delay.

Refer to the upper Columbia River Chinook salmon analysis, as a surrogate for Upper Columbia River sockeye salmon, for additional information in modeled adult fish migration and survival metrics.

<u>Upper Columbia River Summer/Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

Juvenile upper Columbia summer/fall-run Chinook salmon would be similar to the No Action Alternative, with potential increases in juvenile survival due to lower predation in the John Day Dam pool. There may be slightly greater adult migration delay due to higher incidence of adult ladder temperature differentials above 2°C.

*Larval Development/Juvenile Rearing in Mainstem Habitats*

None of the measures of MO1 would change the substrate sizes or distribution in the spawning areas or expand suitable spawning areas; therefore, this alternative is expected to have the same larval development and juvenile rearing habitat conditions as the No Action Alternative. The same is true for river depths in the spawning areas; no change is anticipated for eggs incubating in the gravel. Once juvenile Chinook salmon have emerged and moved to the reservoirs for rearing, lack of summer cooling water may reduce quality of rearing habitat for fish that holdover for their first year; however, the changes for MO1 would not be a measurable difference compared to the No Action Alternative. No change is anticipated in McNary and John Day Dam reservoir plankton communities or shoreline habitats under MO1, relative to the No Action Alternative. Likewise, juvenile rearing habitat below Bonneville Dam is not expected to change relative to the No Action Alternative.

*Juvenile Fish Migration/Survival*

Juvenile summer/fall-run Chinook salmon are especially susceptible to predation in the Columbia River from the Okanogan River to downstream of McNary Dam. Water temperatures would be the same as the No Action Alternative and would not change predation rates in this reach. Downstream migration of juveniles would be similar to the No Action Alternative as well.

*Adult Fish Migration/Survival*

The number of days water temperatures in the McNary Dam tailrace exceed 20°C would not change relative to the No Action Alternative, so no change in migration delay, fallback, or susceptibility to disease are anticipated due to overall warmer mainstem water temperatures at the lower Columbia River Dams. However, the number of days that adult ladder water temperatures were greater than 2°C in difference would increase from 2.8 percent of days (No Action Alternative) to 4.2 percent of days (MO1), which may slightly increase the delay in dam passage for adult fish (Caudill et al. 2013).

Specific to Okanogan upper Columbia River summer/fall-run Chinook salmon, there would be no change in the number of days the mainstem would be 20°C or higher at the confluence of the Okanogan River, relative to the No Action Alternative. This means that there would be no change anticipated in the ability of the Okanogan fish to wait (hold) in the mainstem until water temperatures in the Okanogan River are cool enough for adults to move up from the mainstem without having to migrate through water temperatures typically considered lethal for salmon and steelhead (Ashbrook et al. 2009).

The frequency of meeting the Vernita Bar Agreement to protect fall-run Chinook salmon spawning in and around the Hanford Reach of the Columbia River in Washington is not expected to change under any MOs relative to the No Action Alternative. Other operational changes under the MOs are likewise not anticipated to affect upper Columbia River summer/fall-run Chinook salmon spawning from the tailrace of Chief Joseph Dam to Bonneville Dam in terms of changes in flows, water temperatures, or TDG generated under the MOs.

***Middle Columbia River Salmon and Steelhead***

<u>Middle Columbia River Spring-Run Chinook Salmon</u>

See Upper Columbia River spring-run Chinook analysis as a surrogate for Middle Columbia River Spring-Run Chinook Salmon.

*Summary of Key Effects*

Changes in effects to middle Columbia River spring-run Chinook salmon juvenile and adult migrations and adult returns under MO1 would be similar to the No Action Alternative.

*Juvenile Fish Migration/Survival*

See upper Columbia River spring-run Chinook analysis as a surrogate for juvenile middle Columbia River spring-run Chinook salmon. Middle Columbia River juvenile salmon would typically experience higher absolute survival than upper Columbia River spring-run Chinook salmon because they do not travel as far through the Columbia River System and through up to five non-federal owned dams. However, the surrogate metric used for upper Columbia River spring-run Chinook salmon is survival from McNary to Bonneville Dam and would be similar for middle Columbia spring-run Chinook salmon that pass the same CRS projects.

*Adult Fish Migration/Survival*

Effects to middle Columbia River spring-run Chinook salmon adults would be similar to upper Columbia River spring-run Chinook salmon. Structural improvements and reduced flows would increase adult migration success, but higher spill blocks may cause additional fallback and delay compared to the No Action Alternative. See upper Columbia River spring-run Chinook analysis for surrogate information on adult middle Columbia River spring-run Chinook salmon under MO1 and comparisons to No Action Alternative.

<u>Middle Columbia River Steelhead</u>

*Summary of Key Effects*

Changes in effects to middle Columbia River steelhead juvenile and adult migration and returns under MO1 would be similar to the No Action Alternative. Certain structural measures, including the *Additional Powerhouse Surface Passage* and *Improved Fish Passage Turbines* measures, and higher spill levels under the *Block Spill Test (Base +120/115%)* measure would result in higher survival rates for adult steelhead falling back through the dams and kelts migrating downstream.

*Juvenile Fish Migration/Survival*

Populations of mid-Columbia River steelhead distributed between the Deschutes and Walla Walla Rivers pass two to four CRS dams in the lower Columbia on their downstream migration to the ocean. Modeling was not available for middle Columbia River steelhead, so juvenile survival of upper Columbia steelhead was used as a surrogate of juvenile survival through the Bonneville project (pool and dam) for this portion of the DPS. COMPASS modeling predicted a negligible decrease in survival and slower travel times under MO1, compared to the No Action Alternative. TDG would also be similar to the No Action Alternative. Refer to Upper Columbia River steelhead analysis (Section 3.5.3.3) for surrogate information on Middle Columbia River steelhead.

Predator disruption operations, as described in the Common Effects section, would reduce predation on outmigrating middle Columbia River steelhead smolts and increase juvenile survival. Functionally, reduced predation rates by Caspian terns between McNary and John Day dams that would result in increased juvenile survival, combined with reduced survival between McNary and Bonneville dams would likely result in similar survival of middle Columbia River steelhead in MO1 compared to the No Action Alternative.

*Adult Fish Migration/Survival*

Structural measures such as *Modify Bonneville Ladder Serpentine Weir* are expected to reduce delay associated with upstream passage. Higher spill levels during April periods under the *Block Spill Test (Base + 120/115%)* measure would result in higher survival rates for adult steelhead falling back through dams and kelts migrating downstream, as fewer adults would use powerhouse passage routes with increased availability of spill routes. Downstream passage survival would also increase when surface passage was available (Normandeau et al. 2014; Richins and Skalski 2018).

***Snake River Salmon and Steelhead***

Snake River Spring/Summer-Run Chinook Salmon

*Summary of Key Effects*

Modeling and qualitative analyses indicate that MO1 would result in similar or slightly higher overall returns of Snake River spring/summer-run Chinook salmon. Juvenile survival would be very similar to the No Action Alternative (about 0.5 percent higher). Certain structural measures would provide benefits to adults migrating upstream. Overall abundance of returning adults may increase between 0 and 40 percent based on population and latent mortality assumptions.

*Juvenile Fish Migration/Survival*

This ESU migrates through the Snake and Columbia Rivers downstream past the eight CRS projects: four on the Snake River and four on the lower Columbia River. Structural and operational measures the Common Effects section that describe changes at all of these dams would affect these fish. The combination of several measures would, similar to the No Action Alternative, would be expected to decrease travel time and powerhouse encounters and overall increase juvenile outmigration survival, such as the *Additional Powerhouse Surface Passage*, *Upgrade to Adjustable Spillway Weirs,* and *Improved Fish Passage Turbines* measures. For Snake River spring/summer-run Chinook salmon, the COMPASS and CSS cohort models estimate that MO1 would increase juvenile survival from Lower Granite Dam to Bonneville Dam by less than 1 percent, and travel time would decrease less than 2 percent. The structural measures and increase in spill during block periods would be expected to decrease powerhouse encounters somewhat, with the models predicting a relative decrease of about 16 to 19 percent. The *Predator Disruption Operations* measure, also described in Common Effects, would further increase juvenile survival by reducing predation on outmigrating smolts. TDG exposure would be less than 1 percent higher than the No Action Alternative, with a reach average exposure of 115.1 percent TDG. See Table 3-75 for a list of model outputs related to juvenile migration and survival.

**Table 3-75. Multiple Objective Alternative 1 Juvenile Model Metrics for Snake River Spring/Summer Chinook Salmon**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 50.4% | 51.0% | +0.6% | +1% |
| Juvenile Survival (CSS) | 57.6% | 58.3% | +0.7% | +1% |

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Travel Time (COMPASS) | 17.7 days | 17.4 days | -0.3 days | -2% |
| Juvenile Travel Time (CSS) | 15.8 days | 15.5 days | -0.3 days | -2% |
| % Transported (COMPASS) | 38.5% | 37.8% | -0.7% | -2% |
| % Transported (CSS) | 19.2% | 26.5% | +7.3% | 38% |
| Transport: In-River Benefit Ratio (CSS) | 0.86 | 0.68 | -0.18 | -21% |
| Powerhouse Passages (COMPASS) | 2.25 | 1.88 | -0.37 | -16% |
| Powerhouse Passages (CSS) | 2.15 | 1.74 | -0.41 | -19% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 115.5% TDG | +0.5% TDG | N/A |

Several measures in MO1 would affect juvenile Snake River spring/summer-run Chinook salmon transportation rates. The NWFSC LCM predicted a negligible decrease in the overall proportion of fish transported compared to the No Action Alternative, at about 38 percent of juveniles transported. CSS, however, predicted an increase of 7.3 percent in transportation rate compared to the CSS-modeled No Action Alternative. The CSS also predicted a lower total transport rate with an absolute value of 26.5 percent of smolts transported under MO1, as well as a decrease in the benefit to survival for transported smolts. The difference in modeled transportation rates is likely due to the fact that the COMPASS model only uses natural origin juveniles to assess transport rates while CSS includes hatchery fish as well.

Smolts would be collected for transportation at the three Snake River collector projects starting on April 15 under the *Early Start Transport* measure of MO1, which is earlier than the No Action Alternative start date of April 25. The intent of this measure was to increase the region's understanding of early season transport effects and to benefit early migrating Snake River steelhead. With regard to Snake River spring/summer Chinook, the earlier start to juvenile fish transport would have a neutral effect on the TIR, though hatchery origin Chinook salmon smolts have a greater benefit of transportation during this timeframe than natural origin smolts (Transport COP; Gosselin et al. 2018). However, because of the lower conversion rates associated with fish that were transported as juveniles (Keefer et al. 2008; FPC memo 13-19), without a clear benefit for the early period, earlier transport may slightly decrease Snake River spring/summer-run Chinook salmon adult returns to spawning grounds.

The increased spill in the high spill blocks associated with the *Block Spill Test (Base + 120/115%)* measure, would also increase the number of juveniles passing via spillways and thus not able to be collected in the juvenile fish bypasses for transportation. Reducing transport rates, especially in May and June, would be expected to reduce SARs because those transported fish typically have higher SARs than those of in-river migrants during this period.

Across the entire spring migration season in both the No Action Alternative and MO1, the CSS cohort model predicted lower return rates for juvenile Snake River Chinook that were transported compared to fish that migrated in-river as juveniles. The benefit of transport in MO1 was even less than the No Action Alternative and this difference is likely the result of higher in-river SARs predicted by the CSS model under MO1.

*Adult Fish Migration/Survival*

Several structural measures in MO1 are anticipated to benefit adult Snake River spring/summer-run Chinook salmon passage upstream, including *Lower Granite Trap Modifications, Modify Bonneville Serpentine Weir* (reducing delay), and *Lower Snake Ladder Pumps* if there is cooler water available at depth. However, MO1 has block periods of higher spill under the *Block Spill Test (base + 120/115%)* measure, and fallback rates of Snake River spring/summer-run Chinook salmon may increase because fallback for this ESU has been associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). In recent years, adult passage delays have been observed at Little Goose Dam with spill levels over 30-35 percent. It is important to note that regional managers use in-season management techniques to identify and remedy any excessive fallback, which would likely mitigate for this increase in spill. Potential spill reduction starting during as early as August 1 using a spill trigger may reduce fallback for the few summer migrating adults that may still be migrating in August and no effects on spring migrating adults. However, while fallback rates may be lower, individuals that fell back would experience greater risk of falling back through turbines and juvenile bypass systems compared to spillways once the spill cessation trigger is met at individual lower Snake River projects.

Increasing the reservoir operating range by 6 inches at the lower Snake River Dams (MOP 1.5-foot range) and at John Day Dam (MIP 2-foot range) would have little effect on flow, and thus is not expected to affect adult migration timing or survival rates (NMFS 2019). Similarly, holding contingency reserves within juvenile fish passage spill is likely to have little effect, if any, on adult migration.

Finally, the modified Dworshak releases in MO1 were intended to provide cooler water during more targeted periods when the cooler water could make a difference for upstream migration conditions. However, the water quality effects analysis showed that this measure did not have the intended effect on cooling the lower Snake River corridor appreciably below 20°C during July and September in periods when water temperatures were otherwise above that threshold, and furthermore exacerbated warmwater temperatures in the August timeframe. This measure is unlikely to affect the few Snake River spring/summer-run Chinook salmon still migrating in the latter half of July.

Table 3-76 displays the median model outputs for adult metrics from both NWFSC LCM and CSS. NWFSC LCM results include different scenarios of latent mortality in the ocean survival phase, including decreased mortality of 0 percent, 10 percent, 25 percent, and 50 percent (scenario indicated in parentheses).

**Table 3-76. Multiple Objective Alternative 1 Adult Model Metrics for Snake River Spring/Summer-Run Chinook Salmon**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| LGR-BON SARs[1/] (NWFSC LCM) (Percent) | 0.88% | 0.88% (0%)<br>0.93% (10%)<br>1.00% (25%)<br>1.12% (50%) | 0 (0%)<br>+0.05% (10%)<br>+0.12% (25%)<br>0.24% (50%) | 0% (0%)<br>+6% (10%)<br>+14% (25%)<br>+28% (50%) |
| SARs LGR-BON (CSS) | 2.0% | 2.2% | +0.2% | +10% |

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Abundance of Middle Fork, South Fork and upper Salmon River representative populations (Number of adults; NWFSC LCM)[2/] | 2,351 | 2,411 (0%)<br>2,563 (10%)<br>2,826 (25%)<br>3,290 (50%) | +60 (0%)<br>+212 (10%)<br>+475 (25%)<br>+939 (50%) | +3% (0%)<br>+9% (10%)<br>+20% (25%)<br>+40% (50%) |
| Abundance of Grande Ronde/Imnaha representative populations (CSS)[3/] | 6,114 | 6,428 | +314 | +5% |

1/ NWFSC LCM does not factor latent mortality due to the Columbia River System into the SARS or abundance outputs. For discussion purposes, potential decreases in latent mortality of 10 percent, 25 percent, and 50 percent are shown. The value for 0 percent is the actual model output, the 10 percent, 25 percent, and 50 percent values represent scenarios of what SARs or abundance hypothetically could be under the increased ocean survival scenario if changes in the alternative were to decrease latent mortality by that much.

2/ NWFSC LCM provided results for 16 populations in the upper Salmon River, South Fork Salmon River, and Middle Fork Salmon River major population groups. The absolute values include these populations only, the percent change is considered indicative of the Snake River ESU of spring-run Chinook salmon for the purpose of comparing between MOs.

3/ CSS provided results for six populations in the Grande Ronde/Imnaha major population group. The absolute values represent those populations only; the percent change is considered indicative of the Snake River ESU of spring-run Chinook salmon for the purpose of comparing between MOs.

The NWFSC LCM estimates SARs and abundance of the upper Salmon River, South Fork Salmon River, and Middle Fork Salmon River MPGs. CSS estimates the abundance of Grande Ronde/Imnaha MPG. Both models use a combination of hatchery and natural origin fish. For comparison purposes, the percent change from the No Action Alternative is considered indicative of the effects of MO1 on the Snake River spring-run Chinook salmon ESU.

The NWFSC LCM predicts MO1 would result in a range from no change to a 28 percent relative increase in the smolt to return as adult rates to Bonneville Dam depending on the magnitude of latent mortality assumptions applied. The CSS model predicts a change of 0.2 percent increase (10 percent relative change) in survival of smolts from Lower Granite Dam to return as adults back to Bonneville Dam (from 2.0 percent in the No Action Alternative to 2.2 percent under MO1).

With slight increases in juvenile survival both in the freshwater migration and in the ocean to adulthood, increases in abundance of fish to the spawning grounds would be expected. The NWFSC model, looking at the Middle Fork Salmon and South Fork Salmon MPGs, showed an average overall increase of about 3 percent without factoring in any change to latent mortality. The abundance change in individual populations would range from a 1 percent decrease (Big Creek population) to a 4 percent increase (Bear Valley Creek population). Smolts would experience fewer powerhouse routes, on average, that could potentially reduce latent mortality somewhat from the No Action Alternative and that could increase the adult returns more than indicated by the model. The CSS models, using the Grande Ronde/Imnaha MPG, indicated about 5 percent increase in abundance, with a range of from 5 percent to 12 percent increase in individual populations. With consideration of confidence of the models, this would indicate likely similar abundance.

Qualitatively, MO1 would provide contrasting spill levels to test latent mortality effects under the *Block Spill Test (base + 120/115%)* measure, but would not likely change the overall expected latent mortality much because travel time, powerhouse encounters, and TDG exposure are similar to the No Action Alternative. The CSS models indicate ocean survival would be similar to the No Action Alternative. The NWFSC LCM SARS and abundance results with 0 to 10 percent decreased latent mortality assumptions are similar to CSS results.

<u>Snake River Steelhead</u>

*Summary of Key Effects*

Juvenile survival would be similar to the No Action Alternative, with models showing similar travel time and TDG exposure and lower powerhouse encounters, and predation may be decreased with the predator disruption measure. Structural measures and blocks of higher spill may increase kelt survival but warmer water temperatures in the Snake River would decrease it. The warmer August temperatures driven by operational changes at Dworshak would also reduce upstream migration survival and success. CSS modeled SARs predicted that returning adults to Bonneville may increase by up to 5 percent.

*Juvenile Fish Migration/Survival*

This DPS migrates through the Snake and Columbia Rivers downstream past the eight CRS projects, four on the Snake River, and four on the lower Columbia River. Structural and operational measures described in the Common Effects section that describe changes at these projects would apply to these fish. The combination of several measures would maintain overall travel time, reduce powerhouse encounters, and increase survival including the *Additional Powerhouse Surface Passage* measure at the McNary and John Day Projects, and the *Upgrade to Adjustable Spillway Weirs* measure at the McNary and John Day Projects. For Snake River steelhead, the COMPASS model predicts a decrease in juvenile survival of 0.5 percent, and CSS cohort models estimate that MO1 would increase juvenile survival from Lower Granite Dam to Bonneville Dam by 1.7 percent. Both models agree that travel time would be nearly the same and that powerhouse encounters would decrease 15 to 16 percent. The *Predator Disruption Operations* measure, also described in Common Effects, would further increase juvenile survival by reducing predation on outmigrating steelhead smolts. TDG exposure would be less than 1 percent higher under the *Block Spill Test (Base +120/115%)* measure of MO1 than the No Action Alternative, with a reach average exposure of 115.1 percent TDG and little effect on juvenile survival. See Table 3-77 for a list of model outputs related to juvenile migration and survival.

**Table 3-77. Juvenile Model Metrics for Snake River Steelhead under Multiple Objective Alternative 1**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 42.7% | 42.2% | -0.5% | -1% |
| Juvenile Survival (CSS) | 57.1% | 58.8% | +1.7% | +3% |
| Juvenile Travel Time (COMPASS) | 16.4 days | 16.4 days | 0 days | 0% |

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Travel Time (CSS) | 16.2 days | 16.3 days | +0.1 days | +0% |
| % Transported (COMPASS) | 39.7% | 39.1% | -0.6% | -2% |
| % Transported (CSS) | Unknown | | | |
| Transport: In-River Benefit Ratio (CSS) | 1.41 | 1.08 | -0.33 | -23% |
| Powerhouse Passages (COMPASS) | 1.73 | 1.47 | -0.26 | -15% |
| Powerhouse Passages (CSS) | 1.96 | 1.64 | -0.32 | -16% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 115.5% TDG | +0.4% TDG | N/A |

Several measures in MO1, such as *Early Start Transport* affect juvenile Snake River steelhead transportation rates, and season-wide, the CSS cohort model estimates a reduction in TIR (i.e., reduction in transport benefit, relative to migration in-river) of about 23 percent compared to the TIR under the No Action Alternative. While a MO1 TIR of 1.08 represents a reduction in TIR relative to the No Action Alternative (TIR 1.41), the TIR still represents a season-wide benefit to steelhead that are transported relative to in-river migration, measured in terms of relative SARs (DeHart CRSO-24/2019).

The *Early Start Transport* measure would affect the change in transportation including an earlier start to transport date (April 15) relative to the No Action Alternative start to transport date of April 25. The earlier start to juvenile fish transport would likely increase adult returns for hatchery origin steelhead and would have a neutral effect on natural origin steelhead. Thus, the earlier transport date is likely not a driver of the TIR response relative to the No Action Alternative because the effect should be beneficial or neutral, not adverse.

The *Block Spill Test (Base + 120/115%)* measure would increase the number of juveniles passing via spillways and thus would be unable to be collected in juvenile fish bypasses for transportation. Reducing transport rates, especially in May and June, would be expected to decrease total adult returns of steelhead. Higher MO1 in-river survival compared to the No Action Alternative may also be a factor in the lower season-wide TIR in MO1 and is most likely driver of the change in MO1 relative to the No Action Alternative. Overall, across the entire spring migration season, the CSS cohort model estimated in-river migrants would return at a lower rate than transported migrants under MO1 because the TIR was greater than 1 (average TIR 1.08). This relative return rate of transported fish was less than the return rate of transported fish for the No Action Alternative (TIR 1.41). However, TIR varies throughout the season and so this overall TIR estimate does not provide information on the specific dates within the season when transporting fish may yield higher or lower returns than the season wide average.

The COMPASS and CSS cohort model results support the qualitative expectations that the MO1 survival rates from the lower Snake River to below Bonneville Dam would be similar to the No Action Alternative.

*Adult Fish Migration/Survival*

Several structural measures in MO1 are anticipated to benefit adult steelhead passage upstream, including *Lower Granite Trap Modifications* and *Modify Bonneville Ladder Serpentine Weir* (reducing delay), *Lower Snake Ladder Pumps*, if cooler water is present at depth in the forebays. Structural measures designed to increase juvenile survival (*Additional Powerhouse Surface Passage* and *Upgrade to Adjustable Spillway Weirs*) could also benefit kelt survival by increasing the proportion of downstream migrating kelts going through non-turbine routes. Higher spill periods of block spill could increase survival of kelts by increasing non-turbine routes. Warmer Snake River temperatures in August due to modified operations at Dworshak Dam would decrease steelhead upstream migration survival and success. Adult exposure to TDG would be similar to the No Action Alternative.

Higher spill levels during April periods should result in higher survival rates for adult steelhead falling back through dams and kelts migrating downstream, as fewer adults used powerhouse passage routes when a spill route was available and overall downstream passage increased when surface passage was available (Normandeau et al. 2014).

For Snake River steelhead, the CSS cohort model estimates that SARs would increase 5 percent from the No Action Alternative. Table 3-78 displays the CSS cohort model results for Snake River steelhead. NWFSC LCM modeling for Snake River steelhead was not available.

**Table 3-78. Multiple Objective Alternative 1 Adult Model Metrics for Snake River Steelhead**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| SARs LGR-BON (CSS) | 1.8% | 1.9% | +0.1% | +5% |

Under MO1, fewer steelhead would be transported because of higher spill levels under the *Block Spill Test (Base + 120/115%)* measure. Based on observed data, without considering latent mortality, this is anticipated to result in a negligible change to return rates at Lower Granite Dam.

<u>Snake River Coho Salmon</u>

See Snake River spring/summer-run Chinook as a surrogate for juvenile Snake River coho salmon and Snake River fall-run Chinook as a qualitative surrogate for adult Snake River coho salmon.

*Summary of Key Effects*

Surrogate species modeling predicts a minor increase in survival in juvenile Snake River coho salmon. However, a survival increase for Snake River juvenile coho may be offset by an increase in water temperatures above 20°C that may be experienced by adult Snake River coho migrating through the lower Snake reach. This increase may increase delay, fallback, and susceptibility to disease by adults under MO1, compared to the No Action Alternative.

*Juvenile Fish Migration/Survival*

Based on Snake River surrogate species under MO1, juvenile survival of coho salmon would have minor increases in survival, minor reductions in travel times, and major reductions in powerhouse encounters, compared to the No Action Alternative. Refer to Snake River spring/summer-run Chinook as a surrogate for juvenile Snake River coho salmon for additional information.

*Adult Fish Migration/Survival*

For the lower Snake River reach, MO1 water quality modeling showed an increase in the frequency of water temperatures exceeding 20°C relative to the No Action Alternative. Adult Snake River coho salmon could experience a greater delay in their adult migration, increase in fallbacks at lower Snake River dams, and increase in susceptibility to disease compared to the No Action Alternative. Ultimately, increased (warmer) water temperatures would pose a greater risk to adult survival. This mechanism is described in more detail for *Snake* River fall-run Chinook (Section 3.5.3.3) as a surrogate for adult Snake River coho salmon.

Snake River Sockeye Salmon

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for Snake River sockeye salmon.

*Summary of Key Effects*

Juvenile migration and survival would be similar or slightly better than the No Action Alternative with lower powerhouse encounter rates but similar travel time and TDG exposure. For adults, the most notable effect of MO1 is the increased risk of delay in upstream migration due to warmer river temperatures and increased temperature differential at the fish ladders.

*Juvenile Fish Migration/Survival*

This alternative is expected to result in a slightly faster migration time for juvenile Snake River sockeye salmon based on modeling results for juvenile Snake River Chinook salmon. Refer to the analysis of Snake River spring/summer-run Chinook salmon as a surrogate for Snake River sockeye salmon in Section 3.5.3.2. Juvenile sockeye salmon migrate faster than yearling Chinook, and it is assumed that slightly faster travel times would result in better survival due to less swimming effort and shorter duration of exposure to predators; the overall result is better survival rates. Along with the slightly faster travel time, modeled surrogate analyses predict that juvenile fish would also experience fewer powerhouse encounters relative to the No Action Alternative from MO1's *Additional Powerhouse Surface Passage*, *Upgrade to Adjustable Spillway Weirs,* and *Improved Fish Passage Turbines* measures, which may result in increased survival to adult returns.

Increased block spill rates under MO1's *Block Spill Test (Base + 120/115%)* measure may contribute to the faster travel time, but the change in travel time due to spill rate is not a substantial difference. The mean water temperature during juvenile outmigration is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish. Under the *Predator Disruption Operations* measure, the proposed operations at John Day Dam to increase the reservoir operating range could reduce nesting habitat for birds that eat salmon on the Blalock Islands, which would reduce mortality of juvenile sockeye salmon.

Transportation of sockeye salmon could change due to spill and transportation measures in MO1, including the *Block Spill Test (Base + 120/115%)* and *Early Start Transport* measures. The outmigration window is more compressed, with the bulk of the smolts passing April through the end of May. However, starting transport earlier in April could increase transportation of juvenile sockeye salmon depending on the annual run-timing of downstream migrants.

*Adult Fish Migration/Survival*

Transport for sockeye as juveniles results in more fallback and longer migration time as adults, and more straying during upstream migration. Sockeye transported in the Snake River are more likely to fall back than in-river migrating fish (Crozier et al. 2015). Transportation of juveniles appears to impair adult homing ability (i.e., ability to return to their birth streams), which results in migration delay, increased fallback, and straying. This impaired homing ability may contribute to higher incidental harvest rates in the lower Columbia River than middle Columbia sockeye salmon, which are the targets of the fishery. This impaired homing ability can be lethal during warm water years such as 2015. MO1 may decrease transport, as described in the juvenile section, which could increase adult survival and migration success.

The summer water temperatures in the river during the last week of sockeye migration would reduce migration success and survival of those fish; this represents a small portion of the run. The temperature differential between the river and the fish ladders would change under MO1. This alternative is estimated to have 65.5 percent of all days during the upstream migration period with a greater than 2 degree Celsius temperature difference between the river and the fish ladders compared to 50 percent of all days in the No Action Alternative. Experiencing substantially more days with a greater than 2 degree Celsius temperature differential between river water and the fish ladders would cause a greater risk of delay at the dams. Management of fish ladder temperatures has already been implemented at Little Goose and Lower Granite Dams, which were both identified as the top priority locations. Addition of ladder temperature management at Ice Harbor and lower Monumental Dams is part of MO1's *Lower Snake Ladder Pumps* measure.

Important water quality parameters, such as TDG and its effects in the form of GBT would have no appreciable difference in MO1 from the No Action Alternative for either adults or juveniles. Likewise, there would be no change to sediment concentrations or DO levels from any measures in MO1.

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for additional information on adult Snake River sockeye salmon in Section 3.5.3.2.

<u>Snake River Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

The most notable effect of MO1 is the increased risk of delay of adults migrating upstream at the fish ladders in late August due to water temperature differentials in the ladders.

*Larval Development/Juvenile Rearing*

None of the measures of MO1 would change the substrate sizes or distribution in the spawning areas or expand suitable spawning areas; therefore, this alternative is expected to have the same larval development and juvenile rearing habitat conditions as the No Action Alternative. The same is true for river depths in the spawning areas; no change is anticipated for eggs incubating in the gravel. Once juvenile Chinook salmon have emerged and moved to the reservoirs for rearing, lack of summer cooling water may reduce quality of rearing habitat for fish that hold over for their first year; however, the changes for MO1 would not be a measurable difference compared to the No Action Alternative.

*Juvenile Fish Migration/Survival*

In-river survival would be expected to be similar to the No Action Alternative because summer spill levels are the same. If spill levels were curtailed in August under this MO, the number of fish actively migrating through the Snake River are small enough that while there may be impacts to individual fish, there would not be a population level response expected. Transportation typically benefits Snake River juvenile fall Chinook in August, so any decreases in dam passage survival would likely be offset by increased returns from smolts that were transported downstream. Under MO1, there would be a slight reduction in risk of predation in May through July due to slightly reduced mean temperatures compared to the No Action Alternative. The mean temperature is expected to be 16.4°C, with 25.2 percent of days over 20°C, which is a slight improvement from the No Action Alternative. Additionally, bird predation risk would decrease slightly due to changing operations at John Day Dam to reduce availability of bird nesting habitat under the *Predator Disruption Operations* measure. Effects would be more noticeable for species like spring Chinook salmon and steelhead that migrate earlier, but would still be effective for Snake River fall-run Chinook salmon. None of the measures in MO1 would affect turbidity during the juvenile outmigration months of May through July; therefore, their visual cover from predation would not change.

*Adult Fish Migration/Survival*

Transport as juveniles results in more fallback and longer migration time as adults and more straying during upstream migration. Fish transported in the Snake River are more likely to fall back than in river fish (Bond et al. 2017). Under MO1, the portion of juveniles transported downstream would be approximately 38 percent compared to 39 percent in the No Action Alternative; therefore, the rate of fallback and straying by adult upstream migrants would likely remain the same.

MO1 has a higher risk of delay and fallback because of changes to cooling water augmentation from Dworshak Dam under the *Modified Dworshak Summer Draft* measure. Temperatures at McNary Dam would have a slight increase, and temperatures at Ice Harbor Dam would have a pronounced increase with 62.7 percent of all days over 20°C compared to 54.3 percent in the No Action Alternative. Water temperatures delay adult migration during summer/fall when they exceed ~20°C. Increased adult straying is correlated with elevated temperatures. Warm water temperatures can also increase susceptibility to disease. All of these effects reduce survival and spawning success, including gamete viability.

This alternative is estimated to have 65.5 percent of all days in August and September with a greater than 2 degree Celsius temperature difference between the river and the fish ladders compared to 50 percent of all days in the No Action Alternative; this is an additional 9 days during the migration period. The impact would be most noticeable during low-water/high-temperature years when there is less water available for cooling. Management of fish ladder temperatures has already been implemented at Little Goose and Lower Granite Dams, which were both identified as the top priority locations. Addition of ladder temperature management at Ice Harbor and lower Monumental Dams is part of MO1's *Lower Snake Ladder Pumps* measure.

There would be no change to sediment concentrations or DO levels from the No Action Alternative as a result of any measures in MO1 during the adult migration period.

***Lower Columbia River Salmon and Steelhead***

<u>Lower Columbia River Chinook Salmon</u>

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for lower Columbia River Chinook salmon.

*Summary of Key Effects*

Juvenile survival and travel time would be similar to the No Action Alternative, with the possible exception that the fall run of Lower Columbia River Chinook salmon, which could experience slightly slower outmigration due to 4 to 5 percent lower flows in late summer. Adult migration and survival would be similar to the No Action Alternative, with potentially higher fallback during the higher spill block periods for the spring-run fish.

The results (and change from the No Action Alternative) for metrics for lower Columbia River Chinook salmon follow:

- Negligible increase in juvenile project survival at Bonneville Reservoir and Dam (see surrogate Snake River spring-run/summer-run Chinook salmon) = (+0.1 percent)
- Bonneville Dam outflows, April to June = (-1 percent to -2 percent)
- Bonneville Dam outflows, August to September = (-4 percent to -5 percent)

- Spill, Bonneville Dam = April (+3 percent), May (+1 percent), August (-1 percent)
- Temperature, The Dalles Dam, days exceeding state standard = 72 days (+1 day)
- Temperature, Bonneville Dam, days exceeding state standard = 57 days (-1 day)
- TDG, The Dalles Dam, days exceeding state standard = 29 days (+4 days)
- TDG, Bonneville Dam, days exceeding state standard = 64 days (+3 days)

*Juvenile Fish Migration/Survival*

Five of the 32 populations of Lower Columbia River Chinook salmon pass Bonneville Dam on their downstream outmigration to the ocean. Modeling was not available for this ESU, so juvenile survival of Snake River spring-run/summer-run Chinook salmon at Bonneville Dam was used as a surrogate of juvenile survival. COMPASS modeling predicts juvenile survival to be similar in MO1 to the No Action Alternative. Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for additional information relevant to lower Columbia River Chinook salmon.

Outflows can influence juvenile outmigration if changes in flows are enough to affect travel time and therefore survival. Hydrology modeling predicts spring-run and late-fall-run fish would experience outflows about one to two percent lower than the No Action Alternative. Fall-run fish outmigrate in late summer and may see flows up to 4 or 5 percent lower than the No Action Alternative. This slight decrease in late summer flows could affect the ability of these juveniles to outmigrate and use habitats in the estuary, but it would likely be imperceptible. Likewise, water quality modeling indicated there would not be a perceptible change in temperature nor TDG in the lower river with MO1 operations. MO1 includes the *Predator Disruption Operations* measure to reduce predation by reducing birds nesting in the John Day pool; this measure could decrease predation on the proportion of lower Columbia River Chinook salmon that migrate furthest upstream.

*Adult Fish Migration/Survival*

Structural measures such as the *Modify Bonneville Ladder Serpentine Weir* are expected to reduce delay associated with upstream passage. Fallback rates for spring-run may increase slightly with higher spill in April under MO1 as fallback is associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). However, regional managers use in-season adaptive management to identify and remedy any excessive fallback. Hydrology and water quality modeling predicts flows, temperatures, and TDG that could affect Lower Columbia River Chinook salmon adult migration and survival would all be similar to the No Action Alternative. Slightly lower outflows in August could affect migration success for fall-run fish.

<u>Lower Columbia River Steelhead</u>

Refer to Snake River steelhead analysis as a surrogate for lower Columbia River steelhead.

*Summary of Key Effects*

Juvenile survival and travel time would be similar to the No Action Alternative, with similar modeled dam survival, hydrology, and water quality metrics and a potential increase in survival due to predation disruption. Adult migration and survival would be similar to the No Action Alternative, with potentially higher fallback during the higher spill block periods for the spring-run fish.

The results (and change from the No Action Alternative) for metrics for Lower Columbia River steelhead follow:

- Negligible decrease in juvenile project survival, Bonneville Reservoir and Dam (see Snake River steelhead [used as a surrogate]) = (-0.3 percent)
- Bonneville Dam outflows, March to June = (-1 percent to -2 percent)
- Bonneville Dam outflows, August to September (-4 percent to -5 percent), otherwise (-1 percent to +2 percent)
- Spill, Bonneville Dam = April (+3 percent), May (+1 percent), August (-1 percent)
- Temperature, The Dalles Dam, days exceeding state standard = 72 days (+1 day)
- Temperature, Bonneville Dam, days exceeding state standard = 57 days (-1 day)
- TDG, The Dalles Dam, days exceeding state standard = 29 days (+4 days)
- TDG, Bonneville Dam, days exceeding state standard = 64 days (+3 days)

*Juvenile Fish Migration/Survival*

Four of the 23 populations of Lower Columbia River steelhead pass Bonneville Dam on their downstream outmigration to the ocean. Modeling was not available for Lower Columbia River steelhead, so juvenile survival of Snake River steelhead was used as a surrogate of juvenile survival through the Bonneville project (pool and dam) for this portion of the DPS. COMPASS modeling predicts a negligible decrease in juvenile survival as compared to the No Action Alternative. Outflows and temperatures would be similar to the No Action Alternative, within 1 or 2 percent, which would likely not affect juvenile outmigration noticeably. TDG would be slightly higher from the *Block Spill Test (Base + 120/115%)* measure and may influence survival slightly. A decrease in survival of only 0.5 percent was predicted due to higher TDG for Snake River steelhead, which experience a much longer migration through eight projects instead of one for Lower Columbia River steelhead. Any change to Lower Columbia River steelhead with shorter migrations and fewer projects passed would be imperceptible. The *Predator Disruption Operations* measure, as described in the Common Effects section, would reduce predation on outmigration Lower Columbia River steelhead smolts.

*Adult Fish Migration/Survival*

Structural measures, such as the *Modify Bonneville Ladder Serpentine Weir* measure, are expected to reduce delay associated with upstream passage under MO1. April spill at Bonneville Dam under the *Block Spill Test (Base + 120/115%)* measure would be 3 percent higher than the No Action Alternative that could result in slightly higher survival rates for adult steelhead falling back through dams and kelts migrating downstream. Fewer adults used powerhouse passage routes when a spill route was available and overall downstream passage increased when surface passage was available (Normandeau et al. 2014). Kelts that pass via surface passage at Bonneville Dam experience 100 percent survival (Rayamajhi et al. 2012). Most hydrology and water quality metrics predict flows, and temperatures that could affect Lower Columbia River steelhead adult migration, and survival would be similar to the No Action Alternative. Slightly higher TDG exposure could affect adult survival, and lower (4 to 5 percent) outflows in August could affect migration success for summer-run fish.

<u>Lower Columbia River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile Lower Columbia River coho salmon and Snake River fall-run Chinook salmon as a surrogate for adult Lower Columbia River coho salmon.

*Summary of Key Effects*

Overall, no change or negligible changes would occur for lower Columbia River coho salmon under MO1 due to passage and water temperatures, relative to the No Action Alternative.

*Juvenile Fish Migration/Survival*

Using the surrogate approach, CRS operational changes in MO1 would not change survival rates for Lower Columbia River juvenile coho salmon passing Bonneville Reservoir and Dam. Based on dam-specific COMPASS modeling for Snake River spring-run Chinook juveniles—used as a surrogate species for Lower Columbia River coho juveniles—passage success through the Bonneville project could decline by a fraction of a percent (approximately 0.2 percent). Refer to Snake River spring-run Chinook for surrogate information in Section 3.5.2.3.

*Adult Fish Migration/Survival*

Based on analysis of modeling results, water temperatures around Bonneville Dam specifically may be slightly cooler under all of the MOs compared to the No Action Alternative. Under MO1, the river temperatures near Bonneville Dam that exceed 20°C would occur primarily in August during the early weeks of adult migration and would be similar to the No Action Alternative. Refer to Snake River fall-run Chinook for qualitative surrogate information in Section 3.5.2.3.

<u>Columbia River Chum Salmon</u>

Refer to Snake River spring/summer-run Chinook salmon analysis as a surrogate for Columbia River chum salmon.

*Summary of Key Effects*

MO1 would be similar to the No Action Alternative for chum salmon, with about a 2 percent increase, compared to the No Action Alternative, of years where the flows could not be met without additional drafting of Grand Coulee Dam (additional 2 out of 80 years). Juvenile outmigration could be slightly slower due to decreased outflows in March, and a negligible proportion that pass Bonneville Dam would experience decreased survival at that project. Adult migration and survival would likely be similar to the No Action Alternative. These would be negligible effects to chum salmon.

*Larval Development/Juvenile Rearing*

How operations under MO1 affects the ability of Grand Coulee Dam to provide winter flows to protect chum redds below Bonneville Dam and provide sufficient access to habitat was calculated using hydrology modeling. Under MO1, chum flows would be met in 90 percent of years, compared to 92 percent of years in the No Action Alternative. In years when additional releases from Grand Coulee for chum would be needed, the average additional volume needed would be 0.13 Maf. MO1 would result in 2 percent more years where chum flows would not be met, and decision-makers would have to decide whether to increase risk to chum eggs or reduce spring augmentation flows for spring migrating juvenile salmon.

Maintaining water saturation of 105 percent TDG or less from November 1 to April 30 appears to provide a sufficient level of protection to chum salmon eggs and sac fry incubating in the gravel downstream of Bonneville Dam in the Ives/Pierce Island Complex. In MO1 under the *Block Spill Test (Base + 120/115%)* measure, chum sac fry would be exposed to TDG above 105 percent in 7 out of 80 years, and those exceedances are all in the mid-late April timeframe. This is two more years than in the No Action Alternative.

*Juvenile Fish Migration/Survival*

Chum salmon encounter only one CRS project, Bonneville Dam, so none of the structural measures described in common effects for juvenile salmon and steelhead would apply to these fish, and only a small proportion of spawning occurs above Bonneville. As there is no direct estimate of Bonneville Dam survival specific to juvenile chum, juvenile model metrics for Snake River spring-run/summer-run Chinook salmon are used as a surrogate to estimate any change in juvenile survival for the portion that pass Bonneville Dam. Under MO1, COMPASS modeling of the surrogate species indicates that MO1 would be similar to the No Action Alternative.

*Adult Fish Migration/Survival*

The structural measure, *Modify Bonneville Ladder Serpentine Weir*, would improve passage for the portion of chum that pass this project, but most chum spawn downstream of Bonneville Dam. Migration of chum into the Columbia River is in October and November. Bonneville Dam average monthly outflows would be the same as the No Action Alternative in these months and about 2 percent higher in December under MO1.

**Other Anadromous Fish**

***Pacific Eulachon***

*Summary of Key Effects*

Effects of MO1 would be similar to the No Action Alternative for juvenile eulachon migration and survival.

Compared to the No Action Alternative, MO1 would have no change in the time between the peak spawning runs, egg development, and larval emergence. The spring freshet that disperses larvae to adequate food sources would continue to be highly variable, with an average of 168 days between spawning temperature triggers and peak flows (158 days in high-flow years, and 156 days in low-flow years).

Spring flow rates would be expected to be about 1 to 2 percent lower during outmigration compared to the No Action Alternative, so any changes affecting eulachon feeding would be negligible.

Eulachon would continue to migrate into the Columbia River from November through March, with specific dates of migration and spawning based on a variety of environmental factors, including temperature, high tides, and ocean conditions (NMFS 2017). Modeled data for MO1 (based on the period of record for Bonneville Dam tailwater temperatures) indicate that temperatures would not be substantially different from the No Action Alternative (all temperatures would be within 0.6 degree Celsius of the No Action Alternative). Spawning locations and substrate conditions would not be expected to differ from the No Action Alternative. Although migration as far upstream as Bonneville Dam is unusual, structural measures at the fish ladders could make passage easier for eulachon.

Bird predation risk can be influenced by flow rates. Higher flows are linked to higher predation rates on eulachon, whereas at lower flows, birds tend to switch to marine prey. Under MO1, there would be negligible change (0 to 3 percent) in survival rates due to predation across all months and water year types.

#### ***Green Sturgeon***

*Summary of Key Effects*

The Columbia River use by green sturgeon is primarily foraging habitat for adults and subadults. Key effects of MO1 are focused on how flows and temperatures influence the cues for entering the Columbia River as well as the availability and distribution of food sources. Overall, the lower Columbia River would continue to provide good foraging and rearing habitat for green sturgeon, with negligible decreases in summer foraging habitat from flows that would be 4 to 5 percent lower than the No Action Alternative in August.

#### ***Pacific Lamprey***

Summary of Key Effects

MO1 has several measures that are designed specifically to benefit lamprey: *Lamprey Passage Structures*, *Turbine Strainer Lamprey Exclusion*, *Bypass Screen Modifications for Lamprey*, and *Lamprey Passage Ladder Modifications*. These measures are proposed structural improvements that include converting extended-length submersible bar screens to submersible bar screens, expanding the network of lamprey passage structures to bypass impediments in fish ladders, changing the design for turbine cooling water strainers, and replacing turbines for safer fish passage, among other physical modifications to reduce fish injury and mortality.

As described for the No Action Alternative, upstream and downstream passage at the mainstem Columbia River and Snake River Dams has been the greatest influence on population decline and reduced distribution of Pacific lamprey. The most substantial benefit of MO1 would be the improvements to get fish to enter the fish ladders; this would occur through expanding the network of lamprey passage structures and modifying fish ladders to incorporate lamprey passage criteria into the structural modifications.

Larval Development/Juvenile Rearing

MO1 includes manipulation of the John Day Reservoir for predator disruption under the *Predator Disruption Operations* measure. Water levels would be increased during nesting season and then dropped back down to the normal operating pool. Depending on dewatering rates, larval lamprey could become stranded if they are rearing in the shallows when the pool level would be dropped. Otherwise, ramping rates and dewatering issues would be the same in this alternative as for the No Action Alternative.

Juvenile Fish Migration/Survival

Water temperatures and physical structures affect juvenile lamprey during their outmigration. The *Modified Dworshak Summer Draft* measure would cause changes in temperature downstream in the lower Snake River compared to the No Action Alternative. At Lower Granite Dam, temperatures would be cooler June to August 1, warmer early August to mid-September, and cooler in mid-September to October. Temperatures could increase up to 4 degrees

Fahrenheit with rapid fluctuation to about 3 degrees Fahrenheit cooler in about a week. Lower Granite Dam results in several days warmer than 20°C compared to none in the No Action Alternative which would be a minor adverse effect. The effect continues downstream and would be attenuated with distance from Dworshak Dam. The lower Columbia River temperatures would be similar to the No Action Alternative. Compared to the No Action Alternative, the number of days exceeding the state temperature standards in the lower Snake River would be as follows:

- Lower Granite Dam: 22.6 days (18.2 more than the No Action Alternative)
- Little Goose Dam: 45.6 (8.6 more than the No Action Alternative)
- Lower Monumental Dam: 54.4 (7.2 more than the No Action Alternative)

Several measures would improve conditions for outmigrating juveniles. Proposed actions include the following:

- *Bypass Screen Modifications for Lamprey* measure: Converting the extended-length submersible bar screens to submerged traveling screens would substantially reduce mortality due to lamprey being trapped against intake screens (i.e., impingement). Because turbine routes are generally associated with lower survival of migrating juvenile salmon and steelhead, they are equipped screens that help bypass these fish to higher survival routes. Some of these screens are made of closely spaced bars rather than a mesh material. These screens are effective at diverting juvenile salmon and steelhead, but juvenile lamprey are often so small they become impinged between these bars. The modification or replacement of these screens with woven mesh or more tightly spaced bar material would reduce lamprey mortality by an unknown amount.
- *Turbine Strainer Lamprey Exclusion* measure: A new design of structure for exclusion of juvenile lamprey from cooling water strainer intakes would substantially reduce or eliminate this pathway of mortality. Turbine cooling water intakes within the turbine scroll case are equipped with a strainer that prevents debris from entering the cooling water system. However, these strainers do not prevent the entrainment of juvenile lamprey and some juvenile salmon and steelhead. An unknown number of these fish are entrained and die in the cooling system each year. The retrofitting of these intakes with hoods that allow water flow but prevent debris and juvenile fish entry would reduce lamprey losses in the cooling water intake system.
- *Additional Powerhouse Surface Passage* measure: Additional powerhouse surface passage at Ice Harbor and McNary Projects (described in the Common Effects to Salmon and Steelhead section) could change the dynamics of lamprey passage. Lamprey migrate fairly deep in the water column and most pass the dams via the powerhouse, however a slightly higher percentage of lamprey would be expected to pass via the surface routes instead of the turbines in relation to the No Action Alternative, although the relative effect on lamprey is not known.
- *Improved Fish Passage Turbines* measure: Replacing turbines at the John Day Project (also defined in the Common Effects to Salmon and Steelhead section) with a newer design of turbine would improve conditions for fish passage and reduce the injury rate for lamprey.

Because of the high degree of uncertainty surrounding how many juvenile lamprey are lost or injured on their downstream migration, and the relative effects to juvenile lamprey due to passage via surface routes or turbine routes, it is difficult to quantify the improvement represented by all of the measures. For fish that encounter multiple dams on their migration downstream, reducing the total number of hazards would increase their probability for survival to the adult life stage.

<u>Adult Migration/Survival</u>

Structural measures in MO1 that were intended to provide improvements to adult lamprey passage and survival include:

- *Lamprey Passage Structures* and *Lamprey Passage Ladder Modifications* measures at Bonneville, The Dalles, and John Day Projects: Fish ladders at most of the projects were designed primarily for salmon and steelhead passage. More recent work has shown some parts of the structures create migration delays and even barriers for lamprey.
- *Modify Bonneville Ladder Serpentine Weir* measure: At Bonneville Dam's Bradford Island and Washington Shore ladder flow control sections, the baffles that help slow velocities and control flows do not allow for direct line movement of fish passing the dam, but requires fish to weave through the baffles. This construction reduces fish passage efficiency and increases migration delays. The modification of these baffles would include replacing baffles allow for direct faster movement through the ladder baffles from this section of the ladders and replace them with baffles that have in-line vertical slots and orifices. This measure has the potential to increase adult salmon and steelhead survival by reducing upstream travel times and higher conversion rates. A similar modification at John Day Dam, the only other CRS dam to use this type of ladder, resulted in major passage time reductions for salmon and steelhead. Similar improvements are expected for Bonneville Dam. In addition, these improvements would reduce migration delays and barriers for Pacific lamprey.

Each structural measure in MO1 that targets lamprey is intended to increase their dam passage efficiency either by getting fish to enter rather than turn back from the fishway, or to increase successful passage to the upstream end to continue migrating. Effectiveness of the measure would vary by dam. At Bonneville Dam, the measures that aid in getting adult fish into the fishways would be a substantial improvement over the existing conditions of only 44 to 50 percent of lamprey entering the fishways. If the structural measures were successful at Bonneville Dam, the action agencies expect an improvement to approximately 70 percent of lamprey entering the fishways. Additionally, the *Modify Bonneville Ladder Serpentine Weir* measure would substantially improve upstream passage efficiency for lamprey at Bonneville Dam. Lamprey passage structures would likely represent more overall benefit than ladder improvements because the lampreys do not make it into the structures at Bradford Island fishway. Improvements at John Day Dam ladders to improve lamprey entrance into the fishway resulted in increased efficiency of 46 percent to 83 percent. Dynamics at each dam are very different, so the action agencies cannot infer directly across projects, but lamprey do see improvements in overall dam passage efficiency with improvements in ladder entrance efficiency.

The Dalles Dam has relatively good lamprey passage, so the increment of improvement would be helpful, but not as great as what is expected at Bonneville Dam. At John Day Dam, lamprey passage is about 60 to 70 percent; additional work for the lamprey passage structures on the south and extension on the north would continue to moderately improve overall dam passage efficiency incrementally. Other measures to improve fish passage include the following:

- The *Lower Granite Trap Modifications* measure would improve lamprey passage issues at the adult trap by allowing lamprey to pass when scientists are not trapping fish. This measure is described in detail in the Common Effects to Salmon and Steelhead section.
- The *Lower Snake Ladder Pumps* measure at Lower Monumental and Ice Harbor Dams would be expected to benefit lamprey because this has been successful at Little Goose and Ice Harbor Dams. This measure is described in detail in the Common Effects to Salmon and Steelhead section.
- The *Lamprey Passage Ladder Modifications* measure would involve modifications to The Lower Monumental Project that include diffuser grate plating. This action has been completed at all other ladders except Lower Monumental Dam and has demonstrated slight benefits to lamprey passage.

The overall expected improvements in lamprey passage efficiency should decrease susceptibility to physical stress and mortality, and shorter holding time is beneficial to the fish. These structural measures for lamprey are expected to provide a substantial benefit to the distribution of Pacific lamprey in the Columbia Basin. All of the structural measures to reduce losses would have benefits to the population and recruitment in the next generation. Pacific Lamprey do not exhibit strong homing tendencies to their river of natal origin, hence, improved survival rates from adult return to juvenile outmigration would benefit the north Pacific population rather than only the Columbia Basin.

#### ***American Shad***

<u>Summary of Key Effects</u>

No change is anticipated to juvenile shad because plankton communities and shoreline habitat are not changing in MO1. The proportion of adult shad counted at Bonneville Dam that migrate upstream past McNary Dam is expected remain similar under this alternative.

## RESIDENT FISH

### Region A

#### ***Kootenai River Basin***

<u>Summary of Key Effects</u>

MO1 would have the same key effects as the No Action Alternative. Spring water temperatures would continue to be too cold for the development of many of these aquatic species. Spring flows would also continue to increase at an unnaturally low rate, thereby delaying and reducing productivity associated with inundated riparian and varial zone habitats in the river corridor from the dam to Kootenay Lake in British Columbia. These reduced flow rates would also continue to limit productivity and may adversely impact kokanee and their food sources downstream of Libby Dam.

Under MO1, fluctuations in discharge from Libby Dam in the winter from the *December Libby Target Elevation* measure would continue to adversely affect benthic organisms. Cottonwood seedlings would continue to have variable survival depending on timing, stage and duration of spring flows, along with winter stage during the ensuing winter. In addition, the discharge regime from Libby Dam would not provide for successful burbot recruitment, and spring water temperatures would be too cold to allow for proper larval development.

<u>Habitat Effects Common to All Fish</u>

MO1's *Modified Draft at Libby* measure would also have a lower rate of flow increase from Libby Dam between mid-April and mid-May than the No Action Alternative. This decrease in flow rate combined with more cold water on wet years could result in later warming that would translate to a greater delay in growth and development of resident fish and their food resources.

MO1's *Modified Draft at Libby*, *December Libby Target Elevation,* and *Sliding Scale at Libby and Hungry Horse* measures would increase slightly the potential and area for cottonwood and willow seeding and recruitment compared to the No Action Alternative. Under MO1 there would be a slight increase in the number of days when winter peak stages would not exceed the water levels needed for cottonwood and willow seeding at Bonners Ferry.

<u>Bull Trout</u>

Under MO1, Lake Koocanusa would be above elevation 2,450 feet for seven more days on average (15 percent) than the No Action Alternative during the summer when productivity is critical. The expected result would be slightly higher productivity and improved food availability than under the No Action Alternative.

The average minimum annual pool elevation of Lake Koocanusa under MO1 would be approximately 2 feet lower in dry and average years than under the No Action Alternative. The expected result would be more frequent annual dewatering and decreased benthic insect production, which may result in a decrease in bull trout growth and/or survival. The annual maximum elevation of Lake Koocanusa under MO1 would be higher as shown by the 1.6-foot higher median July 31 elevation than under the No Action Alternative and may result in slightly higher terrestrial insect deposition under this alternative.

Water temperature in Lake Koocanusa under MO1 would not be substantially different from that under the No Action Alternative. However, under MO1, the higher winter pool elevations in wet years associated with flood risk management and power generation could result in a colder thermal mass that warms slowly. In dry years, lower pool elevations would result in quick springtime warming of the forebay, and thus warmer discharge temperatures during the spring and summer when compared to the No Action Alternative.

Under MO1, Libby Dam would provide discharge of 20 kcfs or greater for 12 days, on average, during the spring freshet, which is one day less than mean for the No Action Alternative. The mean flow rate from May 15 to June 15 under MO1 would be slightly less than under the No Action Alternative and would be insufficient to mobilize or reshape tributary deltas that can prevent bull trout access during low flows in the fall spawning season.

While MO1 would have somewhat lower discharges from Libby Dam than the No Action Alternative, these reduced flows would provide slightly more usable habitat.

Kootenai River White Sturgeon

Effects of MO1 would not be different from those of the No Action Alternative for Kootenai River White Sturgeon.

Other Fish

The minimum annual pool elevation of Lake Koocanusa under MO1 would be approximately 2 feet lower in dry and average years than under the No Action Alternative. This would result in reductions in insect larvae production and food available for resident fish species, which may decrease growth and survival of these species. However, in wet years, MO1 would provide a shallower draft and may be more beneficial to benthic insect production during those years. The annual maximum elevation of Lake Koocanusa under MO1 would be higher than under the No Action Alternative as shown by the 1.6-foot higher median July 31 elevation and may result in slightly higher terrestrial insect deposition. Under MO1, higher pool elevation in the early winter followed by aggressive drafting (higher outflows) associated with flood risk management and power generation could result in a warmer winter flows and colder early spring flows than the No Action Alternative. The 75th percentile elevation is slightly higher than the No Action Alternative and this larger cold thermal mass warms slightly slower. On dry years, a lower pool elevation would result in quicker springtime warming of the forebay, and thus warmer discharge temperature during spring and early summer.

MO1 would have slightly lower discharges from Libby Dam for the period May 15 to September 30 than the No Action Alternative and would provide slightly more usable habitat for juvenile and adult rainbow trout than the No Action Alternative. High and variable flows can interrupt burbot spawning migrations, while low (4 kcfs) and stable winter flows encourage successful burbot spawning. Median flows under MO1 as measured at Bonners Ferry would be higher than No Action Alternative flows in January through April and would be less likely to provide conditions conducive to successful burbot recruitment.

### ***Hungry Horse/Flathead/Clark Fork Fish Communities***

<u>Summary of Key Effects</u>

The key effects of MO1 are largely biological responses to changes in Hungry Horse Reservoir elevations and outflows to provide additional water supply under the *Hungry Horse Additional Water Supply* and *Sliding Scale at Libby and Hungry Horse* measures. Lower elevations through the summer decrease food supply for fish with slight reductions in plankton production and surface area for summer terrestrial insects. Benthic insect production important to fish would be appreciably decreased under MO1. Lower surface elevations could also increase issues with predation/exploitation risk as fish migrate into and out of tributaries to fulfill their life cycles, and increased outflows in summer would likely result in increased entrainment of zooplankton and fish out of Hungry Horse reservoir. Increased flows in the South Fork Flathead River would be attenuated with flows from the mainstem Flathead River but would still result in higher summer flows that would increase velocities. These velocity increases could decrease native fish habitat suitability in that reach. MO1 would have negligible effects on Flathead Lake, lower Flathead River, or Clark Fork fish.

<u>Habitat Effects Common to All Fish</u>

In wet and average water years the reservoir would still reach near full pool (elevation 3,560 feet) by early July in most average years and mid-July in wet years. However, in these year types the median elevation at the end of September would be 3,546 feet, or about four to five feet lower than the No Action Alternative. In dry years the reservoir would still approach full pool, miss filling and typically become drawn down faster in the same pattern as the No Action Alternative, but the dry year elevation would be a median of a foot lower than the No Action Alternative dry year. All year types considered, there would be a 69 percent annual probability of reaching elevation 3,559 feet by July 31, or six years more out of 100 that would not reach full compared to the No Action Alternative. In extreme years, MO1 could be up to 11 feet lower than No Action Alternative by the end of September. In fall and winter months, MO1 would be lower than No Action Alternative. The fall and winter elevations would follow the same pattern as modeled, but the difference between No Action Alternative and MO1 would only be up to six or seven feet lower than No Action Alternative. The rate of drop would at times be steeper than No Action Alternative through these months.

Lake elevation in the warm summer months determines the volume of reservoir that would be available to produce plankton (euphotic zone). With lower summer elevations, the euphotic zone decreases slightly under MO1. In June, MO1 and No Action Alternative are similar, but by July they begin to diverge with MO1 zone becoming less than the No Action Alternative. By September under MO1, the euphotic zone is about 32,000 acre-feet smaller than the No Action Alternative in wet and average years, and about 11,500 acre-feet smaller in dry years. The decrease ranges from one to three percent of the total volume. See Appendix E for a table of the calculated euphotic zone predictions under MO1.

Drawdowns any time during the year affect the production of insects that live on the bottom of the reservoir. As reservoir elevations drop, insects that have established in this zone can become dewatered. The insect eggs would have been deposited within the euphotic zone described above. If reservoir levels drop, that zone remains the same thickness and drops with the surface level, but there would be no insects deposited at the lower elevation that is now the euphotic zone. As the elevation drops, the surface for benthic insect production gets smaller. MO1 drops faster than the No Action Alternative in the summer and would be at lower elevation through the following fall and winter. This would result in less area for benthic insect production than the No Action Alternative. Some of the larger aquatic insects have long life cycles that require overwintering where they were deposited; lower winter elevations would reduce the survival of these important insects. Table 3-62 shows size of the lake (surface area in acres) at the end of each month. Using surface area as an index for benthic area, MO1 surface area would decrease by 200 to 800 acres compared to the No Action Alternative, or about 2 to 4 percent from October through February in all year types, and in dry and average years March through May would have similar decreases. Additionally, in dry years the summer months would have surface area 4 percent to 5 percent lower than the No Action Alternative, or a difference of about 530 to 820 acres. The large bays at the upper end of the reservoir could experience a proportionally higher rate of dewatering with dropping levels over the summer due to more shallow slopes. An equal drop in elevation would result in a larger dewatered benthic surface area, therefor actual lost benthic production would be more than surface area indicates, and considerable mortality of established benthic macroinvertebrates would be expected.

Finally, the reservoir elevation determines the surface area available for terrestrial insects to land on the water and be available for fish food in summer, as well as influencing the proximity of the water’s edge to terrestrial vegetation. Therefore, the availability of some important insects to fish through the winter months the reservoir surface would be about 300 to 800 acres smaller, or 2 to 4 percent smaller compared to the No Action Alternative. In summer months as the elevation decreases faster under MO1 the surface area would be about 100 to 400 acres smaller, or 1 to 2 percent smaller than under the No Action Alternative by the end of summer.

Zooplankton would continue to be entrained into the South Fork Flathead River from Hungry Horse reservoir. The zooplankton enhances food supply in the South Fork Flathead River and along the near bank of the Flathead River but decreases food supply for fish in Hungry Horse Reservoir. Outflows, and therefore zooplankton entrainment, under MO1 would be higher in summer and lower in fall, winter, and spring. These zooplankton are concentrated in the withdrawal zone in summer so the entrainment effect from increased summer outflows would be disproportionate; the 9 percent to 21 percent higher flows would likely represent a higher increase in zooplankton entrainment.

Outflow patterns from Hungry Horse Reservoir can also affect how fish are entrained into the South Fork Flathead River, and the habitat conditions, such as river elevation (stage), velocities, and temperatures in the river. These flow changes continue downstream to affect the main

Flathead River in the same patterns, but somewhat attenuated by the flows in the mainstem Flathead. Temperatures in summer are regulated with a selective withdrawal structure that is operated to release water of a temperature that favors native fish. Under MO1 operations, outflows would be from nine to 21 percent higher than the No Action Alternative in July to September, similar in October, and then generally lower than the No Action Alternative through the fall, winter, and spring months. The winter flows would be one percent to 12 percent lower than the No Action Alternative and April to June flows would be four to 17 percent lower.

The temperature control structure would still operate in the summer months as in the No Action Alternative so changes in outflows in this timeframe would not affect summer temperatures downstream.

In the Flathead River down to Flathead Lake, habitat suitability under the No Action Alternative is a key issue due to unnaturally high flows in the summer and winter. Under MO1, July to September flows would be 2 to 10 percent higher than the No Action Alternative summer flows, and winter flows in MO1 would be slightly lower than the No Action Alternative. Spring peaks would also be slightly lower than the No Action Alternative. Winter flows lower than the No Action Alternative would improve winter habitat suitability slightly, and spring peaks only slightly lower than the No Action Alternative would continue to occasionally provide flushing of sediments from gravels to maintain habitat.

The winter water temperature warming influence from the contribution of the South Fork Flathead would be slightly less due to slightly lower winter flows out of Hungry Horse. TDG in the Flathead River would be similar to the No Action Alternative, continuing to fluctuate with spill at Hungry Horse dam but generally-speaking, would not exceed 117 percent, which is within a safe zone for fish.

The influence of MO1 changes to Flathead Lake levels and Seli'š Ksanka Qlispe' Dam operations would be minimal compared to the No Action Alternative, and habitat conditions in these areas would be similar as described in the No Action Alternative.

Bull Trout

MO1 conditions would slightly reduce the summer production of zooplankton that provides forage for bull trout and surface area available for summer terrestrial insect feeding. The lower reservoir elevations and steeper drawdowns would result in substantially lower surface area for benthic insect production throughout the year, especially in the bays at the upper ends of the reservoir lobes. Juvenile bull trout moving into the reservoir in the spring rely on the benthic insects until they transition to eating fish. The prey items that adult bull trout eat also consume the benthic insects and may be in poorer condition or less plentiful in areas. This could result in bull trout being in poorer condition.

Lower reservoir elevations in the fall would increase the risk and exposure to predation and angling pressure for upstream migrating bull trout. The sedimentation of tributary deltas currently is not known, but there could potentially be blockages of passage arise with lower elevations as well. These effects would likely be moderate in wet, average, and most dry years with 3 to 4 feet of difference from the No Action Alternative. In extremely dry years there could be much lower elevations (up to 12 feet lower than the No Action Alternative) and more extreme effects in years when the elevations would already be causing access and varial zone issues under the No Action Alternative.

Bull trout entrainment through the dam would likely increase in MO1 due to increased outflows in late summer. Withdrawals in August and September are generally selected from deep in the water column to release the target temperature, and bull trout have been documented in this stratum at this time of year. Entrainment under the No Action Alternative is likely minimal and has not been quantified but would be expected to increase nine to 21 percent under MO1 as modeled.

The number of individual bull trout in the South Fork Flathead River below Hungry Horse Reservoir may increase with greater entrainment, but these would be lost from their spawning populations because they only spawn above Hungry Horse dam but would be unable to ascend back up past the dam once they were flushed downstream of it. Zooplankton available in the South Fork Flathead River may increase in summer with higher outflows. As in the reservoir, food web relationships are important. MO1 would continue to allow for this transitory use by bull trout and other native fish with adequate food. Higher flows may also increase benthic production of food for bull trout prey fish, but increased velocities would result in lower availability of suitable habitat for bull trout.

Summer flows in the mainstem would be higher than the No Action Alternative, further exacerbating issues with habitat suitability. Muhlfield et al. (2011) found even moderate increases in summer flows resulted in substantial decreases in suitable area for bull trout, and that nighttime habitat for subadult bull trout was most sensitive. The 2 to 10 percent increase due to MO1 would reduce bull trout habitat, especially for subadults. The mainstem Flathead River would be similar to the No Action Alternative in winter, with barely perceptible changes (slightly lower) from the No Action Alternative.

Operations of Seli'š Ksanka Qlispe' Dam (Flathead Lake) would be similar to the No Action Alternative, and the bull trout habitat use and life history functions in Flathead Lake, the Lower Flathead River, and Clark Fork River would be similar to the No Action Alternative.

<u>Other Fish</u>

Hungry Horse Reservoir favors a native fish dominated fish community. Juvenile bull trout and adult whitefish, northern pikeminnow, sculpins, and westslope cutthroat trout feed on zooplankton, aquatic insects, and terrestrial insects, and adult bull trout prey on mountain whitefish, suckers, minnows, etc. The food web effects described above would also apply to all of these species of fish in Hungry Horse Reservoir. Slight decreases in zooplankton and reduced summertime feeding of terrestrial insects could reduce food supply slightly in summer. Substantial decreases in aquatic macroinvertebrate due to dewatering events and reduced surface area for production would decrease the food supply for many of these fish.

Westslope cutthroat trout and other native fish spawn in the spring (April through June), so effects on adults migrating into tributaries to spawn would differ from bull trout. Spring spawning fish migrate when reservoir levels are lower and tend to experience longer varial zones with increased exposure to predation. Under MO1 operations, the modeled April and May elevations were five feet and three feet, respectively, lower than the No Action Alternative. By June, the elevation would be similar to the No Action Alternative. Given the modeling error, however, the April and May elevations would likely be 1 to 4 feet lower than the No Action Alternative. Spring spawning fish such as westslope cutthroat trout would experience greater varial zone effects on their way upstream as adults, and could encounter some tributary blockages, but the delta formation of these tributaries is not known. Juveniles typically outmigrate in June when the effects would be similar to the No Action Alternative.

Entrainment from the reservoir would also continue at unquantified levels and could increase in the summer months with increased outflows. Northern pikeminnow and bull trout have been documented at the depths of late summer withdrawal and would be most susceptible to increased entrainment. Westslope cutthroat trout and other fish may experience some increase but would not be expected to be as susceptible to entrainment as bull trout because they are not commonly found at the depths of outlets. Entrainment would be expected to increase nine to 21 percent in the summer months and decrease slightly in winter.

Habitat suitability described for bull trout would be similar for other native fish in the mainstem Flathead River (Muhlfield et al. 2011), with higher summer flows in MO1 resulting in decreased amount of suitable habitat for them in summer.

Effects to fish in Flathead Lake, the lower Flathead River, and Clark Fork Rivers would be similar as described in the No Action Alternative.

#### ***Lake Pend Oreille (Albeni Falls Reservoir)/Pend Oreille River***

Summary of Key Effects

Hydrology modeling showed that Lake Pend Oreille elevations, inflows, and outflows would be the same as the No Action Alternative. Biological relationships were dependent on these parameters, so the key effects of MO1 for bull trout, fish habitat, and other fish species in the Pend Oreille basin would be the same as those described under the No Action Alternative.

### **Region B**

#### ***Lake Roosevelt/Columbia River from U.S.-Canada Border to Chief Joseph Dam***

Summary of Key Effects

The Columbia River from the U.S.-Canada border would continue to support a white sturgeon population that spawns successfully but primarily relies on fish manager intervention to survive a recruitment bottleneck; conditions for natural recruitment may be further diminished in a small proportion of years. Retention time is a key metric for most fish species in Lake Roosevelt, influencing food that supports the fish as well as influencing how many are entrained.

Retention time would be lower in winter and early spring, especially in the wet years than the No Action Alternative, decreasing productivity and increasing entrainment. Lake elevations under MO1 would increase risk of impeded redband rainbow trout tributary habitat access and eggs drying out. The portion of kokanee that spawn in tributaries would continue to have access in fall similar to the No Action Alternative. Reservoir operations would continue to result in some level of burbot eggs drying out and the portion of kokanee that spawn on lake shorelines and would increase in MO1 compared to the No Action Alternative. MO1 would continue to support both wild and hatchery-raised kokanee, redband rainbow trout and hatchery rainbow trout as well as non-native warmwater game species such as walleye, smallmouth bass, and northern pike. Northern pike would likely continue to increase and invade downstream, and the lake elevations could decrease the ability for boat-based Northern pike suppression efforts. Rufus Woods Lake would continue to provide habitat for fish entrained from Lake Roosevelt and from limited production of shoreline spawning by some species; entrainment could increase in winter and decrease in summer months. TDG would be similar or less than No Action Alternative. The operational measures that could impact fish include the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee, Winter System FRM Space, Lake Roosevelt Additional Water Supply* and *Chief Joseph Dam Project Additional Water Supply*.

<u>Habitat Effects Common to All Fish</u>

Median peak outflows under MO1 would follow the same pattern as the No Action Alternative with peaks in early June and another, smaller peak in July. The MO1 flows in early spring through September are about 2 percent to 5 percent lower than the No Action Alternative. December flows are about 4 percent to 6 percent higher than the No Action Alternative. These peak outflows can influence the rate of entrainment from Lake Roosevelt into Rufus Woods Lake. TDG in the Grand Coulee tailwater is also a concern for fish in Rufus Woods Lake. Under the MO1 TDG would be lower than No Action Alternative.

The duration that water stays in the reservoir (i.e., retention time) is a driving metric for the food web in Lake Roosevelt and influences the populations of several fish species.

Under MO1, median retention time would be similar to the No Action Alternative in late spring, summer, and fall. In average years, retention time under MO1 would be 6 percent lower in December and January, and in dry years would be about 7 percent to 8 percent lower in December through February but slightly higher in May. In wet years is when retention time is lowest because more water is moving through the system, and MO1 would reduce retention times even further in these years by up to 10 percent in February and by 3 to 10 percent in the entire period of December through May.

Kokanee, redband rainbow trout, juvenile burbot, larval sturgeon, and many prey species rely directly on the food source provided by the zooplankton production and higher-level predators such as bull trout prey on these fish. With lower water retention times under MO1 in winter and spring, when retention times are already fairly low, there would be less food available to fish, and they would also tend to follow the food source and crowd down towards the dam, becoming more susceptible to entrainment.

Bull Trout

Under MO1, bull trout in Lake Roosevelt could continue to move to cooler locations in the reservoir and these refuges would remain similar to the No Action Alternative. High flow years would continue to influence bull trout distribution through flushing more of them from the river near the U.S.-Canada border down into Lake Roosevelt. Increased outflows in December could potentially increase entrainment of bull trout, but this would be negligible because of the scarcity of bull trout in Lake Roosevelt.

Bull trout are also sensitive to contaminants that are found in this region and would continue to bioaccumulate contaminants as a top predator, but fluctuation events that mobilize mercury would be the same as the No Action Alternative.

Other Fish

White sturgeon recruitment would be dependent on flows exceeding 200 kcfs and appropriate temperatures in late June/early July. Under MO1, flow over 200 kcfs in June and July would have a slight decrease. These slightly reduced flows at the U.S.-Canada border would result in potentially minor decrease in white sturgeon recruitment window. MO1 reservoir levels would be similar, but slightly lower than the No Action Alternative in June and July. Other factors that would continue to influence sturgeon include predation by fish that are favored by reservoir conditions if larvae are flushed into the Lake Roosevelt. Slightly lower flows in spring could slightly reduce the risk of larvae entering Lake Roosevelt. The uptake of contaminants such as copper closer to the U.S.-Canada border being flushed downstream into the reservoir by high flows would also be slightly lower. Under MO1, recruitment of white sturgeon would continue to be a rare event supplemented by hatchery propagation, as larval sturgeon are captured and raised in hatcheries until they are past the window where recruitment has been shown to fail at a high rate. Once these juveniles are released back into the reservoir they continue to grow and survive well. The reservoir would continue to provide good conditions for growth and survival of these fish.

Wild production of native fish such as burbot, kokanee and redband rainbow trout would continue to provide valuable resources in Lake Roosevelt. As described in the common habitat effects, these fish are the most sensitive to the effects of changing retention times. Under the No Action Alternative an estimated average of over 400,000 fish annually would be entrained, with 30 to 50 percent of them being kokanee, primarily of wild origin. Rainbow trout would be the second most entrained species. Under MO1 operations, increased entrainment would be expected in winter months as the outflows increase over the No Action Alternative and retention times are 7 percent to 10 percent lower. Previous entrainment studies (LeCaire 2000) indicated winter being a period relatively low entrainment; however, the prolonged drawdown period is expected to increase entrainment during this time. In wet years, entrainment would also be higher in March-May (3 percent to 8 percent lower retention time) which could increase entrainment to a moderate effect. Increased entrainment of zooplankton would decrease food availability that is key to winter survival and growth of several fish species including kokanee, juvenile burbot, and other juvenile fish.

For tributary spawning species such as redband rainbow trout and a portion of the wild production of kokanee, tributary access at the right time of year is important. Reservoir drawdown in the spring creates barren tributary reaches through the varial zone, which directly and indirectly impedes migration to and from tributaries and the reservoir. Redband rainbow trout need access tributaries in the spring. Under MO1, reservoir elevations would be lower than the No Action Alternative levels in the critical spawning migration time of April to May in wet and dry years (equaling about 40 percent of years). This would be most critical in wet years (20 percent of years) when the median elevation would be 1,241 feet on April 1, which would be seven feet lower than the No Action Alternative. Migratory impacts, although not well documented, could be severe given the timing and extent of the drawdowns in MO1. Redband rainbow trout spawn in Sanpoil, Blue Creek, Alder, Hall Creek, Nez Perce Creek, Onion Creek, Big Sheep Creek, and Deep Creek. These tributaries higher in the basin are more susceptible to elevation changes because a smaller change in lake elevation would result in a larger area of exposure than tributaries closer to the dam. Additionally, increased exposure during migrations to these tributaries would increase the varial zone effect where migrating fish are more exposed to predation and angling due to lack of cover.

Species such as kokanee and burbot that spawn on shorelines in Lake Roosevelt are susceptible to eggs drying out if reservoir levels drop while eggs are still in the gravel. Kokanee spawn on shoreline gravels September 15 to October 15 and eggs incubate through February. Burbot tend to spawn successfully in depths provided by the No Action Alternative in the Columbia River and in Lake Roosevelt on shorelines near the Colville River in winter with eggs incubating through the end of March (Bonar et al. 2000). MO1, compared to the No Action Alternative, begins dropping 2 months sooner and would likely strand or dewater burbot and kokanee eggs. A higher proportion of eggs at all elevations would be affected.

The portion of kokanee that spawn near the fall water surface elevation are more at greater risk. Fry sometimes also stay in the gravels and could become stranded as well. Burbot spawn later in the winter so would be less affected because the lake level would have already dropped seven feet lower than the No Action Alternative when eggs would be deposited. However, this same mechanism would also decrease habitat available compared to the No Action Alternative. The wet years would have steeper and deeper reservoir draft than the No Action Alternative and would result in increased stranding of burbot eggs. Lake elevations influence river stage clear up to the U.S.-Canada border, so burbot that spawn in the rivers would experience the same patterns of dewatering, but at lower magnitudes as the lake effect lessens with distance.

Kokanee are very sensitive to water temperature, and during summer are found at depths below 120 m to find suitably cool water. Under the No Action Alternative, Lake Roosevelt is very weakly stratified but does have suitably cool water at this depth along with suitable levels of DO. Lake whitefish and mountain whitefish also likely use this cool water in the summer.

Non-native warmwater gamefish, such as walleye, northern pike, smallmouth bass, sunfish, crappie, and others, as well as the prey fish that they eat (such as shiners, dace, and sculpins) all tolerate a wide range of environmental conditions and would continue to contribute to the fishery community under MO1, and continue to adversely impact native species via predation. The invasion downstream by northern pike is of concern, and the Lake Roosevelt Co-Managers are actively suppressing pike populations using gillnets set by boats as soon as they can get on the water in the spring until the boat ramp becomes unusable at an elevation of 1,235 feet. Under the No Action Alternative this occurs on April 15 in wet years. Boat ramp access would remain useable in dry and average years. Under MO1 in wet years, this would occur about six days 6 days sooner and preclude the ability for the pike suppression efforts for that period. For estimation purposes, one crew typically removes about 100 pike per week and they would operate three crews (Colville Tribe unpublished data), so opportunity loss of up to about six days under MO1 could result in an estimated 300 pike not removed. It should be noted that this is applicable to only one specific boat ramp, but the middle of Lake Roosevelt area becomes inaccessible earlier, at lake elevation 1,245’. Additionally, outflows and retention time would continue to influence the entrainment and downstream invasion of non-native gamefish below Chief Joseph Dam where ESA-listed anadromous salmonids would be susceptible to predation by them. During the time when pike juveniles would be most susceptible to entrainment (May to August), retention time under MO1 would be similar or slightly higher so entrainment risk for pike would be similar to the No Action Alternative or slightly lower. However, as adult pike distribution increases downstream in the reservoir, adults and juveniles both would become more susceptible to entrainment and the increased winter outflow would increase entrainment.

Once released, the net pen fish that supplement the rainbow trout fishery in Lake Roosevelt would experience similar effects as their native counterparts except for spawning and early rearing effects. In addition, the net pen locations are situated where the water quality can be affected by changes in reservoir elevations; these fish are sensitive to temperature and TDG, and their eventual recruitment to the fishery can be affected by retention time coupled with reservoir elevation at the time of their release (McLellan et al. 2008), which is typically in May. Under the MO1, the water quality at these locations would be similar to the No Action Alternative, and the water retention time in May would be either similar or slightly higher so entrainment risk would be the same as the No Action Alternative or slightly less. The operators strive to release these fish to coincide with the initiation of reservoir refill when outflows are reduced, which under MO1 would be the same as the No Action Alternative, so these fish would continue to be release when water quality conditions would be suitable.

The fish in Rufus Woods Lake would continue to be supplemented by entrained fish out of Lake Roosevelt to a large extent, with fish mostly entrained during the spring freshet and winter drawdown periods. The earlier start to winter drawdown in MO1 may increase entrainment and boost populations in Rufus Woods Lake, where decreased outflows in August and September likely would decrease entrainment. This lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short water retention time and low productivity. High flows during late spring and early summer would continue to flush eggs and larvae from protected rearing areas similar to the No Action Alternative, but slightly lower magnitude. Median peak outflows occur in early June and would be about 2 2 percent lower than the No Action Alternative. TDG in the Grand Coulee tailwater is a concern for fish in Rufus Woods Lake; modeling showed TDG would be slightly lower than the No Action Alternative.

#### *Chief Joseph to McNary Dam*

Summary of Key Effects

Key effects to fish and aquatic resources from MO1 would be similar to the No Action Alternative for most species. Additional effects under MO1 include slightly reduced spring freshet flows that may lead to minor reductions in white sturgeon spawning success, and slight increases in temperatures during northern pikeminnow and smallmouth bass rearing periods. The operational measures that could impact fish in Region B include the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee, Winter System FRM Space, Lake Roosevelt Additional Water Supply* and *Chief Joseph Dam Project Additional Water Supply*.

Habitat Effects Common to All Fish

Common habitat effects of MO1 are similar to those identified for the No Action Alternative with the exception that flows would be slightly reduced in the spring freshet and water temperatures slightly increased during the late summer and early fall. These changes would have minor effects to fish species in the Columbia River.

Bull Trout

Key effects to bull trout under MO1 would not differ from the No Action Alternative. Bull trout would continue to use mainstem habitats of the Columbia River from November through July for foraging, migration, and overwintering.

Other Fish

Effects to white sturgeon under MO1 are not expected to change from those under the No Action Alternative except that spring freshet flows would be reduced slightly, leading to minor reductions in white sturgeon spawning success. The number of days when flows at McNary Dam would be above 250 kcfs would be reduced by about half a day from 9.3 to 8.8 days during May through July.

Key effects of MO1 relative the No Action Alternative for additional fish resources would include a slight increase of in late summer water temperatures during the rearing period for northern pikeminnow and smallmouth bass. This increase may lead to better growth and survival for these and other species with similar life history requirements. Other effects would be similar to the No Action Alternative.

**Region C**

***Snake River Basin***

<u>Summary of Key Effects</u>

Key effects from MO1 that differ from those found under the No Action Alternative include warmer water temperatures during August and slight increases in TDG April through July from operational measures such as *Block Spill Test (Base + 120/115%)* and *Modified Dworshak Summer Draft*.

<u>Habitat Effects Common to All Fish</u>

Common habitat effects of MO1 are similar to those identified for the No Action Alternative with the exception of the changes discussed in the section above.

<u>Bull Trout</u>

Effects of MO1 to bull trout within the Snake River Basin that differ from the No Action Alternative include a reduction in cooling water releases from Dworshak reservoir in August that would result in an increase in water temperature in the Clearwater and Snake Rivers. However, this would have minor adverse effects to bull trout as they migrate out of mainstem habitats prior to these releases and should be in tributary habitats when this operation occurs. These same cold water releases would start earlier in the year than under the No Action Alternative and would reduce water levels in Dworshak Reservoir and potentially impact bull trout migration access to tributaries in late June and early July.

<u>Other Fish</u>

Effects to white sturgeon under MO1 are not expected to change from those recorded under the No Action Alternative except that slightly higher water temperatures would occur in August as a result of a decrease in the release of cooling water from Dworshak Reservoir. This increase in temperature may increase mortality to white sturgeon on low water years. Mass mortality events and increased single mortalities are observed more frequently during high temperature events, often coupled with sockeye mortality events.

Key effects of MO1 relative the No Action Alternative for additional fish resources would include a slight increase of in late summer water temperatures during the rearing period for northern pikeminnow, smallmouth bass and other cool and warm water fish species, and changes in TDG during spill in the spring, summer, and fall. Water temperatures would increase in August by as much as 4 degrees Celsius. This increase would contribute to better growth and survival for these and other species with similar life history requirements.

Increases in spill under MO1 would increase TDG slightly during the spring and summer spill season and reduce TDG considerably in the fall with the early cessation of spill. High TDG could have adverse effects to early life stages of resident fish that are not able to compensate for high TDG by changing depth. Other effects would be similar to the No Action Alternative.

**Region D**

***Mainstem Columbia River from McNary Dam to the Estuary***

Summary of Key Effects

Bull trout would continue to use the Columbia River in limited numbers and seek thermal refugia available at the mouths of tributaries. White sturgeon could continue to successfully reproduce in years with adequate flow and temperature conditions; recruitment failure has continued to occur in the Columbia basin and the causes are not well understood. The *Block Spill Test (Base + 120/115%), Increased Forebay Range Flexibility, Additional Powerhouse Surface Passage,* and *Improved Fish Passage Turbines* are measures that could provide a beneficial effect to fish on the Mainstem Columbia River from the McNary Project to the estuary.

Habitat Effects Common to All Fish

Outflows from McNary Reservoir influence some of the fish relationships described in this section. Peak spring flows affect habitat maintenance for some species. Modeled monthly median outflows for MO1 are shown below. The percent change compared to the No Action Alternative is shown in parentheses.

- April: 187187187187187,600 cfs (-2 percent)
- May: 254254254254254,300 cfs (-2 percent)
- June: 282282282282282,400 cfs (-1 percent)
- July: 195195195195195,800 cfs (-1 percent)

Other flow parameters referred to in this section refer to outflows of McNary Dam, which are indicative of flows on downstream through the other Projects.

Bull Trout

Bull trout are known to use the mainstem Columbia River to move between tributaries and have been observed at Bonneville Dam and McNary Dam in the spring and summer (Barrows et al. 2016). Water temperature is the most important habitat factor for bull trout in the mainstem Columbia. Under MO1, bull trout would continue to use the mainstem Columbia for migration between tributaries, as well as tributary mouths for passage and thermal refugia.

Adult bull trout move downstream during fall and overwinter in reservoirs (October to February) (Barrows et al. 2016). Although bull trout successfully move between areas on the mainstem, their migration can be delayed at the dams. MO1 includes a structural measure for additional spillway passage at McNary Dam. The *Additional Powerhouse Surface Passage* measure would be in operation from March 1 through August 31, and could slightly improve bull trout downstream passage, but the majority of adult bull trout would have moved out of the mainstem by the time this surface passage route would be in use.

Passage through turbines can cause injury or mortality, as well as migration delays. MO1 includes the *Improved Fish Passage Turbines* measure, which would improve survival (Deng et al. 2019). At John Day, turbine replacement would provide safer passage for any bull trout that move through the dam.

Bird predation on bull trout would continue to occur under MO1. New surface bypass designs under MO1 could shift bull trout into areas that are more susceptible to bird predation.

<u>Other Fish</u>

Under MO1, white sturgeon spawning and recruitment would be similar to the No Action Alternative, with a range of 48 days (2015) to 74 days (2012) with suitable conditions. The number of days with optimal embryo incubation (12°C to 14°C) would also be similar to the No Action Alternative, range from 6 days (2013) to 27 days (2011). In years of low flow conditions, water temperatures could increase beyond the suitable range by early June, resulting in little or no recruitment.

Flows for successful sturgeon spawning and recruitment were analyzed based on the McNary tailrace. Since lower Columbia dams are run-of-river, the outflow at McNary Dam correlates with the outflows at John Day, The Dalles, and Bonneville Dams. Flows of at least 250 kcfs from April 1 to July 31, coupled with suitable temperatures, provide favorable spawning and rearing conditions. Compared to the No Action Alternative, there could be a slight reduction in the number of years with recruitment success under MO1. Model results indicate two fewer days of suitable conditions in median years and three fewer days in high flow years. Low flow years would likely not provide sufficient time with suitable flows for recruitment to occur, similar to the No Action Alternative.

White sturgeon spawning generally occurs in areas with fast-flowing waters over coarse substrates (Parsley et al. 1993). Minor changes in outflow under MO1 would not be large enough to cause discernable velocity changes that would affect sturgeon spawning habitat.

Lack of effective upstream white sturgeon passage for all age classes decreases the connectivity of the population (Parsley et al. 2007). Under MO1, a measure to improve fish passage at Bonneville Dam would likely improve potential passage for sturgeon. The vertical slot fishway would make it easier for sturgeon to pass upstream.

Turbine units at dams can cause injury and mortality in juvenile and adult sturgeon. Under MO1, improvements to turbines at John Day would reduce injuries and mortality of juvenile sturgeon (Deng et al. 2019).

White sturgeon larvae are adversely affected by TDG. Studies have shown high rates of altered buoyancy at 118 percent TDG, and 50 percent mortality at 131 percent TDG (Counihan et al.

1998). Adults are more able to compensate for increased TDG by moving to lower depths, but larvae in shallow water would be more affected. Under MO1, TDG rates would be similar to the No Action Alternative.

Changes in a pool or tailrace elevation can affect juvenile white sturgeon through stranding in shallow water. Under MO1, pool elevations would be about 1 foot higher in the John Day pool from late March through early June (due to bird predation measures), and the drop in early June could strand larvae.

Under MO1, lower flows at Bonneville during dry years in May and August could potentially increase pinniped predation rates, but it is also likely that sturgeon are avoiding the tailrace due to predation pressure.

Resident fish such as sculpin, walleye, and smallmouth bass are predators of embryo and age-0 white sturgeon. Under MO1, predation would continue to affect early life stages of white sturgeon.

Reservoirs in the lower Columbia may be in maturation, in which sedimentation and invasive aquatic plants could reduce habitat value for sturgeon through changes in predation, food availability, and suitability for invasive species. This trend would not be expected to change under MO1.

Under MO1, no changes to resident fish communities would be expected. As shown above, outflow rates below McNary Dam would be very similar to the No Action Alternative. Water quality and food availability would also be similar to the No Action Alternative.

Conditions that promote lower water temperatures and higher spring flows tend to lower the survival rates of warmwater game fish, potentially lowering populations of predators on salmon and steelhead. MO1 would be expected to continue supporting warm water game fish at levels similar to current conditions.

## MACROINVERTEBRATES

Below is a discussion of the macroinvertebrates in Regions A, B, C, and D under MO1. For more detailed information on the effects of MO1 on aquatic invertebrates and implications on food web interactions see the Habitat Effects section of these respective fish community analyses in the Resident Fish section under the applicable region.

### Region A

Project operations under MO1 would affect the aquatic environments provided by Hungry Horse Reservoir, South Fork Flathead River, Flathead River, Flathead Lake, lower Flathead River, Clark Fork River, Lake Pend Oreille, Pend Oreille River, Lake Koocanusa, and the Kootenai River. These include the *Modified Draft at Libby*, *December Libby Target Elevation, Hungry Horse Additional Water Supply,* and *Sliding Scale at Libby and Hungry Horse* measures.

At Hungry Horse reservoir, the varial zone that provides benthic insect production would be appreciably reduced due to steeper drafts in the summer and lower elevations through the winter months, and aquatic insects in this zone would become dewatered faster than under the No Action Alternative. The reservoir would miss filling in six more years out of 100 compared to the No Action Alternative, and the elevation at the end of September would be 4 to 5 feet lower than the No Action Alternative. With lower summer elevations the euphotic zone for summer zooplankton production would also decrease by 1 percent to 3 percent, and zooplankton being carried downstream out of the reservoir and into the South Fork Flathead River would increase with higher outflows of nine to 21 percent in the summer months. Zooplankton entrainment would generally be lower than the No Action Alternative in spring, fall, and winter. These outflows can increase zooplankton levels and wetted area for macroinvertebrate production in the South Fork Flathead River but could also flush more out of this area with higher velocities.

MO1 operations would result in minimal changes to Flathead Lake, the lower Flathead River, and the Clark Fork River. These habitats would continue to support the macroinvertebrates described in the affected environment.

The operations of Albeni Falls Project would be similar to the No Action Alternative operations and would not result in appreciable changes to Lake Pend Oreille or the Pend Oreille River, nor to the macroinvertebrate communities in those habitats.

In the Kootenai basin, Lake Koocanusa would be held above elevation 2450 from three to thirteen more days than the No Action Alternative, which would increase the overall productivity of zooplankton and macroinvertebrates in the system. MO1 operations result in a median minimum pool elevation two feet lower than the No Action Alternative, exposing more varial zone and dewatering insect production, especially in dry years. The shallower draft through the winter compared to the No Action Alternative would lessen the effect to macroinvertebrate production.

**Region B**

The Columbia River from Canada to Lake Roosevelt would continue to produce benthic aquatic insects such as stonefly, caddisfly, and mayfly larvae. The operational measures that could impact macroinvertebrates under MO1 in Region B include the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee, Winter System FRM Space, Lake Roosevelt Additional Water Supply* and *Chief Joseph Dam Project Additional Water Supply*.

MO1 operations would change river elevations at the U.S.-Canada border in the months of December and January, with much steeper drops than the No Action Alternative. MO1 levels would follow the same pattern as the No Action Alternative through April with rising elevations until July, then dropping steeply until September, when they rise again. No Action Alternative and MO1 levels would then level off about November, but in December MO1, levels would drop quickly about 4 feet where No Action Alternative levels would rise slightly and hold steady for another month and then drop at a lower rate. MO1 would result in decreased habitat and more areas becoming dewatered compared to the No Action Alternative from December through about March 1. This change in elevation of 4 feet represents the vertical feet; actual habitat dewatered would depend on the slope of the riverbanks at this elevation. As the river flows downstream closer to Lake Roosevelt, the pattern is the same but the additional drop from MO1 would result in about six feet lower elevation at river mile 720.

In Lake Roosevelt, the production, distribution and persistence of zooplankton is highly variable and sensitive to retention time of water in the reservoir, which is a function if inflows, reservoir volume, and outflows. Under MO1, the average water retention time in the reservoir would be similar to the No Action Alternative in late spring, summer, and fall. Water retention time under MO1 would be lower in December through January, but slightly higher in May in most years. In wet years is when retention time is lowest because more water is moving through the system, and MO1 would reduce retention times even further in these years by up to 10 percent in February and by 3 percent to 10 percent in the entire period of December through May. With lower retention times under MO1 in winter and spring, when retention times are already fairly low, there would be less productivity and increased entrainment of zooplankton. The elevations in Lake Roosevelt would follow the same pattern as in the river sections described above, with MO1 elevations dropping up to 6 feet lower by the end of December, rather than staying steady as in the No Action Alternative. This would result in desiccation of more aquatic macroinvertebrates and overall decreased habitat in shallow areas of the reservoir.

Downstream of Grand Coulee Dam, Rufus Woods Lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short water retention time and low productivity. Regarding aquatic insect production and desiccation, river stage at RM 594 in Rufus Woods Lake would follow the same pattern and magnitude changes as the No Action Alternative, so aquatic macroinvertebrate habitat would be the same. However, zooplankton production may decrease in response to changes in water retention time proposed under MO1.

**Region C**

The operational measures such as *Block Spill Test (Base + 120/115%)* and *Modified Dworshak Summer Draft* could impact macroinvertebrates in Region C. Low benthic production in Dworshak reservoir would be even further reduced under MO1 with a steeper drawdown starting about the third week of June. Extensive variation in water surface elevation, near-shore wave action that causes erosion and the lack of aquatic plants along the shoreline would continue to limit production. Likewise, the steeper drawdown in summer reservoir pool volume would further limit zooplankton production.

In the Clearwater River below Dworshak Dam, flow augmentation released under MO1 would begin earlier in June than the No Action Alternative, but flows in August would be reduced compared to the No Action Alternative. The pattern of high flows followed by a steep drop and then followed by high flows again would limit benthic production in the Clearwater River compared to the No Action Alternative.

The macroinvertebrate community of the lower Snake reservoirs and river would continue similar to the No Action Alternative. Warmer water temperatures could lead to a shift in zooplankton species, and these could experience more growth in the summer. Siberian prawns and opossum shrimp may continue to increase in the reservoir environments. The reservoirs would continue to provide habitat for clams, mussels, etc., as in the No Action Alternative, and crayfish would continue to find ample suitable habitat in the rock and riprap of reservoirs.

#### Region D

MO1 would result in only minor changes to flows or temperatures that could affect macroinvertebrate communities in the lower Columbia River from operational measures such as the *Block Spill Test (Base + 120/115%)* and *Increased Forebay Range Flexibility* measures. Very little benthic macroinvertebrate information is available for the lower Columbia River. Lake habitats in the impounded reaches would continue to support a low diversity of worms, benthic insects, and mollusks. In MO1, pool elevations would be about 1 foot higher in the John Day pool from late March through early June (due to bird predation measures), and then dropped in early June to the original level. During the period of March through early June, aquatic macroinvertebrates could colonize the additional benthic substrate and shallow water habitat afforded by the higher pool elevation but could be stranded or desiccated when levels drop in June. The other run of river dams would continue to be operated at stable elevations that would continue production of these aquatic macroinvertebrates.

### SUMMARY OF EFFECTS

#### Anadromous Fish

MO1 includes several structural measures intended to improve juvenile migration, including the *Additional Powerhouse Surface Passage, Upgrade to Adjustable Spillway Weirs* and *Improved Fish Passage Turbines* measures. Operationally, the *Block Spill Test (Base + 120/115%)* measure in the spring would generally increase the amount of spill at each of the lower Columbia and lower Snake projects for improved juvenile survival. The *Predator Disruption Operations* measure in the John Day reservoir would reduce juvenile predation by birds. Block spill during the spring was designed to test whether latent effects may be reduced slightly so that there could potentially be an increase in ocean survival and subsequent adult returns. Structural measures such as the *Additional Powerhouse Surface Passage* did not result in sizeable increases in juvenile survival or improvements in adult returns. Other structural measures in MO1 (e.g., *Lower Granite Trap Modifications*) would make small, incremental improvements in adult migration, but operational changes at Dworshak that were intended to improve thermal conditions for adult migrations in the Snake River actually would reduce adult migration success. Models predict that returns of salmon and steelhead would be similar to the No Action Alternative or higher. MO1 would have minor adverse effects for chum with mostly beneficial effects for lamprey, although there would be minor localized impacts. These effects are generally expected to be beneficial and negligible to minor as compared to the No Action Alternative.

**Resident Fish**

MO1 would continue many of the same key effects described in the No Action Alternative. Compared to the No Action Alternative, MO1 would have minor to moderate adverse effects in Region A due to changes in reservoir elevations and outflows reducing productivity, higher entrainment, increased varial zone effects where fish are subject to higher predation and access issues at tributary mouths, and diminished habitat in rivers downstream of reservoirs. These would affect bull trout, Kootenai River White sturgeon, and other native fish such as westslope cutthroat trout, and there would be some minor localized beneficial effects. In Region B, there would be minor to moderate adverse effects in Lake Roosevelt fish due to changes in retention time driving productivity and entrainment, habitat connectivity, stranding of kokanee and burbot eggs, habitat access for several species, and varial zone effects to redband rainbow trout. There would be negligible to minor adverse effects to white sturgeon from flow changes. In Region C, minor increases in late summer water temperatures and TDG in certain reaches such as the Snake River Basin would improve conditions for northern pikeminnow and invasive species such as smallmouth bass, adversely affecting conditions for native resident fish. Resident fish in Region D would see minor changes in flows and temperatures resulting in negligible effects to bull trout, white sturgeon, and other resident fish. While MO1 results in both beneficial and adverse effects on resident fish, overall, these effects are expected to be negligible, minor, or in some cases localized moderate as compared to the No Action Alternative.

**Macroinvertebrates**

The production, distribution, and persistence of macroinvertebrates are highly variable and sensitive to retention time of water in the reservoir, which is a function of inflows, reservoir volume, and outflows. In certain areas, such as at Hungry Horse and Dworshak Reservoirs, the varial zone that provides benthic insect production would be appreciably reduced due to steeper drafts in the summer and lower elevations through the winter months would result in aquatic insects becoming dewatered faster than under the No Action Alternative. In other areas, such as Lake Koocanusa, increases in timing of elevation as compared to the No Action Alternative would increase the overall productivity of zooplankton and macroinvertebrates in the system. Overall, MO1 contains both beneficial and adverse effects, which on balance are expected to be negligible to moderately adverse as compared to the No Action Alternative.

### *3.5.3.5 Multiple Objective Alternative 2*

**ANADROMOUS FISH**

**Salmon and Steelhead**

Several different ESU/DPS units of salmon and steelhead share a similar life cycle and experience similar effects from the MOs, but also have ESU/DPS specific traits that specifically drive effects differently from one another. Common effects analyses across all salmon and steelhead are discussed first, and then those ESU/DPS specific effects are displayed. Unless otherwise noted, quantitative results from COMPASS, CSS, and the Life Cycle Model (LCM) are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results.

***Effects Common Across Salmon and Steelhead***

Summary of Key Effects

MO2 includes structural measures to improve survival of juvenile salmon and steelhead, but lower flow and spill would, generally speaking, increase travel time and the number of powerhouse encounters for juvenile outmigrants. Anadromous juveniles outmigrating in the Snake River would be transported at a higher rate than the No Action Alternative, which could result in more reaching Bonneville Dam sooner than in-river fish. Depending on ocean survival dynamics, more or fewer adults could return, and returning adults would likely have higher rates of straying and migration delays due to higher rates of transported juveniles.

Juvenile Fish Migration/Survival

There are several structural measures in MO2 that could affect juvenile salmon and steelhead. Three of these were also in MO1 and were described in detail in the Common Effects to Salmon and Steelhead under MO1 section. Juvenile modeling included adjustments in the models to account for the effects of these measures, and they are considered qualitatively where modeling is not available. These include:

- *Additional Powerhouse Surface Passage* measure at Ice Harbor, McNary, and John Day Projects: This would route additional juvenile fish away from turbine passage routes to spillway or spillway-like routes, likely decreasing travel times and increasing survival. See MO1 Common Effects for details. A key difference in MO2 however is a powerhouse surface collection facility designed to allow for smolt transportation at McNary Dam this significant design modification is different from MO1. Even with the most optimistic 30 percent passage efficiency assumption in place, the effect of these powerhouse surface passage structures on in-river survival and subsequent adult returns was minor. These structures could potentially be more effective at influencing population level dynamics at lower spill levels than those included in MO1, but even with reduced spill levels associated with MO2, there were not enough fish passing via the powerhouse to have a meaningful impact.
- The *Improved Fish Passage Turbines* measure at the John Day Project would improve juvenile survival of the juveniles that pass through this turbine route. See MO1 Common Effects for details.

MO2 also includes measures that would affect juvenile salmon and steelhead that were not in MO1, with the objective of improving power generation or complementing power with increased fish transport. They are:

- *Fewer Fish Screens* measure at Ice Harbor, McNary and John Day Projects:

Fish screens are installed to divert juvenile salmon and steelhead from turbine routes to higher survival spill routes. However, most turbines were designed to operate without screens and the addition of these screens generally reduces turbine efficiency and flexibility. Removing these screens would restore operating ranges and efficiencies while decreasing O&M costs.

Effects on fish from this structural change would be generally adverse to most fish species. We would expect an increase in the numbers of fish experiencing turbine routes at these dams, while juvenile salmon and steelhead, and most other species of fish, would experience increased mortality. By contrast, lamprey, which experience impingement on some of the screens, would likely see increases in survival as they pass the dams.

- *Increase Juvenile Fish Transportation* measure: Increasing juvenile fish transportation would affect Snake River and Columbia River fish. First, all Snake River smolts would be collected for transportation at the three Snake River collector projects, with none being bypassed back to the river. Juvenile fish would also be collected and transported from the powerhouse surface passage structure at McNary Dam. Changes in Snake River transport are incorporated into models, but because COMPASS and CSS models are not calibrated to data utilizing McNary transport facilities, model results do not reflect the effects of this measure. A rough estimate conducted by NMFS indicates that approximately an additional 9 percent of Chinook and 7 percent of steelhead would likely be transported using a powerhouse surface passage for collection. Additionally, the lower spill in MO2 would increase the number of juveniles entering juvenile bypasses and therefore available to be collected for transportation. Increasing the total fraction of natural and hatchery origin smolts transported from Lower Granite, Little Goose, and Lower Monumental dams will increase the average return rates to Bonneville Dam of the outgoing cohort of Snake River spring-run/summer-run Chinook. However, lower adult conversion rates upstream are also associated with fish that were transported as juveniles (Marsh et al. 2015; FPC memo 13-19). The increased conversion risk for adults would offset some of the benefits from the higher adult returns resulting from a higher season-wide transport rate of juveniles. As a result, transportation of natural and hatchery origin Snake River spring-run/summer-run Chinook smolts from McNary Dam may have a neutral effect on SARs (Marsh et al. 2010). Changes in transport are discussed more specifically by ESU/DPS, if applicable.

Several operational measures warrant discussion here individually, regarding effects to juvenile fish. Measures that would result in changes to spill, flows, passage routes, or temperatures were incorporated into the fish models. Others are not readily incorporated into modeling for effects analysis, or are modeled but may be difficult to separate from other factors, and so effects of these measures are discussed qualitatively.

- *Full Range Reservoir Operations* and *John Day Full Pool* measures: Increasing the operating range at the four lower Snake River dams and John Day Dam to their full operating ranges would slightly increase juvenile fish travel times and exposure to predators, but the pools would not be at full pool elevations throughout the migration season. To better understand how these elevations change throughout the season, see the Hydrology and Hydraulics modeling section of this EIS.

- *Contingency Reserves in Fish Spill* measure: Holding contingency reserves within juvenile fish passage spill is likely to have little effect on juvenile migration. Contingency reserves would be expected to be deployed at a level that would impact fish spill levels approximately once a month and are, by definition, limited to no more than 1 hour in duration. See Section 3.7, Power Generation and Transmission for more information.
- *Full Range Turbine Operations* measure: Operating turbines within and above 1 percent efficiency may or may not affect juvenile salmon and steelhead direct survival based on studies finding that peak passage survival does not coincide with observed turbine peak operating efficiency (Mathur et al. 2000; Skalski et al. 2002; Deng et al. 2007). A meta-analysis also found no association between relative turbine efficiency at a site and smolt passage survival (Skalski et al. 2002). However, Ferguson et al. (2006) reported spring-run Chinook delayed mortality resulting from operation of McNary Dam turbines outside the 1 percent range, so it is possible that operating outside 1 percent turbine efficiencies at some dams may decrease juvenile survival.
- *Zero Generation Operations* measure: Extending the zero generation operation measure would not affect juvenile salmon or steelhead because they are not migrating in the late fall/winter timeframe when this measure occurs. However, impacts to adult passage (especially for Snake River steelhead) would be anticipated due to this operation.
- The measures intended to improve conditions for lamprey in this alternative are anticipated to have a negligible effect on salmon and steelhead survival.

MO2's *Spill to Near 110% TDG* decreases the proportion of spill at each of the lower Columbia and lower Snake projects compared to the No Action Alternative. This reduced spill has the net effect of routing more juvenile salmon and steelhead towards powerhouse routes and less salmon and steelhead through spill routes. For juvenile salmon and steelhead, fish modeling was used when available to estimate the effects of these spill changes on fish.

Flow patterns in the Lower Columbia River would also change in MO2 relative to the No Action Alternative and these included median decreases in monthly average flows of 4 percent in March, and increased winter flows of 5 to 9 percent in November and December. Other months would be within 1 to 3 percent of No Action Alternative flows. In the Lower Snake River, flows would be about 18 percent higher in January and 5 percent higher in February, with lower flows in June (-3 percent) and July (-5 percent). Similar to the spill changes, fish modeling was used when available to estimate the effects of these flow changes on juvenile fish. These flow changes were caused by one or a combination of the following operational measures:

- *Slightly Deeper Draft for Hydropower*
- *Sliding Scale at Libby and Hungry Horse*
- *Modified Draft at Libby*

- *December Libby Target Elevation*
- *Update System FRM Calculation*
- *Planned Draft Rate at Grand Coulee*
- *Grand Coulee Maintenance Operations*
- *Winter System FRM Space*

MO2 is similar to the No Action Alternative from a TDG perspective but shows a small reduction in average TDG exposure. UW/CBR TDG modeling, separate from COMPASS and CSS in-river survival estimates, estimated juvenile fish median reach average exposure to TDG indices would decrease by about 2 percent relative to the No Action Alternative.

There may be increases in fish injury under MO2 with the higher number of turbine passages relative to the No Action Alternative, but reduced to some degree by installation of improved fish passage turbines at John Day Dam. However, water velocities and turbidity are not anticipated to change under MO2 relative to the No Action Alternative. There may be an overall increase in juvenile fish predation exposure under MO2 due to these factors relative to the No Action Alternative, but the magnitude is uncertain.

<u>Adult Fish Migration/Survival</u>

MO2 includes one measure, *Lower Snake Ladder Pumps*, which would install pumping systems to provide deeper, cooler water if available in the forebays to adult fish ladders at Lower Monumental and Ice Harbor Dams, intended to reduce delays in upstream adult passage. This measure is also in MO1 and is described and analyzed in more detail in the Common Effects section of MO1.

Reduction in spill throughout the lower Columbia and lower Snake projects is anticipated to reduce adult fallback rates in spring migrants that cause migratory delays (Boggs et al. 2004; Keefer et al. 2005) under MO2 and its *Spill to Near 110%* measure.

Increasing the operating range at the lower Snake River projects and at John Day Project through the *Full Range Reservoir Operations* and *John Day Full Pool* measures would have little effect on flow, and thus is not expected to affect adult migration timing or survival rates. Similarly, holding contingency reserves within juvenile fish passage spill is likely to have little effect, if any, on adult migration.

The following measures are summarized in the juvenile effects section and in detail in the Summary of Common Effects under MO1. These measures are also in MO2, and in additional to juvenile effects would result in the following effects to adult migration and survival:

- *Additional Powerhouse Surface Passage* at Ice Harbor, McNary, and John Day Dams could reduce travel time and improve downstream migration of steelhead kelts.

- Installing Improved Fish Passage (IFP) Turbines at John Day Dam could increase survival of salmon and steelhead that overshoot John Day Dam as well as steelhead kelts that pass back downstream through turbines.

As described under juvenile fish, flows would be about 4 percent lower in March and 3 to 7 percent higher in November and December in the lower Columbia River. Snake River flows would be about 18 percent higher in January and 5 percent higher in February. Any anadromous salmonids in the Columbia River or Lower Snake River at these times may be affected by these changes, as described below.

In general, there are no major water temperature changes expected as a result of MO2 but for some species in some locations, there may be localized effects. Where applicable those effects are discussed in the species-specific write-ups. Summer water temperatures in the Snake River during the most upstream migrations would not change from the No Action Alternative, nor would the percentage of days in which the ladder temperature would be more than 2 degrees Celsius warmer than the river temperature. However, Dworshak Reservoir operations would be affected such that the probability of refilling the reservoir would be lower, resulting in higher risk of not having enough water in the reservoir to provide summer cooling water.

***Upper Columbia River Salmon and Steelhead***

Upstream of McNary Dam, upper Columbia salmon and steelhead migrate past as many as five PUD owned dams and reservoirs that also impact the survival and passage of these species. The federal agencies do not dictate generation or spill levels at the PUD projects so metrics such as powerhouse encounter rate are not directly affected but are influenced by river flow levels coming through the upper Basin. The timing and volume of flow levels affected by CRS operational decisions are reflected in model analysis. COMPASS and LCM estimates of powerhouse encounter rate and SARs include passage effects from a combination of federal and PUD dam passage (Rock Island Dam to Bonneville Dam).

<u>Upper Columbia Spring-Run Chinook Salmon</u>

*Summary of Key Effects*

The structural and operational measures in MO2 overall would reduce juvenile survival from McNary Dam pool to Bonneville Dam with longer travel times and increased powerhouse encounters. Adult migration success may be enhanced by lower spill, but with lower juvenile survival, overall abundance of returning adults to spawning grounds would be about 3 percent lower than the No Action Alternative. Some upper Columbia Chinook salmon would be transported from McNary Dam under this operation, but the effects could not be quantitatively assessed.

*Juvenile Fish Migration/Survival*

This ESU migrates through the Columbia River downstream past the four lower CRS projects as well as up to five non-federal dams. Structural and operational measures described in the Common Effects section that describe changes from the No Action Alternative at McNary, John Day, The Dalles, and Bonneville Projects would apply to these fish. Additional surface passage and upgrading spillway weirs at McNary and John Day Dams may improve juvenile survival but removing fish screens at both dams would result in more juvenile fish going through turbines,, though improved turbines could offset this effect with increased survival of turbine route fish. COMPASS modeling indicates MO2 would decrease juvenile survival about 1.3 percent, increase travel time 7 percent and increase the number of powerhouse routes encountered by juvenile fish by 11 percent. TDG exposure would generally be lower than the No Action Alternative for these fish (Table 3-79). Overall, juveniles would likely encounter increased predation risk in MO2, compared to the No Action Alternative, with longer travel times and increased powerhouse encounters between McNary and Bonneville dams.

**Table 3-79. Multiple Objective Alternative 2 Juvenile Model Metrics for Upper Columbia River Spring-Run Chinook Salmon**

| Metric (Model) | NAA | MO2 | Absolute Change from NAA | Percent Change from NAA |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) McNary to Bonneville | 69.5% | 68.2% | -1.3% | -2% |
| Juvenile Travel time (COMPASS) McNary to Bonneville | 6.1 days | 6.5 days | +0.4 days | +7% |
| % Transported | Not Quantitatively Estimated | | | |
| Powerhouse Passages (COMPASS) Rock Island to Bonneville | 3.29 | 3.66 | +0.37 | +11% |
| TDG Average Exposure (TDG Tool) McNary to Bonneville | 115.9% TDG | 113.0% TDG | -2.9% TDG | -3% |

*Adult Fish Migration/Survival*

There are no structural measures in MO2 to benefit upstream migration of adult upper Columbia River spring-run Chinook salmon. Adult exposure to TDG would be lower than the No Action Alternative, and lower spill levels would generally reduce migration delays and fallback.

With decreased juvenile survival and slower juvenile travel time, the SARs and the resulting abundance of returning adults would be expected to decrease under MO2 compared to the No Action Alternative. NWFSC LCM modeling predicted MO2 would result in a 3 percent decrease in median abundance, based on modeling of the Wenatchee population. This prediction assumes no change in potential latent mortality of juvenile fish compared to the No Action Alternative. Estimates of potential increases or decreases in ocean mortality were not computed for MO2. Table 3-80 displays the model results for the Wenatchee population:

**Table 3-80. Multiple Objective Alternative 2 adult model metrics for Upper Columbia River Spring-Run Chinook salmon**

| Metric (Model) | NAA | MO2 | Change from NAA | %Change |
|---|---|---|---|---|
| Rock Island to Bonneville McNary to Bonneville SARs[1/] (NWFSC LCM) | 0.94% | 0.93% | -0.01% | -1% |
| Abundance[2/] of the Wenatchee population, representative of the ESU (NWFSC LCM) | 498 | 482 | -16 | -3% |

1/ SAR estimates include passage effects from three non-federal dams.
2/ Abundance estimates do not assume any latent effects from Columbia River System passage.

Upper Columbia River Steelhead

*Summary of Key Effects*

COMPASS modeling estimates that MO2 is expected to result in a 4 percent decrease in average juvenile survival for upper Columbia steelhead between McNary and Bonneville dams; no change in average juvenile travel time is expected, but a six percent increase in the number of powerhouse passage events compared to the No Action Alternative would occur.

*Juvenile Fish Migration/Survival*

Juveniles from this DPS migrate downstream past the four lower CRS projects and through up to five PUD owned dams in the mid-Columbia. Operations at upstream reservoirs that affect seasonal flow patterns downstream influence travel time and survival at the PUD owned projects. Structural and operational measures described in the Common Effects section, including the *Additional Powerhouse Surface Passage* measure at McNary and John Day, and the *Upgrade to Adjustable Spillway Weirs* measure at McNary would improve spill passage effectiveness, but removing fish screens at McNary Dam and John Day Dam would increase turbine routes and increase mortality of juveniles. Juveniles collected at the powerhouse surface bypass at McNary would be transported within season. COMPASS modeling predicts juvenile survival under MO2 would decrease 2.4 percent, travel time would be the same as the No Action Alternative, and powerhouse encounters would increase. TDG exposure would be less than the No Action Alternative. MO2 Table 3-81 displays the juvenile metrics for upper Columbia River steelhead. Overall, juveniles could encounter increased predation risk in MO2, compared to the No Action Alternative, with increased powerhouse encounters between McNary and Bonneville dams.

**Table 3-81. Multiple Objective Alternative 2 Juvenile Model Metrics for Upper Columbia River Steelhead**

| Metric (Model) | NAA | MO2 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) McNary to Bonneville | 65.8% | 63.4% | -2.4% | -4% |
| Juvenile Travel Time (COMPASS) McNary to Bonneville | 6.6 days | 6.6 days | 0 days | 0% |
| % Transported (COMPASS) | Not Quantitatively Estimated | | | |

| Metric (Model) | NAA | MO2 | Change from NAA | % Change |
|---|---|---|---|---|
| Powerhouse Passages (COMPASS) Rock Island to Bonneville | 2.72 | 2.89 | +0.17 | +6% |
| TDG Average Exposure (TDG Tool) | 116% TDG | 113.1% TDG | -2.9% TDG | -3% |

MO2 includes a measure to increase transportation, including transport from McNary Dam.

*Adult Fish Migration/Survival*

As described in the Common Effects, upstream migration of adult steelhead would be improved by lower spill and lower TDG. The structural measures designed to improve juvenile fish survival, including additional surface passage, spillway weir upgrades, and improved fish passage turbines, would increase survival of steelhead kelts. Life cycle models were not available for steelhead, but overall abundance would likely be lower than the No Action Alternative due to decreased survival of juveniles.

<u>Upper Columbia River Coho Salmon</u>

See upper Columbia spring-run Chinook salmon analysis as a surrogate for juvenile upper Columbia coho salmon and upper Columbia fall Chinook salmon analysis as a surrogate for adult upper Columbia coho salmon.

*Summary of Key Effects*

The primary challenges for upper Columbia River coho salmon are the conditions they encounter during upstream and downstream migrations. Juvenile Upper Columbia coho salmon would survive similar to juvenile Upper Columbia spring-run Chinook salmon; minor decreases are expected due to operation and structural changes that would result in slower travel time and more powerhouse encounters. Upper Columbia Fall Chinook are the more appropriate surrogate for adult Upper Columbia coho salmon and based on surrogate analysis, minor decreases in adult returns would be expected.

*Juvenile Fish Migration/Survival*

Juvenile survival of upper Columbia River coho salmon is estimated using COMPASS juvenile modeling results for upper Columbia River spring-run Chinook salmon as a surrogate. Structural and operational measures contributing to changes in MO2 include increased surface passage structures, upgrading to adjustable spillway weirs, installation of improved fish passage turbines, and removal of fish screens at McNary Dam. These are discussed in the Common Effects section.

Overall, juveniles would likely encounter increased predation risk in MO2, compared to the No Action Alternative, with longer travel times and increased powerhouse encounters between McNary and Bonneville dams.

*Adult Fish Migration/Survival*

Measures described in the Common Effects section that affect the four lower Columbia River projects would apply to upstream migration and survival of adult upper Columbia River coho salmon. Adult migration conditions would be similar to upper Columbia River fall-run Chinook salmon, which were analyzed in workshops using water quality and hydrology information. MO2 water quality modeling indicated no change in the frequency of water temperatures exceeding 20°C, nor any change in ladder temperature differentials in the lower Columbia relative to the No Action Alternative. The late run of upper Columbia River coho salmon migrates upstream in November and December, when flows would increase an average of 9 percent in the Columbia River below McNary Dam.

See upper Columbia Fall Chinook salmon analysis as a surrogate for adult upper Columbia coho salmon.

<u>Upper Columbia River Sockeye Salmon</u>

Refer to the upper Columbia River Chinook salmon analysis as a surrogate for Upper Columbia River sockeye salmon.

*Summary of Key Effects*

Juvenile sockeye salmon would experience lower survival during outmigration in the river than under the No Action Alternative. The most important change for Columbia River sockeye from MO2 is the potential for transportation of juveniles, which can improve survival but may have the consequence of higher rates of straying when they return as adults.

*Juvenile Migration/Survival*

Reduced spill operations in MO2 is expected to result in minor increases to juvenile upper Columbia River sockeye migration times compare to the No Action Alternative. River flows during the driest 25 percent of years would be slightly lower, but there would not be a substantial difference from the No Action Alternative. Juveniles would encounter more powerhouses, but this may partly be offset by increased survival through expected turbine improvements. TDG exposure would be lower than the No Action Alternative. Overall juveniles would likely encounter increased predation risk and reduced survival, as indicated by a minor decrease in survival indicated by the COMPASS modeling of the surrogate species, upper Columbia River spring-run Chinook salmon.

In MO2, there is potential for transport of juvenile fish starting at McNary Dam, which would likely lead to an increase in the adverse effects of fallback and straying by the adult fish that were transported as juveniles.

Overall, juveniles would likely encounter increased predation risk in MO2, compared to the No Action Alternative, with longer travel times and increased powerhouse encounters between McNary and Bonneville dams.

*Adult Migration/Survival*

MO2 would have a minor increase in the percentage of days over 18°C as measured at McNary and Chief Joseph Dams. For sockeye salmon, the inflection point for the survival/temperature relationship is 18°C. This relationship is not as strong for upper Columbia sockeye because they typically migrate 5 to 7 days earlier than Snake River sockeye. The water temperature at Chief Joseph Dam influences sockeye that use the nearby tributary of Okanogan River. Okanogan sockeye arrive at the confluence of the Okanogan River with the Columbia River when water temperatures are warmer than 21°C, and then hold in the mainstem Columbia River. From around July 1 until the end of August, sockeye hold in the mainstem of the Columbia River until they get a temperature break in the Okanagan River and are then able to move upstream toward their spawning areas. Earlier runs of fish are more successful. The cumulative stress of moving up through warm water in the Columbia River and then experiencing warm water at the confluence of the Okanogan River where they hold could increase the cumulative stress, which may decrease adult fish survival. The minor increase in days over the 18°C under MO2 would have a corresponding increase in stress from elevated water temperatures.

<u>Upper Columbia River Summer/Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

See Upper Columbia River spring-run Chinook analysis as a surrogate for upper Columbia River Summer/Fall Run Chinook Salmon.

No change is anticipated in McNary and John Day reservoir plankton communities or shoreline habitats under MO2, relative to the No Action Alternative. Likewise, juvenile rearing habitat below Bonneville Dam is not expected to change relative to the No Action Alternative. Overall, no changes are anticipated for juvenile upper Columbia summer/fall-run Chinook.

*Juvenile Fish Migration/Survival*

Upper Columbia River Summer/Fall Run Chinook Salmon would likely experience lower juvenile survival, with small increases in travel time and powerhouse encounters. Lower TDG would benefit both juvenile and adult fish, and adult migration would be increased with lower fallback and delays due to spill. Overall abundance under MO2 would likely be less than No Action Alternative due to juvenile effects.

*Adult Fish Migration/Survival*

The number of days water temperatures in the McNary tailrace exceed 20°C and the number of days that adult ladder temperature differentials exceed 2°C would not change relative to the No Action Alternative. No changes in migration delay, fallback, or susceptibility to disease are anticipated due to overall warmer mainstem water temperatures at the lower Columbia dams (Caudill et al. 2013).

Specific to Okanogan upper Columbia summer/fall-run Chinook, there is no change in number of days the mainstem would be 20°C or higher at the confluence of the Okanogan, relative to the No Action Alternative as opposed to the 18°C threshold discussed above for sockeye salmon. This means that there would be no change anticipated in the ability of the Okanogan fish to hold in the mainstem until temperatures in the Okanogan are cool enough that adults can move up from the mainstem without having to migrate through water temperatures typically considered lethal for salmon and steelhead (Ashbrook et al. 2009).

The frequency of meeting the Vernita Bar Agreement to protect the prolific fall-run Chinook spawning in and around the Hanford Reach of the Columbia River in Washington is not expected to change under any MOs relative to the No Action Alternative. Other operational changes under MOs are likewise not anticipated to affect upper Columbia River summer/fall-run Chinook spawning from the tailrace of Chief Joseph Dam to Bonneville Dam in terms of changes in flows, water temperatures, or TDG generated under the MOs.

***Middle Columbia River Salmon and Steelhead***

Middle Columbia River Spring-Run Chinook Salmon

See Upper Columbia River spring-run Chinook analysis as a surrogate for Middle Columbia River Spring-Run Chinook Salmon.

*Summary of Key Effects*

Middle Columbia River spring-run Chinook salmon would likely experience lower juvenile survival, with small increases in travel time and powerhouse encounters. Lower TDG would benefit both juvenile and adult fish, and adult migration would be increased with lower fallback and delays due to spill. Overall abundance under MO2 would likely be less than No Action Alternative due to juvenile effects.

*Juvenile Fish Migration/Survival*

See upper Columbia River spring-run Chinook salmon analysis as a surrogate for juvenile middle Columbia River spring-run Chinook salmon. Under MO2, surrogate analysis results predict CRS operational changes may result in lower survival, higher travel times, and increased powerhouse passage events on juvenile middle Columbia River Chinook.

Measures described in the Common Effects section that refer to the lower four projects in the Columbia River would apply to middle Columbia River spring-run Chinook salmon. Middle Columbia River juvenile salmon would typically experience higher absolute survival than upper Columbia River spring-run Chinook salmon because they don’t experience the higher mortality associated with the Columbia River from Chief Joseph Dam downstream to McNary Dam, but the percent change in juvenile survival would be similar because they experience the same CRS projects between McNary and Bonneville dams.

*Adult Fish Migration/Survival*

See upper Columbia River spring-run Chinook salmon analysis as a surrogate for adult migration and survival of middle Columbia River spring-run Chinook salmon. As described in Common Effects, lower spill may increase the upstream migration success of middle Columbia River spring-run Chinook salmon by reducing fallback and delays. Under MO2, decreased juvenile survival would likely result in reduced abundance of adult returns to the spawning grounds.

Middle Columbia River Steelhead

Refer to Upper Columbia River steelhead analysis as a surrogate for Middle Columbia River steelhead.

*Summary of Key Effects*

Juvenile middle Columbia River steelhead survival would be improved by structural measures but decreased overall by operations. The portion of the middle Columbia River steelhead that do not pass McNary or John Day dams (e.g., Deschutes MPG) would have better survival than the ones that encounter all four Columbia River dams, including two of the dams considered with fish screens removed. Adult migration conditions and kelt survival would increase but overall abundance may be lower.

*Juvenile Fish Migration/Survival*

Populations of middle Columbia River steelhead distributed between the Deschutes and Walla Walla Rivers pass two to four dams in the lower Columbia on their downstream outmigration to the ocean. Upper Columbia River steelhead modeling results were used as a surrogate for middle Columbia River steelhead (refer to Section 3.5.3.4). Under MO2, modeling results predicted that survival from McNary to Bonneville would experience minor decreases, although populations that only pass two dams would likely see a smaller decrease, when compared to No Action Alternative, due to the removal of fish screens at McNary and John Day which would not affect those populations with natal streams below John Day Dam. Increased powerhouse passage events were also indicated by the model and would reduce juvenile survival. Operational and structural measures contributing to this decrease are discussed in Common Effects section.

*Adult Fish Migration/Survival*

Under MO2, lower spill would increase adult migration success compared to the No Action Alternative. Structural measures designed for juvenile fish passage improvements such as increased surface passage would also improve survival of kelts. However, the decrease in juvenile survival metrics may result in fewer returning adults. Refer to upper Columbia River steelhead analysis as a surrogate for middle Columbia River steelhead.

#### ***Snake River Salmon and Steelhead***

Snake River Spring/Summer-Run Chinook Salmon

*Summary of Key Effects*

Juvenile survival of in-river migrating fish would be lower than the No Action Alternative, though the models disagree somewhat on the magnitude of changes. MO2 would increase transportation of juvenile fish. The increased survival and faster travel time for this transported component of juveniles would help offset survival decreases of in-river fish when considered in the life cycle because more smolts would arrive at Bonneville Dam. The predictions of ocean survival and subsequent returns to the Columbia River system varies by model. The NWFSC LCM predicts slightly higher returns because more smolts would arrive at Bonneville Dam sooner, thus a higher number would survive the ocean phase and return. CSS predicts the benefit of transported juveniles would increase the number of smolts arriving at Bonneville, but lower ocean survival, likely due to increased latent mortality from the system experience. The CSS model ultimately predicts far fewer fish returning to spawning grounds compared to the No Action Alternative.

*Juvenile Fish Migration/Survival*

This ESU migrates through the Snake and Columbia Rivers downstream past the eight CRS projects, four on the Snake River, and four on the lower Columbia River. Structural and operational measures described in the Common Effects section that describe changes at all of these dams would apply to these fish. This includes structural measures designed to reduce the proportion of smolts passing through powerhouse routes and increase survival of smolts that do pass through the turbines, as well as measures to improve power generation that may increase smolt passage through these routes. Transport of smolts from the lower Snake River Projects would increase, but the effects of transportation from McNary Dam were not qualitatively evaluated by either the CSS or COMPASS models. See the Common Effects section for details.

For Snake River spring-run/summer-run Chinook salmon, both models indicated a decrease in juvenile survival and increased travel time and more powerhouse passages, but vary on the magnitude of change. TDG modeling indicates lower reach average exposure for juveniles. Table 3-82 displays the juvenile metrics for MO2 predicted by each of the models.

**Table 3-82. Juvenile Model Metrics for Snake River Spring/Summer-Run Chinook Salmon under Multiple Objective Alternative 2**

| Metric (Model) | NAA | MO2 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 50.4% | 50.1% | -0.3% | -1% |
| Juvenile Survival (CSS) | 57.6% | 53.7% | -3.9% | -7% |
| Juvenile Travel Time (COMPASS) | 17.7 days | 18.3 days | +0.6 days | +3% |
| Juvenile Travel Time (CSS) | 15.8 days | 17.5 days | +1.7 days | +11% |

| Metric (Model) | NAA | MO2 | Change from NAA | % Change |
|---|---|---|---|---|
| % Transported from Snake River (COMPASS) | 38.5% | 47.4% | +8.9% | +23% |
| % Transported from Snake River (CSS) | 19.2% | 33.8% | +14.6% | +76% |
| Transport: In-River Benefit Ratio (CSS) | 0.86 | 1.18 | +0.32 | +37% |
| Powerhouse Passages (COMPASS) | 2.25 | 3.02 | +0.77 | +34% |
| Powerhouse Passages (CSS) | 2.15 | 3.48 | +1.33 | +62% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 112.8% TDG | -2.3% TDG | -2% |

As described in Common Effects, the measures to increase juvenile fish transportation and decrease spill would result in more juveniles transported than the No Action Alternative. COMPASS, which uses only wild fish to assess transport, indicates the percentage of Snake River spring Chinook transported would increase from 38.5 percent in the No Action Alternative to 47.4 percent in MO2. CSS includes hatchery and wild fish both in the model and predicts 19.2 percent of all smolts would be transported under the No Action Alternative but increase to 33.8 percent under the No Action Alternative. CSS also predicts the benefit of being transported (the Transport: In-River Benefit Ratio) would increase from below one under the No Action Alternative to 1.18 under MO2. This means that, on average throughout the transport season, under the No Action Alternative fish left in-river would have overall better survival odds, but under MO2, it would be more beneficial to be transported. Neither model accounts for changes in proportion of the run that would be transported nor the additional effects if McNary Dam was used as an additional collection point. Further discussion of effects of transport later in the life cycle is in the following section on adult fish migration and survival.

*Adult Fish Migration/Survival*

The structural measure in MO2 to install pumping systems at Ice Harbor and Lower Monumental would benefit adult Snake River spring-run/summer-run Chinook salmon passage upstream if cooler water is available in the forebays. The reduced spill in MO2 may add benefit for adult migration with lower fallback rates, since fallback for this ESU has been associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). The fish that fell back were significantly less likely to reach their spawning areas compared to fish that never fell back.

The NWFSC LCM results indicated a very small increase in overall SARs (+0.02 percent) and that there would be an average of 11 percent increase in median adult abundances across all the Snake River spring-run/summer-run Chinook populations modeled relative to the No Action Alternative. CSS model results, however, indicate reduced SARs (-0.6 percent) and large decreases in abundances (-43 percent average, with a range among populations in the Grande Ronde/Imnaha major population group of -38 percent to -55 percent). These decreases are largely driven by a large decrease in ocean survival (2.8 percent in MO2, compared to 3.6 percent in the No Action Alternative). See Table 3-83 for a summary of model outputs.

**Table 3-83. Multiple Objective Alternative 2 Adult Model Metrics for Snake River Spring/Summer-Run Chinook Salmon**

| Metric (Model) | NAA | MO2 | Change from NAA | %Change |
|---|---|---|---|---|
| LGR-BON SARs (NWFSC LCM) | 0.88% | 0.90% | +0.02% | +3% |
| LGR-BON SARs (CSS) | 2.0% | 1.4% | -0.6% | -30% |
| Abundance of South Fork and Middle Fork Salmon River representative populations (NWFSC LCM) | 2,351 | 2,602 | +251 | +11% |
| Abundance of representative Grande Ronde/Imnaha River populations (CSS)[1] | 6114 | 3508 | -2606 | -43% |

[1] CSS provided results for six populations in the Grande Ronde/Imnaha Major Population Group. The absolute values represent those populations only; the percent change is considered indicative of the Snake River ESU for the purpose of comparing between MOs.

The differences in model assumptions and the resulting predictions discussed in the methods section (3.5.3.1) are applicable in understanding MO2 effects on Snake River spring/summer-run Chinook salmon. To calculate the smolt to adult return rate for the population, the NMFS LCM uses input metrics from COMPASS results such as juvenile survival and travel timing. The model continues to estimate a population's survival once the individuals pass Bonneville Dam, enter the ocean, rear and grow for several years, and then return as adults to Bonneville Dam. The model then adds an adult migration module that starts with the number of adults reaching Bonneville dam and computes expected survival on migration upstream to spawning grounds in the upper Snake River basin. It is important to remember that the juvenile survival indicated in the COMPASS metrics in the juvenile survival table applies to in-river travelling smolts only. Based on previous research, transported smolts are estimated to have a survival rate of 98 percent from Lower Granite to Bonneville, compared around 50 percent for in-river smolts. In MO2, the higher proportion of transported fish results in more smolts experiencing the higher transported survival rate.

Similarly, CSS also indicates a benefit to transported fish in this alternative when comparing the SARs between the two groups, likely due to decreased survival of in-river migrating fish in MO2.

One of the drivers of the LCM ocean survival module is the arrival timing of smolts to the ocean; because more smolts are transported, and transported fish have better initial survival rates and much faster arrival timing than in-river fish. The results from the model are increased abundance of adults arriving back to Bonneville Dam, as indicated by an increase in SAR. Timing is also important; generally speaking, fish transported later in the season experience better SARs than in-river fish. Earlier in the season, there is generally a higher benefit to in-river travel. Seasonal changes can be driven by reduced in-river survival due to increased predation and thermal stress.

The NWFSC LCM indicates a higher abundance of fish returning to spawning grounds because higher transportation rates increase SARs, especially later in the season, and those adults then experience higher migration success from Bonneville to spawning grounds. It is important to note, however, that the higher rate of transported smolts would result in more adults straying to different populations than their origin.

One major difference between the models is in the ocean survival module. CSS incorporates data indicating latent mortality that is dependent on the hydrosystem experience of each smolt. For MO2, ocean survival was predicted to decrease from 3.6 percent under the No Action Alternative to 2.8 percent. Latent mortality associated with powerhouse passage rates and increased travel time in the CSS model are the likely drivers in the different SAR predictions between the two models.

<u>Snake River Steelhead</u>

*Summary of Key Effects*

Juvenile survival of in-river migrating fish would be lower than the No Action Alternative; both models indicate decreases, though magnitude varies between the models. MO2 would increase transportation of juvenile fish; the increased survival and faster travel time for this transported component of juveniles would help offset survival decreases of in-river fish when considered in the life cycle. More smolts would arrive at Bonneville Dam. CSS predicts the benefit of transported juveniles would be higher but predicts lower SARs. Neither model was able to predict abundance. Adults would likely express higher rates of straying.

*Juvenile Fish Migration/Survival*

This DPS migrates through the Snake and Columbia Rivers downstream past eight CRS projects, four on the Snake River, and four on the lower Columbia River. Structural and operational measures described in the Common Effects section that describe changes at these dams would apply to these fish. This includes structural measures designed to reduce the proportion of smolts passing through powerhouse routes and increase survival of smolts that do pass through the turbines, as well as measures to improve power generation that may increase smolt passage through these routes at some dams. Transport of smolts from the lower Snake River Projects would be increased but the effects of transportation from McNary Dam were not evaluated by either the CSS or the COMPASS models. See the Common Effects section for details. For Snake River steelhead, both models indicated a decrease in juvenile survival, increased travel time and more powerhouse passages, but vary somewhat on the magnitude of change. TDG modeling indicates lower reach average exposure for juveniles, and a reduction in juvenile mortality associated with TDG exposure. Table 3-84 displays a summary of the juvenile metrics:

**Table 3-84. Multiple Objective Alternative 2 Juvenile Model Metrics for Snake River Steelhead**

| Metric (Model) | NAA | MO2 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 42.7% | 40.2% | -2.5% | -6% |
| Juvenile Survival (CSS) | 57.1% | 44.4% | -12.7% | -22% |
| Juvenile Travel Time (COMPASS) | 16.4 days | 16.9 days | +0.5 days | +3% |
| Juvenile Travel Time (CSS) | 16.2 days | 17.2 days | +1.0 days | +6% |
| % Transported (COMPASS) | 39.7% | 47.7% | +8.0% | +20% |
| % Transported (CSS) | N/A | | | |
| Transport: In-River Benefit Ratio (CSS) | 1.41 | 2.23 | +0.82 | +58% |

| Metric (Model) | NAA | MO2 | Change from NAA | % Change |
|---|---|---|---|---|
| Powerhouse Passages (COMPASS) | 1.73 | 2.26 | +0.53 | +31% |
| Powerhouse Passages (CSS) | 1.96 | 3.26 | +1.30 | +66% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 112.7% TDG | -2.4% TDG | -2% |

As described in Common Effects, the measure to increase juvenile fish transportation and decreased spill would result in more juveniles transported than the No Action Alternative. COMPASS, considering only wild fish in the equation, indicates the percentage transported would increase from about 40 percent to about 48 percent. CSS did not provide an estimate of proportion transported, but predicts the Transport: In-River Benefit Ratio would increase from 1.41 under the No Action Alternative to 2.23 under MO2. Steelhead experience higher benefits from transportation than Snake River spring-run/summer-run Chinook salmon.

On average throughout the transport season, under the No Action Alternative transported fish would have long-term survival advantages over in-river fish, and under MO2 the difference in this metric would be larger (i.e., higher survival benefits for transported fish). Neither of the models account for changes in the proportion of the run that would be transported, nor the additional effects if McNary Dam was used as an additional collection point. Further discussion of effects from transport later in the life cycle is in the following section on adult fish migration and survival.

*Adult Fish Migration/Survival*

CSS cohort modeling estimated smolt to adult return (SAR) estimates from Lower Granite to Bonneville would decrease from 1.8 percent under the No Action Alternative to 1.2 percent in MO2. Lower SARs would indicate that total abundance of adult steelhead would decrease as well. No other life cycle modeling was available.

Qualitatively speaking, the benefit of transport would be higher (i.e., resulting in higher SARs for transported fish) in MO2, and more fish would be transported as juveniles, which could increase the ocean survival of steelhead, but it is unknown if the benefit of transport would sufficiently overcome the reduction in in-river survival to increase or decrease adult returns. Conversely, CSS modeling predicted decreased ocean survival (2.5 percent compared to 2.9 percent in the No Action Alternative) that would result in lower abundances of adult returns. Higher proportions of fish that were transported as juveniles may increase the rate of straying in adult returns. Keefer and Caudill (2012) reported a 2 to 7 percent stray rate for non-transported steelhead vs. 7 to 9 percent among transported fish.

Transportation has been shown to provide a benefit to steelhead. Full life cycle modelling from COMPASS was not available, however, modelled data shows that MO2 would increase transportation rates by 8 percent and result in increased return rates at Lower Granite Dam, in the absence of latent mortality effects predicted in the CSS model.

Lower spill levels during April and May would likely result in lower survival rates for adult steelhead falling back through dams and kelts migrating downstream, as more adults would use powerhouse passage routes that are generally associated with lower survival rates (Normandeau et al. 2014; Ham et al. 2012).

<u>Snake River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon as a surrogate for juvenile Snake River coho salmon and Snake River fall-run Chinook as a surrogate for adult Snake River coho salmon.

*Summary of Key Effects*

Juvenile Snake River coho salmon survival would decrease in MO2, but the models predict different magnitudes of decrease for the surrogate species (Snake River spring/summer-run Chinook salmon). Juveniles would experience more powerhouses and have slower migration times, and more juveniles would be transported than under the No Action Alternative. These transported juveniles would experience higher survival than in-river fish.

*Juvenile Fish Migration/Survival*

Refer to MO2 Snake River juvenile spring Chinook results as a surrogate for Snake River Coho Salmon.

*Adult Fish Migration/Survival*

Abundance of Snake River coho salmon was not modeled, but some inferences can be made from life cycle modeling of Snake River spring/summer-run Chinook salmon. This ESU was used as a surrogate for Snake River coho salmon juvenile metrics, indicating more coho salmon would be destined for transport than in the No Action Alternative. The net effect of these factors under MO2 on coho salmon returns is uncertain. If greater survival of transported fish was offset by decreased juvenile survival, there could be minor net increase of adults. If latent effects of powerhouse encounters decrease ocean survival, there would be fewer adults.

<u>Snake River Sockeye Salmon</u>

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for Snake River sockeye salmon.

*Summary of Key Effects*

The key effects of MO2 are the slightly slower migration time that puts juvenile sockeye at greater risk of predation. Although the proposal for transporting juveniles might improve survival for that life stage, this action is likely to cause a greater rate of fallback and straying of adults on their upstream migration compared to the No Action Alternative. Overall abundance of returning fish would depend on how increased transport, later arrival timing, and any latent effects from increased powerhouse encounters affect ocean survival.

*Juvenile Migration/Survival*

MO2 is expected to result in a slightly slower migration time for juvenile sockeye (approximately one day) based on modeling results for surrogate species juvenile Snake River spring-run Chinook because they migrate downstream at approximately the same time of year. Travel rates for juvenile sockeye are typically faster than yearling Chinook and therefore the use of this surrogate may provide a conservative estimate. See upper Columbia River sockeye salmon (Section 3.5.3.2) for additional travel time information compared to yearling Chinook salmon that migrate through the middle Columbia River. Spill rates under MO2 may contribute to a slower travel time, and the proportion of fish going through the powerhouse would be higher.

It is assumed that slower travel times result in lower survival rates due to greater swimming effort and longer duration of exposure to predators. Predation by fish in reservoirs would continue to occur at the same rate as in the No Action Alternative based on water temperature, which is used as an index to estimate predator activity. However, based on the slightly slower travel time as described above, juvenile sockeye salmon would have a slightly longer exposure time for risk of predation in MO2. Among bird predators, their nesting population is expected to be the same as in the No Action Alternative, but again the slower travel time would put the juvenile sockeye at greater risk of exposure.

*Adult Migration/Survival*

In MO2, the surrogate species for Snake River sockeye salmon, Snake River spring/summer-run Chinook salmon, would have approximately a 10 percent increased rate of transportation as juveniles compared to the No Action Alternative. This substantial increase in transport would likely lead to a proportional increase in the adverse effects for the adult fish that were transported as juveniles. These adverse effects would include impaired ability to find their birth streams (i.e., homing ability), migration delay, increased fallback, and straying. This impaired homing ability may contribute to higher un-intentional catch during other fisheries in the lower Columbia River, and can be lethal during warm water years (NMFS 2015).

The summer water temperatures in the river during the upstream migration would not change from the No Action Alternative, nor would the percentage of days in which the ladder temperature would be more than 2 degrees Celsius warmer than the river temperature. However, Dworshak Reservoir operations would be affected such that the probability of refilling the reservoir would be lower, resulting in higher risk of not having enough water in the reservoir to provide summer cooling water. In MO2, fewer days per year would have TDG over 120 and 125 percent at all projects. This change is substantial enough that MO2 would have fewer adverse effects from TDG on Snake River sockeye compared to the No Action Alternative. The other important water quality parameters of suspended sediment and DO would have no change compared to the No Action Alternative.

Snake River Fall-Run Chinook Salmon

*Summary of Key Effects*

Although the proposal for transporting juveniles might improve survival for that life stage, this action is likely to cause a greater rate of fallback and straying as adults on their upstream migration compared to the No Action Alternative.

*Larval Development/Juvenile Rearing*

None of the measures of MO2 would change the substrate sizes or distribution in the spawning areas or expand suitable spawning areas; therefore, this alternative is expected to have the same larval development and juvenile rearing habitat conditions as the No Action Alternative. The same is true for river depths in the spawning areas; no change is anticipated for eggs incubating in the gravel. MO2 would not have a measurable difference compared to the No Action Alternative for juvenile Chinook rearing in reservoirs; therefore, their visual cover from predation would not change.

*Juvenile Migration/Survival*

None of the measures in MO2 would affect turbidity during juvenile Chinook outmigration months of May through July. The combination of structural measures intended to improve juvenile survival and operational and structural measures that would decrease survival would likely result in a net decrease in juvenile survival. See the Common Effects section of MO2 for a description of these measures.

*Adult Migration/Survival*

Adult straying rate is expected to increase in MO2 due to the operational measure to maximize transport. This would reduce the total number of adult fall-run Chinook returning to the Snake River because of the expected increase in rate of straying and fallback. Depending on the overall transport to in-river benefit ratio, this may cause a decrease in adult returns to spawning areas of the Snake River basin.

River water temperatures during the upstream migration period are expected to be the same as in the No Action Alternative. The same is true for the temperature difference between the river and the fish ladders. However, the probability of Dworshak filling would be lower in MO2, resulting in more years where the volume of water required for cooling the Snake River with Dworshak water would not be sufficient. This would affect the early part of the Snake River fall Chinook salmon run. There would be no change to sediment concentrations or DO levels from any measures in MO2 during the adult migration period.

***Lower Columbia River Salmon and Steelhead***

Lower Columbia River Chinook Salmon

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for lower Columbia River Chinook salmon.

*Summary of Key Effects*

Juvenile survival and travel time would be similar to the No Action Alternative, with slight increases in modeled metric of surrogate species (Snake River spring/summer-run Chinook salmon), but slight decreases in qualitative analysis. Adult migration and survival would be expected to be higher with lower flows, lower spill, and lower TDG.

Results (and change from the No Action Alternative) for metrics for Lower Columbia River Chinook salmon:

- Negligible increase in juvenile project survival at Bonneville Reservoir and Dam (see surrogate species Snake River spring-run/summer-run Chinook) = (+0.5 percent)
- Bonneville outflows, April-June = (-1 percent to -2 percent)
- Bonneville outflows, August-September = (August: -1 percent to -2 percent, September: +1 percent to +2 percent)
- Spill, Bonneville = April (-42 to -28kcfs), May (-40kcfs), August (-87kcfs)
- Temperature, The Dalles, days exceeding state standard = 71 days (0 days)
- Temperature, Bonneville, days exceeding state standard = 57 days (-1 day)
- TDG, The Dalles, days exceeding state standard = 11 days (-22 days)
- TDG, Bonneville, days exceeding state standard = 46 days (-18 days)

*Juvenile Fish Migration/Survival*

Five of the 32 populations of Lower Columbia River Chinook salmon pass Bonneville Dam on their downstream outmigration to the ocean. Modeling was not available for this ESU so juvenile survival at Bonneville Dam of Snake River spring-run/summer-run Chinook salmon was used as a surrogate of juvenile survival for the proportion that pass this project. COMPASS modeling under MO2 predicted similar juvenile survival through the Bonneville Dam compared to No Action Alternative, which is consistent with the expectation that lower spill at Bonneville Dam could result in slightly higher survival.

Outflows can influence juvenile outmigration if changes in flows are enough to noticeably affect travel time, and therefore survival. Hydrology modeling predicts spring-run and late-fall-run fish would experience outflows about 1 to 2 percent lower than the No Action Alternative. Fall-run fish outmigrate in late summer and may see flows 1 to 2 percent lower than the No Action Alternative except in September when flows would be 1 to 2 percent higher than the No Action

Alternative. Changes of this magnitude would likely be imperceptible on effects to juvenile outmigration. Likewise, water quality modeling indicated there would not be a perceptible change in temperature in the lower river with MO2 operations, and TDG would be lower than under the No Action Alternative.

*Adult Fish Migration/Survival*

MO2 does not include the structural measure to modify the upper ladder serpentine sections at Bonneville Dam seen in other MOs. Lower spill in MO2 would decrease fallback rates and lower TDG could reduce impacts on adults. Hydrology and water quality modeling predicts flows and temperatures that could affect lower Columbia River Chinook salmon adult migration and survival would be similar to the No Action Alternative.

<u>Lower Columbia River Steelhead</u>

Refer to Snake River steelhead analysis as a surrogate for lower Columbia River steelhead.

*Summary of Key Effects*

Juvenile survival would be similar to or slightly lower than the No Action Alternative, with similar modeled dam survival but slightly reduced flows in March and slower travel time. Adult migration of a portion of the winter run could be decreased slightly with higher winter flows, and survival of kelts would be lower with reduced spill, although lower TDG may increase survival.

MO2 results (and change from the No Action Alternative) for metrics for Lower Columbia River steelhead:

- Negligible decrease in juvenile project survival, Bonneville Reservoir and Dam (see Snake River steelhead [used as a surrogate]) = (-0.1 percent)
- Bonneville outflows, March = (-4 percent), April-June = (-1 percent to -2 percent)
- Bonneville outflows, November-December = (+3 to +7 percent), otherwise (+/- 0 to 2 percent)
- Spill, Bonneville = April through June = (-28kcfs to -39kcfs), August (-87kcfs)
- Temperature, The Dalles, days exceeding state standard = 71 days (0 days)
- Temperature, Bonneville, days exceeding state standard = 57 days (-1 day)
- TDG, The Dalles, days exceeding state standard = 11 days (-22 days)
- TDG, Bonneville, days exceeding state standard = 46 days (-18 days)

*Juvenile Fish Migration/Survival*

Four of the 23 populations of Lower Columbia River steelhead pass Bonneville Dam on their downstream outmigration to the ocean. Modeling was not available for Lower Columbia River steelhead, so juvenile survival at Snake River steelhead was used as a surrogate of juvenile survival through the Bonneville project (pool and dam) for this portion of the DPS. COMPASS modeling predicts a negligible decrease or similar juvenile survival under MO2 compared tothe No Action Alternative. Four percent lower outflows in March and generally lower spill may reduce juvenile migration success; the remainder of the outmigration period would be similar (-1 percent to -2 percent) to the No Action Alternative. Temperatures would be similar to the No Action Alternative, and TDG would be lower with reduced spill.

*Adult Fish Migration/Survival*

MO2 does not include structural measures for adult passage improvements for Lower Columbia River steelhead. Under MO2, lower spill through spring and summer and spill reduction in August would lower survival rates for adult kelts, but generally reduce adult fallback and delay. A higher proportion of kelts moving downstream would pass Bonneville Dam via turbines, which have lower survival rates than spill. Winter run steelhead migrating in December would experience flows about 7 percent higher than the No Action Alternative. Otherwise, adult passage conditions due to flows would be similar to the No Action Alternative. Temperatures would be similar to the No Action Alternative, and adult fish would generally experience lower TDG, with 18 to 22 more days under the state water quality standard than the No Action Alternative.

<u>Lower Columbia River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile Lower Columbia River coho salmon and Snake River fall-run Chinook salmon as a surrogate for adult Lower Columbia River coho salmon.

*Summary of Key Effects*

Lower Columbia River coho salmon juvenile survival and adult migration factors would be similar or slightly better than the No Action Alternative based on surrogate information. Juvenile survival would have negligible to minor decreases. TDG exposure would be lower, and temperatures would be cooler around Bonneville Dam.

*Juvenile Fish Migration/Survival*

Juvenile survival of Lower Columbia River coho salmon passing Bonneville Dam, based upon project survival of Snake River spring/summer-run Chinook salmon as a surrogate, would have negligible to minor decreases in MO2, relative to No Action Alternative. Generally speaking, lower spill at Bonneville Dam results in higher survival through the dam. Refer to Snake River spring-run Chinook for surrogate information (Section 3.5.3.5).

*Adult Fish Migration/Survival*

Lower Columbia River coho salmon adults are similar in upstream migration characteristics to Snake River fall-run Chinook salmon and were used as a surrogate; Snake River fall-run Chinook salmon were analyzed in workshops using modeled water quality and hydrology data. The results of modeled water quality and hydrology data depicted that water temperatures around Bonneville Dam may be slightly cooler under MO2 compared to the No Action Alternative and could benefit upstream migrating Lower Columbia River coho salmon. MO2 operational changes would not change the number of days when lower Columbia River water temperatures in reservoirs would exceed 20°C and/or fish ladder temperature differentials exceed 2°C, cause adult salmon to stop or delay migration, increase fallback at dams, and increase susceptibility to disease Refer to Snake River fall-run Chinook for surrogate information in Section 3.5.2.4.

Lower Columbia River Chum Salmon

Refer to Snake River spring/summer-run Chinook salmon analysis as a surrogate for Columbia River chum salmon juvenile dam passage.

*Summary of Key Effects*

MO2 operations would result in more difficulty in meeting chum flows, with a 3 percent increase, compared to the No Action Alternative, of years where the flows could not be met downstream of Bonneville Dam without additional drafting of Grand Coulee. Juvenile outmigration could be slower due to decreased outflows in March, and the small proportion that pass Bonneville Dam would experience negligible increased survival at the dam. Adult migration and survival would likely be similar to the No Action Alternative.

*Larval Development/Juvenile Rearing*

How operations under MO2 affect the ability of Grand Coulee to provide winter flows to protect chum redds and provide sufficient access to habitat was calculated using hydrology modeling. Under MO2, chum flows would be met in 89 percent of years, compared to 92 percent of years in the No Action Alternative. In years when additional releases from Grand Coulee for chum would be needed, the average additional volume needed would be 0.12 million acre-feet (Maf). MO2 would result in 3 percent more years where chum flows would not be met, and agencies would thus have to decide whether to increase risk to chum eggs or reduce spring augmentation flows for spring migrating juvenile salmon.

Maintaining water saturation of 105 percent TDG or less from November 1 to April 30 appears to provide a sufficient level of protection to chum salmon eggs and sac fry incubating in the gravel downstream of Bonneville Dam in the Ives/Pierce Island Complex. In MO2, chum sac fry would be exposed to TDG above 105 percent in four out of the 80-year record modeled, all in the mid- to late April timeframe. This is one year less than the No Action Alternative where this TDG threshold would be exceeded.

*Juvenile Fish Migration/Survival*

Chum salmon only encounter one CRS project, Bonneville Dam; therefore, none of the structural measures described in common effects would apply to these fish, and only a small proportion of spawning occurs above Bonneville Dam. As there is no direct estimate of

Bonneville Dam survival specific to juvenile chum, juvenile model metrics for Snake River spring-run/summer-run Chinook salmon are used as a surrogate to estimate any change in juvenile survival for the portion that pass Bonneville.

Bonneville Dam outflows would be about 4 percent lower than the No Action Alternative in March, when chum juveniles begin outmigration. This could result in a minor increase in their travel time, thus increasing exposure to predation. Under MO2, COMPASS modeling of the surrogate species, Snake River spring/summer-run Chinook salmon, indicates that CRS operational changes are expected to result in negligible increases in survival for juvenile fish passing downstream of Bonneville Dam compared to the No Action Alternative. MO2 would not change the outmigration conditions for juvenile chum that spawn below Bonneville Dam, other than they may experience lower TDG than under the No Action Alternative.

*Adult Fish Migration/Survival*

Most chum spawn downstream of Bonneville Dam. Upstream migration of chum into the Columbia River occurs in October and November. Bonneville Dam average monthly outflows would be about 3 percent lower than the No Action Alternative in October, while in November they would be about 3 percent higher than the No Action Alternative. Adults spawning in December would encounter outflows about 7 to 13 percent higher than the No Action Alternative.

**Other Anadromous Fish**

***Pacific Eulachon***

<u>Summary of Key Effects</u>

Eulachon would continue to migrate into the Columbia River from November through March, with specific dates of migration and spawning based on a variety of environmental factors including temperature, high tides, and ocean conditions (NMFS 2017). Modeled data for MO2 (based on the period of record for Bonneville tailwater temperatures) indicate that temperatures would not be substantially different from the No Action Alternative (all temperatures would be within 0.6 degrees of the No Action Alternative.) Spawning locations and substrate conditions would not be expected to differ from the No Action Alternative.

Compared to the No Action Alternative, MO2 would have no change in the time between the peak spawning runs, egg development, and larval emergence. The spring freshet that disperses larvae to adequate food sources would continue to be highly variable, with an average of 168 days between spawning temperature triggers and peak flows (157 days in high flow years, and 158 days in low flow years).

Spring flow rates would be expected to be about 1 percent to 2 percent lower during outmigration compared to the No Action Alternative.

Bird predation risk can be influenced by flow rates. Higher flows are linked to higher predation rates on eulachon, whereas at lower flows birds tend to switch to marine prey. Under MO2, there would be a minor change (2 to 6 percent) in all months and water year types (the change is low enough to be likely immeasurable). Higher flows in winter (November to January) could pose a minor increase in predation risk when the bulk of the eulachon run is migrating up the Columbia River.

***Green Sturgeon***

Summary of Key Effects

The Columbia River use by green sturgeon is primarily foraging habitat for adults and subadults. Key effects of MO2 are focused on how flows and temperatures influence the cues for entering the Columbia River as well as the availability and distribution of food sources. Under MO2, flows in the area used by green sturgeon would be similar to the No Action Alternative (0 percent to 2 percent variation). Modeled flows indicate flows could be slightly higher in September (+2 percent), and lower in October (-2 percent), which could result in minor shifts in location for feeding from downstream in September to further upstream in October.

***Pacific Lamprey***

Summary of Key Effects

MO2 has several measures that are designed specifically to benefit lamprey. These measures are proposed structural improvements that include converting extended-length submersible bar screens to submersible bar screens, expanding the network of Lamprey Passage Structures to bypass impediments in fish ladders, changing the design for turbine cooling water strainers, replacing turbines for safer fish passage, and other physical modifications to reduce fish injury and mortality.

Larval Development/Juvenile rearing

MO2 has no measures that would either benefit or harm juvenile lamprey rearing. All ramping rates and dewatering issues would be the same in this alternative as for the No Action Alternative.

Juvenile Migration/Survival

A substantial amount of injuries and mortality can occur for outmigrating juveniles on their downstream migration including impingement on screens. Several measures would improve conditions and reduce injuries and losses. These measures are also in MO1 and their effects are described in more detail in the lamprey section in that alternative. Briefly, the measures and their anticipated effects would be:

- Converting the extended-length submersible bar screens to submerged traveling screens would substantially reduce mortality due to impingement.

- A new design of structure for exclusion of juvenile lamprey from cooling water strainer intakes would substantially reduce or eliminate this pathway of mortality.
- Additional powerhouse surface passage at Ice Harbor and McNary Projects would change the dynamics of lamprey passage. A higher percentage of lamprey would be expected to pass via the surface routes instead of the turbines in relation to the No Action Alternative, but the overall relative effect to juvenile lamprey passage is unknown.
- Replacing turbines at John Day Project with a newer design of turbine would improve conditions for fish passage and reduce the injury rate for lamprey.
- Ceasing the installation of fish screens at Ice Harbor, McNary, and John Day Projects would eliminate the effects of lamprey impingement on screens.

Because of the high degree of uncertainty surrounding how many juvenile lamprey are lost or injured on their downstream migration, it is difficult to quantify the improvement represented by all of the measures. For fish that encounter multiple dams on their migration downstream, reducing the total number of hazards would increase their probability for survival to adult life stage.

<u>Adult Migration/Survival</u>

Similarly, there are measures in MO2 that were also in MO1 and that improve adult lamprey passage. These include:

- Expanding the network of lamprey passage structures would improve lamprey passage.
- Modify the upper ladder serpentine flow control ladder sections at Bonneville Dam would reduce migration delays caused by baffles in this section.
- Adding cooler water in the fish ladders at Lower Monumental and Ice Harbor would be expected to benefit lamprey because this has been successful at Little Goose and Ice Harbor.
- Modifications to Lower Monumental include diffuser grate plating. This has been done at all other ladders except Lower Monumental and demonstrated slight benefits to lamprey passage.

Each structural measure in MO2 that targets lamprey is intended to increase their dam passage efficiency either by getting fish to enter rather than turn back from the fishway, or to increase successful passage to continue migrating. See MO1 for more details on effects of these measures. Collectively they would provide incremental improvements to adult migration and survival.

The overall expected improvements in lamprey passage efficiency should decrease susceptibility to physical stress and mortality, and shorter holding time would be beneficial to the fish. These structural measures for lamprey are expected to provide an incremental benefit to the population size and distribution of Pacific lamprey in the Columbia Basin. Compared to the No Action Alternative, all proposed structural measures to reduce losses would have benefits to the population and recruitment to the next generation. The combined effect of all proposed structural modifications would be a substantial improvement for lamprey survival and fitness. However, most of the water management and water supply operational measures have no benefit and might make migration conditions worse for juvenile lamprey compared to the No Action Alternative.

***American Shad***

<u>Summary of Key Effects</u>

No change is anticipated to juvenile shad because plankton communities and shoreline habitat would not change in MO2. The proportion of adult shad counted at Bonneville Dam that migrate upstream past McNary Dam is expected to increase under this alternative due to decreases in outflows during shad migration months.

**RESIDENT FISH**

**Region A**

***Kootenai River Basin***

<u>Summary of Key Effects</u>

MO2 would have the same key effects as the No Action Alternative. Discharges from Libby Dam would continue to have detrimental effects to fish species in the Kootenai River downstream of Libby Dam. Spring water temperatures would continue to be too cold for optimum development of some aquatic species. Spring flows would also continue to increase at a rate similar to the No Action Alternative, with ongoing delay and impaired productivity associated with inundated riparian and varial zone habitats in the river corridor from the dam to Kootenay Lake in British Columbia. These reduced flow rates would also continue to limit productivity and may adversely impact kokanee and their food sources downstream of Libby Dam.

Under the MO2, cottonwood seedlings would continue to have variable survival depending on timing, stage and duration of spring flows, along with winter stage during the ensuing winter. In addition, the discharge regime from Libby Dam would not provide for successful burbot recruitment, and spring water temperatures would be too cold to allow for proper larval development.

<u>Habitat Effects Common to This Fish Community</u>

MO2 would not change water temperatures in the spring from those under the No Action Alternative. However, MO2 would provide deeper end-of-December drafts than the No Action Alternative, with deep drafts of 26.7 feet in some years that may enhance reservoir warming during the spring and early summer.

Under MO2 there would be a lower rate of flow increase from Libby Dam between mid-March and mid-May than the No Action Alternative This decrease in flow rate under MO2 would result in a greater delay in commencement of river productivity than under the No Action Alternative.

MO2 would decrease the potential for cottonwood and willow seeding and recruitment compared to the No Action Alternative. Under MO2, there would be fewer days when the winter peak stage does not exceed the seeding peak stage. There would also be a smaller difference in river elevation between the winter and spring peak stage at Bonners Ferry when compared to the No Action Alternative.

MO2 would not differ from the No Action Alternative in the rate of recession of river stage at Bonners Ferry during the seeding season.

Bull Trout

Effects to bull trout under MO2 that differ from those of the No Action Alternative include lower minimum and maximum water levels at Lake Koocanusa, lower flows below Libby Dam, less habitat for adult bull trout, but more habitat for juvenile bull trout.

Under MO2, Lake Koocanusa would be above elevation 2,450 feet for two more days than under the No Action Alternative. This short period would not be sufficient to have different effects on the Bull trout population than the No Action Alternative.

The median minimum elevation of Lake Koocanusa under MO2 would be 11 foot lower than under the No Action Alternative, but the drier forecast years could be ten to twenty feet deeper. These elevations would increase the risk of annual dewatering and decrease benthic insect production, which could result in a decrease in bull trout growth and/or survival. However, in wet years, MO2 would provide a shallower draft and may be more beneficial to benthic insect production during those years. At the same time, the maximum elevation of Lake Koocanusa under MO2 would be 1 foot higher than under the No Action Alternative. This may result in slightly higher terrestrial insect deposition under MO2.

Under MO2, Libby Dam would provide discharge of 20 kcfs or greater for two less days than under the No Action Alternative. These flows would be insufficient to mobilize or reshape tributary deltas that can prevent bull trout access during the late summer and early fall. MO2 would have lower discharges than the No Action Alternative and would provide less usable habitat for adult bull trout, but more usable habitat for juvenile bull trout than the No Action Alternative.

Kootenai River White Sturgeon

On average, MO2 would provide one less day than the No Action Alternative when flows are greater than or equal to 30 kcfs at Bonners Ferry between May 15 and July 15. This reduction in the number of days with high flows would not differ biologically in the number of spawning adult Kootenai River white sturgeon that migrate to spawning habitat upstream of Bonners

Ferry when compared to the No Action Alternative. However, in dry water years, flows would be more than 24 percent lower during this critical period and could reduce the spawning and recruitment of Kootenai River white sturgeon.

Other Fish

The median minimum elevation of Lake Koocanusa under MO2 would be one foot, but the drier forecast years could be ten to twenty feet lower. These conditions would have the same effects identified in the discussion above for bull trout.

Under MO2, there would be fewer days when Libby Dam would provide a discharge of 20 kcfs or greater when compared to the No Action Alternative. In addition, the mean flow rate under MO2 would be less than under the No Action Alternative. These flows would be insufficient to mobilize or reshape tributary deltas that can prevent bull trout access during the fall spawning season.

MO2 would have slightly lower discharges from Libby Dam for the period May 15 to September 30 than the No Action Alternative but would provide slightly more usable habitat for juvenile and adult redband rainbow trout than the No Action Alternative. Higher usable habitat may result in increased growth and/or survival of all life stages of redband rainbow trout.

Changes in effects to burbot under MO2 include reduced flows. Median flows under MO2 as measured at Bonners Ferry between January 1 and April 30 would be lower than those under the No Action Alternative. These flows would be more likely than the No Action Alternative to provide the low and stable flows that imitate pre-dam hydrographs during burbot spawning and incubation, and thus most conducive to successful burbot recruitment.

***Hungry Horse/Flathead/Clark Fork Fish Communities***

Summary of Key Effects

The key effects of MO2 are largely biological responses to changes in Hungry Horse Reservoir elevations and outflows to provide additional power generation in winter. Benthic insect production important to fish would be appreciably decreased under MO2. Lower surface elevations could also increase issues with predation/exploitation risk as fish migrate into and out of tributaries to fulfill their life cycles, although bull trout would likely not be as affected because of their migration timing. Increased outflows in winter would likely result in increased entrainment of zooplankton and fish out of Hungry Horse reservoir. Winter habitat and food supply would be adversely affected in the South Fork Flathead River and mainstem Flathead River. MO2 would have negligible effects on Flathead Lake fish other than to populations that migrate into the Flathead River, and fish in the lower Flathead River and Clark Fork Rivers would encounter more stressful conditions due to flow fluctuations and increased winter flows.

Habitat Effects Common to This Fish Community

Winter elevations would be lower than the No Action Alternative. In wet and average years, deeper drafts in winter would result in much lower elevation upon starting refill, so with all year types considered, there would be a 67 percent annual probability of reaching elevation 3,559 feet by July 31, meaning 8 more years more out of 100 that would not reach full compared to the No Action Alternative. In fall months, the elevation would be the same as the No Action Alternative, but beginning in January, MO2 reservoir elevations in wet and average years would be steeply drafted, ending the draft about seven lower than the No Action Alternative. Elevations from February through April would be 4 to 8 feet lower than the No Action Alternative. Dry year elevations would be similar through the fall and winter.

Zooplankton would continue to be entrained into the South Fork Flathead River from Hungry Horse reservoir. The zooplankton enhances food supply in the South Fork Flathead River and along the near bank of the Flathead River but decreases food supply for fish in Hungry Horse Reservoir. Outflows, and therefore zooplankton entrainment, under MO2 would be roughly double the loss as compared to the No Action Alternative in January and into February, and see spikes in entrainment when flows peak and drop in April and May. Fish entrainment would also follow a similar pattern.

Outflow patterns from Hungry Horse Reservoir can also affect insect production and the habitat conditions, such as river elevation (stage), velocities, and temperatures in the river. These effects continue downstream to affect the main Flathead River in the same patterns, but somewhat attenuated by the flows in the mainstem Flathead. Temperatures in summer are regulated with a selective withdrawal structure that is operated to release water of a temperature that favors native fish. The temperature control structure would continue to operate in summer under MO2 operations. In winter, the temperature control structure is not operated, and MO2 January and February outflows would be roughly double (or more in some year types) compared to the No Action Alternative. Extreme fluctuations between high and low flows would disrupt the production of aquatic insects every time flows are increased for a time and then dropped again. Due to the removal of ramping rate restrictions there could potentially be large fluctuations in outflows throughout the year that would cause disruptions to the aquatic insects; successful recruitment of these important food sources would likely fail. These extremes in flows in winter would also substantially reduce habitat for native fish due to increased velocities making much of the habitat unsuitable.

In the Flathead River down to Flathead Lake, habitat suitability is a key issue due to extremely high flows in winter and in late summer. Under MO2, January outflows in wet years would nearly double compared to the No Action Alternative. Winter flows of that magnitude could decrease the amount of suitable habitat for native fish by over 30 percent in wet years and over 20 percent in average years (Muhlfeld et al. 2011). Higher-than-normal winter flows would continue to limit establishment of riparian vegetation important to fish, and spring peaks only slightly lower than the No Action Alternative would continue to occasionally provide flushing of sediments from gravels to maintain habitat. Summer temperatures would continue to be similar to the No Action Alternative because the temperature control structures would continue to operate. Higher flows in winter would increase the proportion of South Fork Flathead River flows in the mainstem Flathead River; this would increase the temperature in the mainstem Flathead River because South Fork Flathead River flows would be warmer than mainstem flows.

Increased temperatures in winter could favor non-native fish over native fish, such as bull trout and westslope cutthroat trout, due to changes in productivity and metabolism. the Similar to the South Fork Flathead River described in the preceding paragraph, the removal of ramping rate restrictions there could potentially be large fluctuations in outflows throughout the year that would that would cause disruptions to the aquatic insect production in the mainstem Flathead River as well as increase stress on fish seeking out suitable habitat.

The winter water temperature warming influence from the contribution of the South Fork Flathead River would be higher in MO2 with higher winter outflows. The increased flows in the South Fork Flathead would contribute a greater proportion of reservoir water that would be warmer than river water, resulting in a larger departure from normalized temperatures than the No Action Alternative. TDG in the Flathead River would be similar to the No Action Alternative, continuing to fluctuate with spill at Hungry Horse Dam but generally would not exceed 117 percent, which is within a safe zone for fish.

The influence of MO2 changes to Flathead Lake levels would be minimal. Median outflows in January would be 43 to 53 percent higher than the No Action Alternative, and February median flows would be 6 to 19 percent higher. Median April, May and June flows would be 4 to 6 percent lower, and increased fluctuations would be expected compared to the No Action Alternative. In lower flow years, median summer flows would also be 5 to 6 percent lower.

<u>Bull Trout</u>

Under MO2, Hungry Horse Reservoir summer phytoplankton and zooplankton production would be minimally affected compared to the No Action Alternative. However, failing to refill more often than the No Action Alternative would result in a smaller area for aquatic insect production in those years, and steep drafts in winter would greatly reduce production of aquatic insects. Insects that had overwintered for the following spring would not be available for juvenile bull trout moving into the reservoir in the spring, and prey base for adult bull trout would be reduced. The lower reservoir elevations would result in a decrease greater than 4 to 8 percent of surface area for benthic insect production all winter, especially in the bays at the upper ends of the reservoir lobes, and the steep drops would reduce the production of the large, 2-year invertebrates. Juvenile bull trout moving into the reservoir in the spring rely on the benthic insects until they transition to eating fish. The prey items that adult bull trout eat also consume the benthic insects and may be in poorer condition or less plentiful in areas. Zooplankton are an important winter food source for bull trout so increased entrainment of zooplankton would decrease their food supply in January and February. These changes in food sources could result in bull trout being in poorer condition.

Under MO2, elevations in August or September would be either similar to the No Action Alternative or slightly higher (in dry years). Varial zone effects to bull trout would be similar to the No Action Alternative.

Bull trout entrainment through the dam would likely increase in MO2 due to increased outflows in winter. Entrainment would be about double the No Action Alternative in January in wet and average years and February of wet years. Lower monthly outflows in spring would likely result in lower entrainment in April through June. Bull trout are likely to be near the dam during overwintering, but they would not be as concentrated there as they would be in late summer months. Late summer entrainment would be similar to the No Action Alternative. Entrainment has not been quantified but would be expected to increase under MO2 compared to the No Action Alternative.

The number of individual bull trout in the South Fork Flathead River below Hungry Horse Reservoir may increase with greater entrainment, but these would be lost from their spawning populations, and would be deposited in the South Fork Flathead River during high flows that limit habitat suitability. Zooplankton available in the South Fork Flathead River may increase in winter with higher outflows, but aquatic insect production would be heavily disrupted with frequent fluctuations. As in the reservoir, food web relationships are important. The MO2 operations would likely continue to allow for this transitory use by bull trout and other native fish at most times of the year, but adequate food and habitat may become limiting. Increased outflows in winter would result in much lower availability of suitable habitat for bull trout due to higher velocities.

Winter flows in the mainstem Flathead River would be much higher than the No Action Alternative, further exacerbating issues with habitat suitability. Relationships described in Muhlfield et al. (2011) between winter flows and bull trout habitat suitability indicate that bull trout habitat would be reduced by 20 percent to 30 percent in wet and average years under MO2. Nighttime habitat use by subadult bull trout would be most disrupted. At all times of the year, more extreme fluctuations would cause stress for bull trout in the mainstem Flathead River and would limit food production in this reach.

The lake elevations of Flathead Lake would be similar to the No Action Alternative, as would the bull trout habitat use and life history functions in Flathead Lake. Changes described above, though, would affect bull trout from this population as they migrate into the mainstem Flathead River.

MO2 would change the operations of Seli'š Ksanka Qlispe' Dam into the Lower Flathead River in a similar pattern as Hungry Horse operations. Outflows would be much higher in winter months and experience more variability throughout the year. The higher flows would come at a time when the area near the dam provides suitable temperatures for bull trout, so they could be subject to entrainment. Entrainment of bull trout from Flathead Lake could increase by 43 to 53 percent in January and 6 to 19 percent in February. Entrained bull trout become lost from the spawning populations. Bull trout in the Lower Flathead River may experience stress as they move into freshly inundated habitats as flows increase but there would not be food available in these habitats. Decreases in flows in May and June would likely not affect bull trout in the lower river at that time of year. In summer, temperatures would make this area mostly unsuitable for bull trout under both the No Action Alternative and MO2.

<u>Other Fish</u>

Hungry Horse Reservoir would continue to favor a native fish-dominated fish community under MO2. There could be effects to native fish, but the habitat is somewhat protected from non-native fish invasion by the dam. Juvenile bull trout and adult whitefish, northern pikeminnow, sculpins, and westslope cutthroat trout feed on zooplankton, aquatic insects, and terrestrial insects, and adult bull trout prey on mountain whitefish, suckers, minnows, etc. The food web effects described above would also apply to all of these species of fish in Hungry Horse Reservoir. Zooplankton and summertime feeding of terrestrial insects would be similar to the No Action Alternative. Substantial decreases of at least 4 to 18 percent in aquatic macroinvertebrates would be expected due to reduced habitat, and dewatering events would further reduce the food supply for many of these fish.

Westslope cutthroat trout and other native fish spawn in the spring (April through June) so effects on adults migrating into tributaries to spawn would differ from bull trout. Spring spawning fish migrate when reservoir levels are lower and tend to experience longer varial zones with increased predation exposure. Under MO2 operations, the modeled April and May elevations were 5 to 7 feet lower than the No Action Alternative in wet and average years, and similar in dry years. By June, the elevations would be similar to the No Action Alternative. Spring spawning fish such as westslope cutthroat trout would experience greater varial zone effects on their way upstream as adults, and they could encounter some tributary blockages, but the delta formation of these tributaries is not known. Juveniles typically outmigrate in June when the effects would be similar to the No Action Alternative.

Entrainment from the reservoir would also continue at unquantified levels and could increase in the winter months with increased outflows. By winter, all species of fish can be distributed throughout the reservoir; entrainment has not been quantified but would be roughly twice as much as the No Action Alternative in winter months.

Habitat suitability described for bull trout would be similar for other native fish (Muhlfield et al. 2011) in the mainstem Flathead River, with higher winter flows in MO2 resulting in decreased amount of suitable habitat, and food supply becoming scarcer with decreased aquatic invertebrates.

Fish in Flathead Lake would be mostly unaffected by changes in operations in MO2. The lower Flathead River and Clark Fork Rivers would provide conditions that would be more stressful to fish with rapid and more frequent fluctuations in outflows. In these scenarios, juvenile fish, especially, would be forced to seek refuge from increased flows into newly inundated habitats where no food would be available.

#### *Lake Pend Oreille (Albeni Falls Reservoir)/Pend Oreille River*

Summary of Key Effects

Key effects under MO2 include a slight reduction in flows March through June that would reduce the threat of fish entrainment through Albeni Falls Dam relative to the No Action Alternative.

Habitat Effects Common to All Fish

Habitat effects from MO2 common to all fish would include the flow reduction identified above in the summary of key effects section.

Bull Trout

Flows would be lower in March through June under MO2 compared with the No Action Alternative. As a result, the potential for bull trout entrainment would be slightly less under this alternative.

Other Fish

The mean flow under MO2 would be reduced by up to 2.7 percent, depending on the time of year, when compared with the No Action Alternative. Consequently, the potential for the entrainment of other resident fish, including kokanee, westslope cutthroat trout, and northern pike, would decrease slightly under this alternative.

### Region B

#### *Lake Roosevelt/Columbia River from U.S.-Canada Border to Chief Joseph Dam*

Summary of Key Effects

Flow, elevations, and water quality affect the quality of habitat for various resident fish species above, in, and downstream of Lake Roosevelt. The Columbia River from the U.S.-Canada border would continue to support a white sturgeon population that spawns successfully but primarily relies on fish manager intervention to survive a recruitment bottleneck; conditions for natural recruitment may be further diminished in a small proportion of years. In Lake Roosevelt, retention time is a key metric for most fish species, driving the food web that supports the fish as well as influencing how many are entrained and would be lower in winter than the No Action Alternative. Lake elevations under MO2 would increase risk of impeded tributary habitat access and egg drying out or stranding for redband rainbow trout. The portion of kokanee that spawn in tributaries would continue to have access in fall similar to the No Action Alternative, except conditions could be more difficult in dry years. Reservoir operations would continue to result in some level of eggs drying out of the burbot spawn and the portion of kokanee that spawn on lake shorelines and would increase in MO2 compared to the No Action Alternative. These effects would be a higher magnitude than MO1. MO2 would continue to support both wild and hatchery-raised kokanee, redband rainbow trout, and hatchery rainbow trout as well as non-native warmwater game species, such as walleye, smallmouth bass, and northern pike, with some effects to populations. However, decreased water retention times are expected to adversely influence reservoir productivity and increase entrainment. Northern pike would likely continue to increase and invade downstream, and the lake elevations could decrease the ability for boat suppression efforts. Rufus Woods Lake would continue to provide habitat for fish entrained from Lake Roosevelt and from limited production of shoreline spawning by some species; entrainment could increase in winter and decrease in summer months. TDG would be similar or less than the No Action Alternative.

Habitat Effects Common to This Fish Community

The elevation hydrograph for MO2 is very similar to MO1. Median peak outflows would follow the same pattern as the No Action Alternative with peaks in early June and another smaller peak in July. MO2 spring flows are the same as the No Action Alternative. October flows would be about eight to nine percent lower than the No Action Alternative, and December flows would be about eight to fifteen percent higher than the No Action Alternative. These peak outflows can influence the rate of entrainment from Lake Roosevelt into Rufus Woods Lake. TDG in the Grand Coulee tailwater is also a concern for fish in Rufus Woods Lake. Under MO2, TDG would be lower than the No Action Alternative.

Retention time of water through the reservoir is a driving metric for the food web in Lake Roosevelt and influences the populations of several fish species. Generally speaking, under MO2 median retention time would be similar to MO1. Both would be similar to or slightly higher than the No Action Alternative in late spring, summer, and fall. Retention time under MO2 would be nine percent higher in all year types in October, 13 percent lower in December, and three percent to nine percent lower in January than the No Action Alternative. February would be six percent lower in dry years and 17 percent lower in wet years. In wet years is when retention time is lowest because more water is moving through the system, and MO2 would reduce retention times even further in winter.

Kokanee, redband rainbow trout, juvenile burbot, larval sturgeon, and many prey species rely directly on the food source provided by the zooplankton production, and higher-level predators such as bull trout prey on these fish. Zooplankton are more widespread, more plentiful, and have a larger body size when retention times are higher, and tend to be smaller bodied, swept out of the reservoir faster, and more concentrated near Grand Coulee Dam with a lower retention time. With lower retention times under MO2 in winter and spring, when retention times are already fairly low, there would be less food available to fish, and they would also tend to follow the food source and crowd down towards the dam, becoming more susceptible to entrainment. These are the same mechanisms of effects as MO1 but at higher magnitudes for a moderate effect. Decreased retention time in September in MO2 would flush out zooplankton that provide key winter food sources.

Bull Trout

Bull trout are temperature sensitive and would continue to use this reach for foraging, migration, and winter habitat until temperatures reach stressful levels that would be the same as the No Action Alternative. Bull trout in Lake Roosevelt could continue to move to cooler locations in the reservoir, and these refuges would remain similar to the No Action Alternative. High flow years would continue to influence bull trout distribution through flushing more of them from the river near the U.S.-Canada border down into Lake Roosevelt. Peak flows at the U.S.-Canada border were modeled showing flows similar to the No Action Alternative. Similar to MO1, increased outflows in December could potentially increase entrainment of bull trout, but this is negligible because of the scarcity of bull trout in Lake Roosevelt.

Bull trout prey base would continue to fluctuate, as the fish they eat are sensitive to changes in productivity and location of zooplankton in Lake Roosevelt that is influenced by the retention time of water in the reservoir, which would be adversely affected by lower retention times in winter under MO2. Bull trout are also sensitive to contaminants that are found in this region and would continue to bioaccumulate contaminants as a top predator. Similar to MO1, fluctuation events that mobilize mercury would be the same as the No Action Alternative.

Other Fish

In the Columbia River reach from the U.S.-Canada border to Lake Roosevelt, white sturgeon are typically able to spawn as evidenced by capture of young of the year larvae (Howell and McLellan 2018), but rarely experience successful recruitment from larvae to juvenile sturgeon, and only in extremely high water years. Successful recruitment appears to be dependent on a combination of flows exceeding 200 kcfs and water temperatures of about 14°C for 3 to 4 weeks in late June/early July (Howell and McLellan 2011 and Howell and McLellan 2014). In MO2, flow over 200 kcfs in June and July would be slightly decreased. The timing of these flows coinciding with lower reservoir levels can also increase recruitment ability with the longer riverine habitat provided by a lower reservoir. MO2 reservoir levels would be very similar to the No Action Alternative and the time window for white sturgeon recruitment would be the same as the No Action Alternative. Other factors that would continue to influence sturgeon include predation by fish that are favored by reservoir conditions if larvae are flushed into the Lake Roosevelt. Spring flows would be the same as the No Action Alternative. The uptake of contaminants such as copper closer to the U.S.-Canada border being flushed downstream into the reservoir by high flows would also be the same as the No Action Alternative. Under MO2, recruitment of white sturgeon would continue to be a rare event supplemented by hatchery propagation, as larval sturgeon are captured and raised in hatcheries until they are past the time window where recruitment has been shown to fail at a high rate. Once these juveniles are released back into the reservoir they continue to grow and survive well. The reservoir would continue to provide good conditions for growth and survival of these fish.

Wild production of native fish such as burbot, kokanee and redband rainbow trout would continue to provide valuable resources in Lake Roosevelt. As described in the common habitat effects, these fish are the most sensitive to the effects of changing retention times. Under the

No Action Alternative an estimated average of over 400,000 fish annually would be entrained, with 30 to 50 percent of them being kokanee, primarily of wild origin and rainbow trout the second most entrained species. Under MO2 operations, increased entrainment would be expected in winter months as the outflows increase over the No Action Alternative, and retention times would be 12 percent to 13 percent lower in December and 3 percent to 9 percent lower in January. Previous entrainment studies (LeCaire 2000) indicated winter being a period relatively low entrainment. The prolonged drawdown period is expected to increase entrainment in winter months under MO2. In wet years entrainment would also be higher in March to May (2 percent to 6 percent lower retention time) which could increase entrainment at a disproportionately high rate. Decreased food sources due to flushing of zooplankton in fall could limit kokanee growth, and juvenile burbot rely on this food as well.

For tributary spawning species such as redband rainbow trout and a portion of the wild production of kokanee, tributary access at the right time of year is important. Reservoir drawdown in the spring creates barren tributary reaches through the varial zone, which directly and indirectly impedes migration to and from tributaries and the reservoir. The operational metric of reaching a lake elevation of 1,283 feet by the end of September would be met under MO2 in wet and average years and would protect the access for the portion of kokanee that spawn in tributaries. In dry years, the reservoir would only reach elevation of 1,279 feet by September and may cause some access issues. Redband rainbow trout need access to tributaries in the spring. Under MO2, similar to MO1, reservoir elevations would be lower than the No Action Alternative levels in the critical spawning migration time of April-May in wet and dry years (equaling about 40 percent of years). This would be most critical in wet years (20 percent of years) when the median elevation would be 1,241 feet on April 1, which is lower than the No Action Alternative. Migratory impacts, although not well documented, could be severe for Redband rainbow trout given the timing and extent of drawdowns in MO2. Redband rainbow trout spawn in Sanpoil, Blue Creek, Alder, Hall Creek, Nez Perce Creek, Onion Creek, Big Sheep Creek, and Deep Creek. These tributaries higher in the basin are more susceptible to elevation changes, because a smaller change in lake elevation would result in a larger area of exposure than tributaries closer to the dam. Additionally, increased exposure during migrations to these tributaries would increase the varial zone effect where migrating fish are more exposed to predation and angling due to lack of cover.

Species such as kokanee and burbot that spawn on shorelines in Lake Roosevelt are susceptible to eggs drying out if reservoir levels drop while eggs are still in the gravel. Kokanee spawn on shoreline gravels September 15 to October 15 and eggs incubate through February. Burbot tend to spawn successfully in depths provided by the No Action Alternative in the Columbia River and in Lake Roosevelt on shorelines near the Colville River in winter with eggs incubating through the end of March (Bonar et al. 2000). MO2, like MO1, would begin dropping 2 months sooner than the No Action Alternative and would likely strand or dewater burbot and kokanee eggs. A higher proportion of eggs at all elevations would be affected.

The portion of kokanee that spawn in the shallower 6 feet of elevations could have eggs dry out when these drops occur. Any eggs near the fall surface elevation would be at higher risk. Fry sometimes also stay in the gravels and could become stranded as well. Burbot spawn later in the winter so would be less affected because the lake level would have already dropped seven feet lower than the No Action Alternative when eggs would be deposited. However, this same mechanism would also decrease habitat available compared to the No Action Alternative. The wet years would have steeper and deeper reservoir draft than the No Action Alternative and would result in increased stranding of burbot eggs. The magnitude of this effect is even higher than MO1 because MO2 would drop steeper in February than MO1, both of which would be considerably more drop than the No Action Alternative.

Kokanee are very sensitive to water temperature, and during summer are found at depths below 120 m to find suitably cool water. Under the No Action Alternative, Lake Roosevelt is very weakly stratified but does have suitably cool water at this depth along with suitable levels of DO. Lake whitefish and mountain whitefish also likely use this cool water in the summer.

Non-native warmwater gamefish, such as walleye, northern pike, smallmouth bass, sunfish, crappie, and others, as well as the prey fish that they eat (such as shiners, dace, and sculpins) all tolerate a wide range of environmental conditions and would continue to contribute to the fishery community under the No Action Alternative, and continue to adversely impact native species via predation. The invasion downstream by northern pike is of concern, and the Lake Roosevelt Co-Managers are actively suppressing pike populations using gillnets set by boats as soon as they can get on the water in the spring until the boat ramp becomes unusable at elevation of 1,235 feet. Under the No Action Alternative, this occurs on April 15 in wet years, and would not occur at all in dry and average years. Like MO1, under MO2 in wet years this would occur up to 6 days and preclude the ability for the pike suppression efforts for that period. For estimation purposes, one crew typically removes about 100 pike per week and they would operate three crews (Colville Tribe unpublished data), so the lost opportunity of up to 6 days under MO2 could result in an estimated 300 pike not removed. Additionally, outflows and retention time would continue to influence the entrainment and downstream invasion of non-native gamefish below Chief Joseph Dam where ESA-listed anadromous salmonids would be susceptible to predation by them. During the time when pike juveniles would be most susceptible to entrainment, (May to August), retention time under MO2 would be similar or slightly higher so entrainment risk for juvenile pike could be similar to the No Action Alternative or slightly lower. However, as pike distribution increases downstream in the reservoir, adults and juveniles both would become more susceptible to entrainment and the increased winter outflow would increase entrainment.

Once released, the net pen fish that supplement the rainbow trout fishery in Lake Roosevelt would experience similar effects as their native counterparts except for spawning and early rearing effects. In addition, the net pen locations are situated where the water quality can be affected by changes in reservoir elevations; these fish are sensitive to temperature and TDG, and their eventual recruitment to the fishery can be affected by retention time coupled with reservoir elevation at the time of their release (McLellan et al. 2008), which is typically in May. Under the MO2, the water quality at these locations would be similar to the No Action Alternative in most locations, although a decrease in DO was shown in the Spokane arm, which could reduce the suitability of that location. The retention time in May would be either similar or slightly higher so entrainment risk would be the same as the No Action Alternative or slightly less. The operators strive to release these fish to coincide with the initiation of reservoir refill when outflows are reduced, which under MO2 would be the same as the No Action Alternative, so these fish would continue to be release when water quality conditions would be suitable.

The fish in Rufus Woods Lake would continue to be supplemented by entrained fish out of Lake Roosevelt to a large extent, with fish mostly entrained during the spring freshet and winter drawdown periods. The earlier start to winter drawdown and increased outflows for power generation in MO2 may increase entrainment and boost populations in Rufus Woods Lake. Decreased outflows in August and September likely would decrease entrainment. This lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. High flows during late spring and early summer would continue to flush eggs and larvae from protected rearing areas similar to the No Action Alternative, but slightly lower magnitude. Median peak outflows occur in early June and would be about 3 percent lower than the No Action Alternative. TDG in the Grand Coulee tailwater is a concern for fish in Rufus Woods Lake; modeling showed TDG would be lower than the No Action Alternative.

***Chief Joseph to McNary Dam***

<u>Summary of Key Effects</u>

Key effects from alternative MO2 would not be different from the No Action Alternative.

<u>Habitat Effects Common to All Fish</u>

Habitat effects from alternative MO2 common to all fish would be similar to those found in the No Action Alternative.

<u>Bull Trout</u>

Important effects to bull trout under alternative MO2 would not be different from the No Action Alternative.

<u>Other Fish</u>

Effects of alternative MO2 to the current fish community in this reach of the Columbia River would be similar to the No Action Alternative.

**Region C**

***Snake River Basin***

<u>Summary of Key Effects</u>

Effects from MO2 that differ from the No Action Alternative would include decreases in dam passage survival for fish passing downstream, lower water levels at Dworshak Reservoir that would reduce connectivity with tributary streams, reduced levels of TDG from lower spill volumes, and increased risk of kokanee entrainment at Dworshak Reservoir from increased winter flows.

<u>Habitat Effects Common to All Fish</u>

Common habitat effects of MO2 are similar to those identified for the No Action Alternative with the exception of the changes discussed in the section above.

<u>Bull Trout</u>

Effects to bull trout from MO2 would include a slight increase in mortality from downstream passage of the lower Snake River Dams. Reductions in spill and associated TDG that would reduce the risk of GBT to bull trout in May and June, and large reductions in pool elevations at Dworshak Dam from May through July that would decrease connectivity of reservoir and tributary habitats. Under MO2 more flow would be put through turbines relative to the No Action Alternative. Because turbine survival is generally lower than spillway or bypass survival there would be a minor increase in mortality of bull trout routed through these turbines.

Because relatively more flow would be routed through the powerhouse at the Snake River dams under MO2, spill would be reduced, as would the risk of GBT for all species of fish.

Under MO2, winter releases from Dworshak Reservoir would be increased considerably. Reservoir pool elevation could be lower in June, which could increase migratory risks for bull trout in a much larger varial zone.

<u>Other Fish</u>

Effects of MO2 to white sturgeon would be similar to those for bull trout. Downstream passage at dams in the lower Snake River would be associated with increased mortality relative to the No Action Alternative while risks of GBT would decrease as spill and TDG are reduced.

Effects of MO2 to other resident fish species would also be similar to those for bull trout. Kokanee, particularly, in Dworshak Reservoir tend to congregate towards the dam during winter, and median winter outflows would be three times higher than the No Action Alternative in January and 40 percent higher in February in median years. This magnitude of outflows would likely result in major increased kokanee entrainment out of Dworshak. In the lower Snake River, downstream passage of fish through CRS projects would be associated with increased mortality relative to the No Action Alternative while risks of GBT would decrease as spill and TDG are reduced.

## Region D

### *Mainstem Columbia River from McNary Dam to the Estuary*

Summary of Key Effects

Bull trout would continue to use the Columbia River in limited numbers and seek thermal refugia available at the mouths of tributaries. White sturgeon would continue to successfully reproduce in years with adequate flow and temperature conditions.

Habitat Effects Common to this Fish Community

Outflows from McNary Reservoir influence some of the fish relationships described in this section. Peak spring flows affect habitat maintenance for some species. Modeled median outflows for MO2 indicate that outflows would be within 2 percent of the No Action Alternative (no discernable change).

Other flow parameters referred to in this section refer to outflows of McNary Dam, which are indicative of flows on downstream through the other Projects.

Bull Trout

Bull trout are known to use the mainstem Columbia River to move between tributaries and have been observed at Bonneville Dam and McNary Dam in the spring and summer (Barrows et al. 2016). Water temperature is the most important habitat factor for bull trout in the mainstem Columbia. Under MO2, bull trout would continue to use the mainstem Columbia for migration between tributaries, as well as tributary mouths for passage and thermal refugia.

Passage through turbines can cause injury or mortality. MO2 includes turbine replacement, with IFP turbines, which would improve survival (Deng et al. 2019). At John Day, turbine replacement would provide safer passage for any bull trout that move through the dam.

Bull trout would continue to be subject to bird predation.

Other Fish

Under MO2, white sturgeon spawning and recruitment would be similar to the No Action Alternative during high and average flow years. In low flow years, it is likely that there is very little spawning and recruitment anyway, but overall conditions would be similar to the No Action Alternative.

Model results indicate suitable spawning temperatures would be similar to the No Action Alternative. In years of low flow conditions, water temperatures could increase beyond the suitable range by early June, resulting in little or no recruitment.

White sturgeon spawning generally occurs in areas with fast-flowing waters over coarse substrates (Parsley et al. 1993). Minor changes in outflow under MO2 would not be large enough to cause discernable velocity changes that would affect sturgeon spawning habitat.

MO2 does not include any measures to improve passage at the dams for sturgeon.

White sturgeon larvae are adversely affected by TDG. Studies have shown high rates of altered buoyancy at 118 percent TDG, and 50 percent mortality at 131 percent TDG (Counihan et al. 1998). Adults are more able to compensate for increased TDG by moving to lower depths, but larvae in shallow water would be more affected. Under MO2, TDG rates would less than the No Action Alternative, because spill rates would be limited to 110 percent TDG.

MO2 would be similar to the No Action Alternative in terms of pool fluctuation (potential juvenile stranding), predation from pinnipeds and warmwater game fish, and reservoir maturation.

Under MO2, no changes to resident fish communities would be expected. As shown above, outflow rates below McNary Dam would be very similar to the No Action Alternative. Water quality and food availability would also be similar to the No Action Alternative.

Conditions that promote lower water temperatures and higher spring flows tend to lower the survival rates of warmwater game fish, potentially lowering populations of predators on salmon and steelhead. MO2 would be expected to continue supporting warmwater game fish at levels similar to current conditions.

**MACROINVERTEBRATES**

Below is a discussion of the macroinvertebrates in Regions A, B, C, and D under MO2. For more detailed information on the effects of MO2 on aquatic invertebrates and implications on food web interactions see the Habitat Effects section of these respective fish community analyses in the Resident Fish section under the applicable region.

**Region A**

At Hungry Horse reservoir, the varial zone that provides benthic insect production would be similar to the No Action Alternative in the summer, except that the reservoir would miss filling more often due to lower winter elevations. Winter elevations would be about four to eight feet lower than the No Action Alternative and be drafted faster. There would be less habitat and aquatic insects in this zone would become dewatered faster than under the No Action Alternative, which would especially impact the insects with two-year life cycles. The elevation at the end of September would be similar to the No Action Alternative, with dry years actually slightly higher than the No Action Alternative due to implementing a sliding scale. With similar summer elevations, the euphotic zone for summer zooplankton production would be similar. However, increased numbers of zooplankton would leave out of the reservoir and into the South Fork Flathead River with higher outflows in January and February (often more than double those of the No Action Alternative) and in April and May. These outflows would increase zooplankton levels and wetted area for macroinvertebrate production in the South Fork Flathead River, but water level fluctuations in the South Fork Flathead River in January to February, April to May, May to June, and June to July would all cause disruptions to the aquatic insects. These fluctuations would not allow enough continuous time at steady river elevations for invertebrates to fulfil their life cycle. Additionally, higher flows would flush more macroinvertebrates out of the immediate downstream area with higher velocities than the No Action Alternative. This flow pattern would continue to the mainstem Flathead River and increase wetted area there but also dewater macroinvertebrates with frequent fluctuations, reduce amount of low velocity habitat, and flush macroinvertebrates out of the river downstream into Flathead Lake. Increased winter flows would continue downstream through the Clark Fork River and could slightly increase aquatic invertebrate habitat in winter.

The MO2 operations of the Albeni Falls Project would result in similar lake elevations as the No Action Alternative, but increased inflows from upstream in January would be passed through so inflows to the Pend Oreille River would about 22 percent higher in January. Macroinvertebrate communities could occupy those habitats but would become dewatered as flows recede again in February.

In the Kootenai basin, Lake Koocanusa would be held above elevation 2450 for a similar duration as the No Action Alternative; overall productivity of zooplankton and macroinvertebrates in the system would be similar. Likewise, MO2 operations would result in a median minimum pool elevation within a foot of the No Action Alternative and typically slightly lower, exposing similar or slightly less varial zone production to dewatering.

**Region B**

The Columbia River from Canada to Lake Roosevelt would continue to produce benthic aquatic insects such as stonefly, caddisfly, and mayfly larvae. The river elevation in this reach is influenced by Lake Roosevelt operations and inflows so is somewhat variable, which would constrain benthic production to some degree.

MO2 operations would be very similar to MO1. This would change river elevations at the U.S.-Canada border in the months of December and January, with much steeper drops than the No Action Alternative. MO2 levels would follow the same pattern as the No Action Alternative through April with rising elevations until July, then dropping steeply until September, when they rise again. The No Action Alternative and MO2 levels would then level off about November, but in December MO2 levels would drop quickly, whereas No Action Alternative levels would rise slightly and hold steady for another month and then drop at a lower rate. This would result in decreased habitat and more benthic production becoming dewatered than the No Action Alternative from December through about March 1. This change in elevation drops of 4 feet represents the vertical feet; actual habitat dewatered would depend on the slope of the riverbanks at this elevation. As the river flows downstream closer to Lake Roosevelt, the pattern is the same but the additional drop from MO2 would result in about six feet lower elevation at river mile 720.

In Lake Roosevelt, the production, distribution and persistence of zooplankton is highly variable and sensitive to retention time of water in the reservoir, which is a function if inflows, reservoir volume, and outflows. The longer residence times allow for increased abundance and larger-bodied zooplankton to be more widely distributed throughout the reservoir. Lower retention times result in fewer and smaller-bodied zooplankton that get concentrated near the dam, where they would be subject to high rates of entrainment. Retention time under MO2 would be very similar to MO1; meaning median retention time would be similar to the No Action Alternative in late spring, summer, and fall. Retention time under MO2 would be lower in December through January, but slightly higher in May in most years. In wet years is when retention time is lowest because more water is moving through the system, and MO2 would reduce retention times even further in these years by up to 10 percent in February and by 3 percent to 10 percent in the entire period of December through May. With lower retention times under MO2 in winter and spring, when retention times are already low, there would be less productivity and increased entrainment of zooplankton. The larger, longer-lived species would be disproportionately affected. The elevations in Lake Roosevelt would follow the same pattern as in the river sections described above, with MO2 elevations dropping about 7 feet December 1st rather than staying steady as in the No Action Alternative. This would result in desiccation of more aquatic macroinvertebrates and overall decreased habitat in shallow areas of the reservoir.

Downstream of Grand Coulee Dam, Rufus Woods Lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. Here the macroinvertebrate community consists of production of aquatic insects similar to upstream of Lake Roosevelt, as well as the zooplankton entrained out of Lake Roosevelt. Regarding aquatic insect production and desiccation, river stage at RM 594 in Rufus Woods Lake would follow the same pattern and magnitude changes as the No Action Alternative from April through December. At that time, however, the river stage would rapidly increase about a foot for a short time period and then drop back down to similar to the No Action Alternative. In the month of March, the stage would be slightly lower by about a half of a foot for less than a month. Aquatic macroinvertebrate habitat would be relatively similar to the No Action Alternative most of the year. The temporary increase in December could result in colonization of a small amount of habitat that would then become dewatered and desiccate these invertebrates, as could the minor, temporary decrease in March.

**Region C**

MO2 operations would result in a steep, 34-foot drop in elevation in January through March, while the elevation under the No Action Alternative would stay fairly level at this time. This steep drop would severely decrease benthic habitat and further desiccate any established production. Summer elevations would be similar to the No Action Alternative, with steep drops from July through September. Already low levels of benthic production in Dworshak reservoir would be even further reduced. More extensive variation in water surface elevation, near-shore wave action that causes erosion, and the lack of aquatic plants along the shoreline would further limit production. The summer euphotic zone for zooplankton production would be similar to the No Action Alternative.

In the Clearwater River below Dworshak Reservoir, flows would be about five times higher than the No Action Alternative outflows in January, and then variably lower and higher than the No Action Alternative in February and March. This extreme increase in winter flows would greatly reduce the suitability of benthic habitat in the Clearwater River in winter. Summer flows would be similar to the No Action Alternative, which are also unsuitably high for natural production of macroinvertebrates in a river system.

Conditions in the lower Snake River would be similar to the No Action Alternative. The macroinvertebrate community of the lower Snake reservoirs and river would continue similar to the No Action Alternative. Siberian prawns and opossum shrimp may continue to increase in the reservoir environments. The reservoirs would continue to provide habitat for clams, mussels, etc., as in the No Action Alternative, and crayfish would find ample suitable habitat in the rock and riprap of reservoirs. Soft substrates of the reservoirs would continue to be dominated by low species diversity, mostly worms. Harder substrates would provide habitat for a relatively poor diversity of aquatic insect larvae.

**Region D**

MO2 would result in only minor changes to flows or temperatures that could affect macroinvertebrate communities in the lower Columbia River. Very little benthic macroinvertebrate information is available for the lower Columbia River. Lake habitats in the impounded reaches would continue to support a low diversity of worms, benthic insects, and mollusks. The other run of river dams would continue to be operated at stable elevations that would continue production of these aquatic macroinvertebrates.

**SUMMARY OF EFFECTS**

**Anadromous Fish**

MO2 includes structural measures to improve survival of juvenile salmon and steelhead. However, operational measures such as lower spill and lower spring flows for flood risk management and hydropower would increase travel time and the number of powerhouse encounters for juvenile outmigrants. MO2's spill to near 110 percent TDG decreases the proportion of spill at each of the lower Columbia and lower Snake projects. This reduced spill has the net effect of routing more juvenile salmon and steelhead towards powerhouse routes and less salmon and steelhead through spill routes. Structural measures such as powerhouse surface collectors did not result in sizeable increases in juvenile survival or improvements in adult returns.

TDG exposure levels under MO2 are expected to be similar or slightly reduced compared to the No Action Alternative. Modeled species such as juvenile upper Columbia River spring-run Chinook and upper Columbia River steelhead, are expected to see decreases in survival, increases in travel time, increases in powerhouse passage events, and decreased adult return rates.

The expected effects of MO2 on anadromous species varied depending on the species, location, and by the outputs from the two distinct models (CSS and LCM) used in this analysis. For upper Columbia River Chinook salmon and steelhead, the LCM predicted one to four percent relative reductions in-river survival as well as a one percent relative reduction in the SAR estimate for upper Columbia River spring Chinook.

For Snake River spring Chinook and steelhead, the CSS model generally predicted adverse effects, a 30 percent relative reduction in SARs for spring Chinook, while the LCM generally predicted negligible to minor beneficial effects relative to anadromous species that were modeled in the No Action Alternative. The minor beneficial effects result from increases in transportation rates.

MO2 also includes structural modifications at the dams to benefit passage of adult salmon, steelhead, and Pacific lamprey. While structural modifications may provide some benefit to lamprey passage, the overall shift to more powerhouse flow and passage makes this alternative less effective at meeting the objective to improve conditions for lamprey than the other action alternatives. Greater numbers of lamprey would likely pass near fish bypass screens and would be at a higher risk of injury or impingement compared to the No Action Alternative.

**Resident Fish**

In some regions, MO2 would generally have some key effects similar to the No Action Alternative, with minor to major adverse effects in localized areas. In Region A, discharges from Libby Dam would continue to have detrimental effects to fish species downstream, with lower food production and less habitat. Benthic insect production would be decreased in Region A reservoirs under MO2 due to changes in reservoir operations to provide additional power generation in winter. Reductions in flows would reduce the threat of fish entrainment at certain projects in summer but increases in winter outflows at Hungry Horse would cause a major decrease in bull trout habitat in the Flathead River, as well as increase entrainment of fish and winter food sources. In Region B, changes in elevations and outflows of Lake Roosevelt (Grand Coulee Dam) would result in moderate adverse effects to kokanee, burbot, and redband rainbow trout due to reduced retention times, more severe adfluvial effects limiting access to tributaries, and increased egg desiccation. In Region C, Dworshak Reservoir outflow increases in winter would likely result in major adverse effects due to increases in kokanee entrainment. In the lower Snake River, more flow would be put through the turbines relative to the No Action Alternative; species such as bull trout migrating downstream in the Snake River would see a minor increase in mortality compared to spillway or bypass passage. In Region D, effects in the Lower Columbia River would be minor adverse to negligible.

**Macroinvertebrates**

Changes in operations at projects such as Hungry Horse and Lake Roosevelt would result in winter elevations lower than the No Action Alternative that are drafted faster, resulting in less habitat and aquatic insects. In areas such as the Clearwater River below Dworshak Reservoir, extreme increases in winter flows and variability would greatly reduce the suitability of benthic habitat. Conditions in the lower Snake and Columbia Rivers are expected to be similar to those in the No Action Alternative. Overall, effects are expected to be moderate.

### *3.5.3.6 Multiple Objective Alternative 3*

**ANADROMOUS FISH**

**Salmon and Steelhead**

Several different ESU/DPS units of salmon and steelhead share a similar life cycle and experience similar effects from the MOs, but also have ESU-DPS specific traits that specifically drive effects differently from one another. Common effects analyses across all salmon and steelhead are discussed first, and then those ESU/DPS specific effects are displayed.

***Effects Common Across Salmon and Steelhead***

<u>Summary of Key Effects</u>

MO3 would involve breaching the lower Snake River embankments, which would end juvenile fish transportation at the collector projects, and would have effects on both juvenile outmigration and adult upstream migration.

Upon the breaching of the LSR dams, Bonneville would no longer have an obligation to fund US Fish and Wildlife Service for the operations and maintenance of the LSRCP facilities. Bonneville's funding authority is directly tied to the operation of the LSR dams. The co-lead agencies also recognize that there would be transitional needs that would be addressed in the additional mitigation measures for MO3 discussed in Chapter 5. Additionally, the Bonneville F&W Program funding for offsite mitigation projects in the Snake River Basin, implemented by local, state, tribal, and federal entities, would be reviewed and potentially adjusted. Any changes of this nature would be implemented over time as the effectiveness of dam breaching is observed and would be done in consultation with fish and wildlife managers, regulatory agencies, and the Northwest Power and Conservation Council. Consistent with this, offsite mitigation projects for the other CRS dams would be reviewed and could be adjusted as operations change over time. Proposed project modifications would be coordinated with project sponsors and regional stakeholders to determine appropriate funding levels.

<u>Juvenile Fish Migration/Survival</u>

With the breaching of lower Snake River dams, hatchery mitigation would change, as noted above. Currently, hatchery fish account for 80 to 90 percent of all juvenile Snake River fish passing CRS projects. COMPASS and CSS models do not account for this potential major reduction in juvenile fish production and as noted throughout this chapter, unless otherwise specified, quantitative results from COMPASS, CSS, and the LCM are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results. Consequently, qualitative analyses are added to these modeling results.

MO3's spill to 120 percent TDG at the lower Columbia projects increases the proportion of spill at each of the lower Columbia projects. This increased spill at the lower Columbia projects has the net effect of routing more juvenile salmon and steelhead towards spill routes and less salmon and steelhead would pass through powerhouse routes. For juvenile salmon and steelhead, fish modeling was used when available to estimate the effects of these spill changes and dam breach on fish.

Flow patterns in the Lower Columbia River also changed in MO3 relative to the No Action Alternative and these included decreases in monthly average flows of 1 to 3 percent from March to August. Similar to the spill changes, fish modeling was used when available to estimate the effects of these flow changes on juvenile fish. These flow changes were caused by one or a combination of the following operational measures:

- Sliding Scale at Libby and Hungry Horse
- Modified Draft at Libby
- December Libby Target Elevation
- Update System FRM Calculation
- Planned Draft Rate at Grand Coulee
- Grand Coulee Maintenance Operations
- Lake Roosevelt Additional Water Supply
- Hungry Horse Additional Water Supply
- Chief Joseph Dam Project Additional Water Supply

Increasing the operating range by 6 inches John Day Dam relative to the No Action Alternative would slightly increase juvenile fish travel times and exposure to predators (NMFS 2019). Similarly, holding contingency reserves within juvenile fish passage spill is likely to have little effect on juvenile migration. These measures were both included in the 80-year modeling datasets.

Several measures in MO3 are not readily incorporated into modeling for effects analysis, or are modeled but may be difficult to separate from other factors, and so effects of these measures are discussed qualitatively.

As discussed in the analysis for MO1 and MO2, the replacement of existing weirs (top spill or removable) with adjustable spillway weirs would likely allow greater flexibility to address tailrace eddies. This would also allow for longer spillway weir operation under lower flow conditions towards the end of the juvenile spring/summer-run Chinook outmigration.

The removal of fish screens at some dams would reduce in-river survival in the COMPASS model to some degree but would not have an effect on in-river survival in the CSS model. Removing fish screens would shift fish that would have otherwise entered the juvenile bypasses into other routes, likely turbine routes. This measure was included in the modeling datasets.

Operating turbines within and above 1 percent efficiency may or may not affect juvenile Snake River spring/summer-run Chinook direct survival based on studies finding that peak passage survival does not coincide with observed turbine peak operating efficiency (Mathur et al. 2000; Skalski et al. 2002; Deng et al. 2007). A meta-analysis also found no association between relative turbine efficiency at a site and smolt passage survival (Skalski et al. 2002). However, Ferguson et al. (2006) reported spring-run Chinook delayed mortality resulting from operation of McNary Dam turbines outside the 1 percent range; so it is possible that operating outside 1 percent turbine efficiencies at some dams may decrease Snake River spring/summer-run Chinook survival.

The measures intended to improve conditions for lamprey in MO3 are anticipated to have a negligible effect on salmon and steelhead survival.

No juvenile fish would be transported. Overall, MO3 is somewhat similar to the No Action Alternative from a TDG perspective but shows a small reduction in overall TDG exposure.

UW/CBR TDG modeling, separate from COMPASS and CSS in-river survival estimates, estimated juvenile fish median reach average exposure to TDG indices would change depending on dams passed, from a decrease of about 5 percent for Snake River fish to an increase of up to 1 percent for upper Columbia fish relative to the No Action Alternative.

There would be anticipated decrease in fish injury from dam passages under MO3 due to breach of the four lower Snake Dams, installation of improved fish passage turbines at John Day Dam, and higher spill in the lower Columbia, relative to the No Action Alternative, and anticipated concomitant decrease in juvenile predation exposure due to these factors.

Turbidity is anticipated to change under MO3 during the breach phase and years immediately following the breach especially (see Section 3.4, *Water Quality*). The increase in turbidity during these periods is anticipated to reduce predation. Over time, turbidity is likely to reach an equilibrium close to the No Action Alternative and it is unclear how overall predation would change relative to the No Action Alternative. However, the predators that would remain are more likely to be native predators adapted to riverine system and shift away from predators that are well adapted to reservoir habitats. Decreased travel time through the lower Snake River will also reduce juvenile salmon and steelhead predation by birds and fish. The reduced predation risk due to faster travel times and increased turbidity may be offset by some unknown amount due to reduced predator swamping effects stemming from the loss of hatchery fish.

<u>Adult Fish Migration/Survival</u>

Overall, the Bonneville Dam ladder structural measure may reduce delay for adult fish passing under crowded conditions; however adult fallback rates may also increase under MO3 due to higher spill levels at the lower Columbia projects, which could increase adult fish delay (Boggs et al. 2004; Keefer et al. 2005). It is important to note that regional managers use in-season adaptive management to identify and remedy any excessive fallback.

Increasing the reservoir operating range at John Day Dam would have little effect on flow, and thus is not expected to affect adult migration timing or survival rates. Similarly, holding contingency reserves within juvenile fish passage spill would be likely to have little effect, if any, on adult migration.

Several changes affecting migration through the breached section would occur, including: Maximum summer water temperature would increase slightly; water temperature variability would increase; and water temperatures would not stay cool as long into the spring and would cool earlier in the fall with the removal of the thermal inertia of the lower Snake Dam reservoirs. See additional information in Section 3.4, *Water Quality*, and Appendix D.

The breached areas are not expected to delay adult migration because they would be designed to pass fish at flows up to 170,000 cfs, equivalent to a 5-year high-flow event. Flows less than 5 feet per second (ft/s) are not considered to impede adult upstream migration and would require no additional resting structures. All Lower Snake breaches would provide velocities between 2 to 3 ft/s and flow depths around eight feet for total river flows of 15,000 cfs. As river flows increase, so do velocities and flow depths. Typical overbank velocities associated with 170,000 cfs range between 3 ft/s to 8 ft/s with flow depths between 22 and 28 feet. Velocities in the breach area at flows greater than 170,000 cfs could be in ranges that may impede movement even with structures. The high flow periods occur in the spring when spring-run Chinook salmon, sockeye salmon, and some steelhead migrate upstream through the lower Snake River.

In any breached areas where velocities are predicted to be above 5 ft/s at flows less than 170,000 cfs, channel enhancement features would be installed to assist fish in migrating upstream in steps. Where overbank velocities exceed 5 ft/s, channel enhancement features, such as precast 6-foot boulders, would be placed to provide energy dissipation along the bank to provide resting locations. The spacing of these features ranges from about 200 feet at 5 ft/s to 10 feet for 12 ft/s. The location and extent of channel enhancement features would be detailed in future hydraulic modeling efforts.

***Upper Columbia River Salmon and Steelhead***

Upstream of McNary Dam, upper Columbia salmon and steelhead migrate past as many as five PUD owned dams and reservoirs, which also impact the survival and passage of these species. The federal agencies do not dictate generation or spill levels at the PUD projects so metrics such as powerhouse encounter rate are not directly affected but are influenced by river flow levels coming through the upper Basin. The timing and volume of flow levels affected by CRS operational decisions are reflected in model analysis. COMPASS and LCM estimates of powerhouse encounter rate and SARs include passage effects from a combination of federal and PUD dam passage (Rock Island Dam to Bonneville Dam). CSS model results are not available for upper Columbia stocks.

<u>Upper Columbia Spring-Run Chinook Salmon</u>

*Summary of Key Effects*

COMPASS modeling estimates that MO3 is expected to result in a 1 percent increase in upper Columbia River Chinook average juvenile survival, an 8 percent decrease in average juvenile travel time, and a 12 percent decrease the number of powerhouse passage events.

*Juvenile Fish Migration/Survival*

CSS cohort modeling for upper Columbia spring-run Chinook was not available for this analysis, but the COMPASS model estimates based on a combination of hatchery and wild fish that MO3 would have the following effects on upper Columbia spring Chinook, compared to the No Action Alternative, described below in Table 3-85:

**Table 3-85. Multiple Objective Alternative 3 Juvenile Model Metrics for Upper Columbia River Spring-Run Chinook Salmon**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) McNary to Bonneville | 69.5% | 71.0% | +1.5% | +2% |
| Juvenile Travel Time (COMPASS) McNary to Bonneville | 6.1 days | 5.4 days | -0.7 days | -11% |
| % Transported | No upper Columbia River spring-run Chinook transported | | | |
| Powerhouse Passages (COMPASS) Rock Island to Bonneville | 3.29 | 2.9 | -0.39 | -12% |
| TDG Average Exposure (TDG Tool) | 115.9% TDG | 116.7% TDG | +0.8% TDG | 0.05% |

The COMPASS modeling results support initial qualitative expectations that the predicted MO3 survival rates from McNary Dam to Bonneville Dam would increase slightly and travel times would be reduced slightly.

For upper Columbia spring-run Chinook salmon, UW/CBR modeling estimated that the McNary to Bonneville Dam reach-average TDG exposure index would change less than 1 percent in MO3 relative to the No Action Alternative.

*Adult Fish Migration/Survival*

NMFS LCM results were provided for the only extant upper Columbia spring-run Chinook MPG: the North Cascades MPG, using the Wenatchee River population. CSS LCMs for upper Columbia species are not available for this analysis. Based on LCM model predictions, a negligible increase in SARs for upper Columbia Chinook and a variable increase in abundance is estimated based on latent mortality assumptions. See Table 3-86 for details:

**Table 3-86. Model Metrics Related to Adult Survival and Abundance of Upper Columbia River Spring-Run Chinook Salmon under Multiple Objective Alternative 3**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| SARs – Rock Island to Bonneville (NWFSC LCM) | 0.94% | 0.95% | +.01% | +1% |
| NWFSC LCM abundance range with decreased latent mortality[1] | 498 | 519 (0%)<br>636 (10%)<br>882 (25%)<br>1228 (50%) | +21 (0%)<br>+138 (10%)<br>+384 (25%)<br>+730 (50%) | +4% (0%)<br>+28% (10%)<br>+77% (25%)<br>+147% (50%) |

[1] NWFSC LCM does not factor latent mortality due to the hydrosystem into the SARS or abundance output. For discussion purposes, potential decreases in latent mortality of 10 percent, 25 percent, and 50 percent are shown. The value for 0 percent is the actual model output, the 10 percent, 25 percent, and 50 percent values represent scenarios of what SARs, or abundance hypothetically could be under the increased ocean survival if changes in the alternative were to decrease latent mortality by that much.

Current life-cycle models do not incorporate interactions between populations (straying, source-sink dynamics, etc.) or between MPGs, though these dynamics are generally known to occur. That said, they provide useful frameworks for assessing how populations are likely to respond to factors that are correlated with survival or abundance.

For upper Columbia spring-run Chinook, the (NMFS LCM estimates that MO3 would have the following effects compared to operations under the No Action Alternative:

- No change in smolt to adult (SAR) return rate from, Rock Island to Bonneville (this estimate includes passage past three Public Utility District dams) but large increase in SAR if productivity also increases by 50 to 100 percent (i.e., additional reduction in latent mortality that could be a result of reduced powerhouse encounters in the lower Columbia);
- Upper Columbia spring-run Chinook adult abundance would increase over time with overall small increases in median abundance, but potentially substantial increases across the modeled population if productivity also increases by 50 to 100 percent (i.e., additional reduction in latent mortality).

<u>Upper Columbia River Steelhead</u>

*Summary of Key Effects*

COMPASS modeling estimates that MO3 is expected to result in a less than 1 percent decrease in average juvenile survival for upper Columbia steelhead, a less than 1 percent increase in average juvenile travel time, (roughly 2 hours) and a 7 percent decrease in the number of powerhouse passage events from McNary to Bonneville Dam.

*Juvenile Fish Migration/Survival*

CSS modeling for upper Columbia steelhead was not available for this analysis, but the COMPASS model estimates that MO3 would have the following effects compared to the No Action Alternative, described below in Table 3-87.

**Table 3-87. Multiple Objective Alternative 3 Juvenile Model Metrics for Upper Columbia River Steelhead**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) McNary to Bonneville | 65.8% | 65.6% | -0.2% | 0% |
| Juvenile Travel Time (COMPASS) McNary to Bonneville | 6.6 days | 6.7 days | +0.1 days | 0% |
| % Transported (COMPASS) | No transport of upper Columbia steelhead | | | |
| Powerhouse Passages (COMPASS) Rock Island to Bonneville | 2.72 | 2.52 | -0.20 | -7% |
| TDG Average Exposure (TDG Tool) | 116% TDG | 117.0% TDG | +1% TDG | 0% |

For upper Columbia River juvenile steelhead, UW/CBR modeling estimated that the McNary to Bonneville Dam reach-average TDG exposure index would increase by about one percent relative to the No Action Alternative.

*Adult Fish Migration/Survival*

No LCM results were provided for the upper Columbia River steelhead DPS, which is composed of a single MPG: the North Cascades MPG. NMFS LCM for steelhead are still in development and not available for this analysis and CSS LCM of MOs was not provided for upper Columbia species.

Upper Columbia River Coho Salmon

See upper Columbia River spring-run Chinook salmon analysis as a surrogate for juvenile upper Columbia coho salmon and upper Columbia fall Chinook salmon analysis as a qualitative surrogate for adult upper Columbia River coho salmon.

*Summary of Key Effects*

The primary challenges for upper Columbia coho salmon are the conditions they encounter during upstream and downstream migrations. Overall, minor increase in survival is anticipated for juvenile upper Columbia coho between McNary and Bonneville dams, based on modeling completed for the surrogate species of upper Columbian River spring-run Chinook juveniles (Table 3-88). CRS operational changes are not likely to affect survival rates for upper Columbia adult coho migrating upriver.

*Juvenile Fish Migration/Survival*

See Upper Columbia River spring run Chinook salmon for estimated, surrogate measures of juvenile survival under MO3 compared to the No Action Alternative. Modeling of surrogate species indicates that juvenile coho survival would have minor increases and that under MO3 could also slightly reduce upper Columbia coho juveniles' susceptibility to predation by other fish and birds of prey based on modeled changes in the number of turbine passages, travel time, and installation of improved fish passage turbines at John Day Dam.

For an overview of juvenile and adult predation generally under MO3, see the Effects Common Across Salmon and Steelhead section, under Section 3.5.3.6.

*Adult Fish Migration/Survival*

See the Effects Common across Salmon and Steelhead section, under Section 3.5.3.6, for an overview of change in adult migration/survival for salmon and steelhead under MO3 relative to the No Action Alternative.

Under MO3, CRS operational changes are not likely to affect survival rates for upper Columbia adult coho migrating upriver. For more information, see surrogate effects analysis of MO3 for *Upper Columbia Fall Chinook*.

<u>Upper Columbia River Sockeye Salmon</u>

Refer to the upper Columbia River Chinook salmon analysis as a surrogate for Upper Columbia River sockeye salmon.

*Summary of Key Effects*

The most notable effects for Columbia River sockeye from MO3 are the minor benefits that would occur downstream from the confluence with the Snake River. Breaching of the lower Snake River dams would increase turbidity during breaching and in high water events for some unknown period after the breach. Increased turbidity reduces predation on juvenile salmon from sight feeding predators. In addition, increased abundance of Snake River salmon populations, following dam breach may contribute to Columbia River population survival as larger numbers of outmigrating juveniles may swamp predators. However, the magnitude of these changes is uncertain.

*Juvenile Migration/Survival*

This alternative (MO3) is expected to have small decrease to migration time for juvenile sockeye as measured from Rock Island Dam to Bonneville Dam, and would have a small increase in juvenile survival during their migration period of April 15 to June 15. Modeled river flows during the driest 25 percent of years would be slightly lower, but not a substantial difference from the No Action Alternative.

A minor increase in survival is expected for the upper Columbia River sockeye due to effects of breaching the lower Snake River Dams. These effects would come from the increase in turbidity levels from the Snake River, which may help the survival of smolts as they would be less visible to predators.

Under MO3 there would be displacement of some predators below the confluence of the Snake and Columbia Rivers following breaching until conditions stabilize and populations return to affected areas. Overall, there would be a negligible decrease in risk of sockeye predation by larger fish at the time of breaching, followed by gradual increases in risk of exposure to these predators as the habitat and water quality stabilize.

An increase in colonial waterbird nesting habitat is expected in the area of the lower Ice Harbor pool. Only those islands that would not be inundated in spring flows are suitable habitat. This may increase the local bird population in McNary pool and would affect the rate of predation on Columbia River sockeye.

Refer to the upper Columbia River Chinook salmon analysis, as a surrogate for Upper Columbia River sockeye salmon, for additional information in modeled juvenile fish migration and survival metrics.

*Adult Migration/Survival*

The summer water temperatures in the river during the upstream migration would not change. Likewise, TDG and its effects in the form of GBT would have no appreciable difference in MO3 for either adults (or juveniles).

Refer to the upper Columbia River Chinook salmon analysis, as a surrogate for Upper Columbia River sockeye salmon, for additional information in modeled adult fish migration and survival metrics.

<u>Upper Columbia River Summer/Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

Overall, no changes are anticipated for juvenile upper Columbia summer/fall-run Chinook. There may be slightly less adult migration delay due to slightly fewer days when water temperatures in the McNary tailrace exceed 20°C, but slightly greater adult migration delay due to slightly higher incidence of adult ladder temperature differentials above 2°C.

*Juvenile Fish Migration/Survival*

No change is anticipated in McNary and John Day Reservoir plankton communities or shoreline habitats under MO3, relative to the No Action Alternative (see Section 3.4, Water Quality, and the Resident Fish subsection of Section 3.5.2.5 for additional information). Likewise, juvenile rearing habitat below Bonneville Dam is not expected to change relative to the No Action

Alternative. Overall, no changes are anticipated for juvenile upper Columbia summer/fall-run Chinook.

*Adult Fish Migration/Survival*

Specific to Okanogan upper Columbia summer/fall-run Chinook, there is no change in number of days the mainstem would be 20°C or higher at the confluence of the Okanogan River, relative to the No Action Alternative. This means that there would be no change anticipated in the ability of the Okanogan fish to hold in the mainstem until temperatures in the Okanogan River are cool enough that adults can move up from the mainstem without having to migrate through water temperatures typically considered lethal for salmon and steelhead (Ashbrook et al. 2009).

The frequency of meeting the Vernita Bar Agreement to protect the prolific fall-run Chinook spawning in and around the Hanford Reach of the Columbia River in Washington is not expected to change under any MOs relative to the No Action Alternative. Other operational changes under MOs are likewise not anticipated to affect upper Columbia summer/fall-run Chinook spawning from the tailrace of Chief Joseph Dam to Bonneville Dam in terms of changes in flows, water temperatures, or TDG generated under the MOs.

***Middle Columbia River Salmon and Steelhead***

<u>Middle Columbia River Spring-Run Chinook Salmon</u>

See Upper Columbia River spring-run Chinook analysis as a surrogate for Middle Columbia River Spring-Run Chinook Salmon.

*Summary of Key Effects*

CRS operational changes under MO3 will result in increased survival, faster travel times, and decreased powerhouse passage events on juvenile middle Columbia River Chinook salmon. These effects would lead to negligible to minor benefits to Middle Columbia River Spring Chinook.

*Juvenile Fish Migration/Survival*

See Upper Columbia River spring-run Chinook analysis as a surrogate for Middle Columbia River Spring-Run Chinook Salmon.

*Adult Fish Migration/Survival*

See upper Columbia River spring-run Chinook salmon analysis as a surrogate for adult migration and survival of middle Columbia River spring-run Chinook salmon.

<u>Middle Columbia River Steelhead</u>

Refer to Upper Columbia River steelhead analysis as a surrogate for Middle Columbia River steelhead.

*Summary of Key Effects*

Juvenile and adult middle Columbia River Steelhead would be exposed to moderate increases in TDG. Other effects to juvenile fish would be similar to those experienced by Upper Columbia steelhead. Adult middle Columbia River steelhead would experience minor increases in fallback rates, but kelts would also experience minor increases in survival.

*Juvenile Fish Migration/Survival*

Populations of middle Columbia River steelhead distributed between the Deschutes and Walla Walla Rivers pass two to four dams in the lower Columbia on their downstream outmigration to the ocean. COMPASS modeling for juvenile upper Columbia River steelhead was used as a surrogate for middle Columbia River steelhead. Under MO3, juvenile survival, travel time and powerhouse encounters would both have a small decrease from the No Action Alternative. However, these fish would experience a moderate increase in elevated TDG. Refer to upper Columbia River steelhead analysis as a surrogate for middle Columbia River steelhead for additional information.

*Adult Fish Migration/Survival*

Under MO3, higher spill levels at the lower Columbia projects during spring outmigration would result in minor increases in fallback rates. However, there would also be minor increases in survival of kelts as they migrate downstream because fewer adults would pass through the powerhouse (Normandeau et al. 2014). There would also be moderate increases in TDG under MO3 compared to the No Action Alternative. Refer to upper Columbia River steelhead analysis as a surrogate for middle Columbia River steelhead for additional information.

***Snake River Salmon and Steelhead***

<u>Snake River Spring/Summer-Run Chinook Salmon</u>

*Summary of Key Effects*

COMPASS and CSS modeling results indicate that survival rates would increase and travel times would decrease (fish would migrate downstream faster). However, the potential reduction of hatchery fish noted in the common effects analysis may reduce numbers of juvenile Snake River Chinook salmon by as much as 85 percent. This reduction would potentially result in lower survival rates of wild Chinook as they navigate through the predators inhabiting the migratory corridor. The model estimates for both CSS and LCM presented in this section are based on a combination of hatchery and wild fish. The CSS model was able to produce similar estimates using wild fish only, but because those estimates still assume that hatchery fish are present and migrating along with the natural origin fish, they do not represent an estimate of a wild fish only migration such as may occur if hatchery production was reduced or eliminated post-dam breach. The CSS wild fish estimates are presented in memo form (See appendix E) for reference.

*Juvenile Fish Migration/Survival*

For Snake River spring/summer-run Chinook salmon, the COMPASS and CSS models estimate that MO3 would have the following effects compared to operations under the No Action Alternative, described below in Table 3-88. As noted above, the model estimates in Table 3-89 were developed with a combination of hatchery and natural origin fish data. COMPASS results reflect data obtained from the Salmon River wild and hatchery combined estimates.

**Table 3-88. Multiple Objective Alternative 3 Juvenile Model Metrics for Snake River Spring/Summer-Run Chinook Salmon**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 50.4% | 59.9 | +9.6% | +19% |
| Juvenile Survival (CSS) | 57.6% | 68.2% | +14.9% | +25.9% |
| Juvenile Travel Time (COMPASS) | 17.7 days | 12.2 days | -5.5 days | -31% |
| Juvenile Travel Time (CSS) | 15.8 days | 11.3 days | -4.5 days | -28% |
| % Transported (COMPASS) | 38.5% | 0% | -38.5% | -100% |
| % Transported (CSS) | 19.2% | 0% | -19.2% | -100% |
| Transport: In-River Benefit Ratio (CSS) | 0.86 | No transport | N/A | N/A |
| Powerhouse Passages (COMPASS) | 2.25 | 0.74 | -1.51 | -74% |
| Powerhouse Passages (CSS) | 2.15 | 0.62 | -1.53 | -71% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 109.3% TDG | -5.1% TDG | -4% |

The COMPASS and CSS modeling results indicate that survival rates would increase by as much as 25 percent and travel times would decrease by nearly 30 percent (resulting in fish moving faster through the current hydrosystem) relative to the No Action Alternative. However, reductions in hatchery fish could reduce numbers of juvenile Snake River Chinook salmon by as much as 85 percent. This reduction in the number of hatchery fish would likely result in a reduction of these predicted survival rates of wild Chinook because of increased predation rates. The dam breach measures in MO3 would eliminate the transportation program for juvenile Snake River spring/summer-run Chinook.

For Snake River spring/summer-run Chinook salmon, UW/CBR TDG modeling estimated that the Lower Granite to Bonneville reach-average TDG exposure index would decrease by about 5 percent in MO3.

### *Adult Fish Migration/Survival*

**Table 3-89. Multiple Objective Alternative 3 Adult Model Metrics for Snake River Spring/Summer-Run Chinook Salmon**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| LGR-BON SARs (NWFSC LCM)[1/] | 0.88% (0%) | 1.0% (0%)<br>1.1% (10%)<br>1.2% (25%)<br>1.5% (50%) | +0.12% (0%)<br>+0.12% (10%)<br>+0.36% (25%)<br>+0.61% (50%) | +14% (0%)<br>+25% (10%)<br>+42% (25%)<br>+70% (50%) |
| LGR-LGR SARs (CSS) | 2.0% | 5.4% | +3.4% | +170% |
| Abundance of Middle Fork Salmon and South Fork Salmon representative populations (NWFSC LCM) | 1527 | 1659 (0%)<br>1951 (10%)<br>2345 (25%)<br>3160 (50%) | +132 (0%)<br>+424 (10%)<br>+818 (25%)<br>+1633 (50%) | +9% (0%)<br>+28% (10%)<br>+54% (25%)<br>+107% (50%) |
| Abundance (CSS)[2/] | 6114 | 14055 | +7941 | +103% |

1/ NWFSC LCM does not factor latent mortality due to the hydrosystem into the SARS or abundance output. For discussion purposes, potential decreases in latent mortality of 10 percent, 25 percent, and 50 percent are shown. The value for 0 percent is the actual model output, the 10 percent, 25 percent, and 50 percent values represent scenarios of what SARs, or abundance hypothetically could be under the increased ocean survival if changes in the alternative were to decrease latent mortality by that much.

2/ CSS provided results for six populations in the Grande Ronde/Imnaha Major Population Group. The absolute values represent those populations only; the percent change is considered indicative of the Snake River ESU for the purpose of comparing between MOs.

For Snake River spring/summer-run Chinook salmon, the NMFS LCMs and CSS LCM indicate that MO3 may result in a wide range of predicted increases to SAR rates. CSS predicts SARs from Lower Granite to Lower Granite would increase by about 170 percent relative to the No Action Alternative. The NMFS Life Cycle Model predicts relative increases in Lower Granite to Bonneville SARs that range from 14 percent to 70 percent depending on the magnitude of potential reductions in latent mortality.

The NWFSC LCM results generally indicate high variability in potential fish response to dam breach depending on the breach scenario input dataset used for calibration. The CSS LCM results generally indicate that MO3 adult abundance over time would show substantial increases from the No Action Alternative.

Several structural measures in MO3 are anticipated to benefit adult Snake River spring/summer-run Chinook passage upstream and these include modifying the upper ladder serpentine sections at Bonneville Dam (reducing migration delay). Overall, as with the other MOs, neither CSS nor the LCM indicates that powerhouse surface passage structures in MO3 would have a substantial effect on adult abundance over a 30-year period.

Fallback rates of Snake River spring/summer-run Chinook at the lower Columbia dams may increase under MO3 since fallback for this ESU has been associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). In those studies, fish that fell back were less likely to reach their spawning areas compared to fish that never fell back. For example, of the 11 percent of Snake River spring- summer Chinook that fell back at Bonneville dam nearly 14 percent failed to reascend (Boggs et al. 2004). Thus, the MO3 higher spill operation may result in a small increase in the fallback of Snake River spring/summer-run Chinook salmon adults as they migrate upstream. It is important to note that regional managers use in-season adaptive management to identify and remedy any excessive fallback. So while the average survival for Snake River spring/summer-run Chinook salmon adults may decrease slightly from the recent averages of about 89 percent in the Bonneville to McNary Dam reach under the No Action Alternative, increased fallback is not anticipated to have a large effect under this alternative.

Spill cessation starting August 1 at the lower Columbia River dams would likely have negligible effects on summer migrating adults (fallback-related effects) and no effects on spring migrating adults. While fallback rates may be lower, individuals that fell back would experience greater risk of falling back through turbines and juvenile bypass systems compared to spillways once the spill cessation trigger is met at individual lower Snake projects. Adult migration through the breached lower Snake segment is discussed in the following section.

Increasing the reservoir operating range at John Day Dam would have little effect on flow, and thus is not expected to affect adult migration timing or survival. Similarly, holding contingency reserves within juvenile fish passage spill would have negligible effects on adult migration.

Collectively, the water management measures and water supply measures in MO3 would have negligible effects to Snake River spring/summer-run Chinook.

Several changes would occur affecting migration through the breached section, including the following: Maximum summer water temperature would increase slightly; water temperature variability would increase; and water temperatures would not stay cool as long into the spring and would cool earlier in the fall with the removal of the thermal inertia of the lower Snake dam reservoirs. See additional information in Section 3.4, Water Quality, and Appendix D.

The breached areas are not expected to delay adult migration because they would be designed to pass fish at flows up to 170,000 cfs, equivalent to a five-year high flow event. Flows less than this rate are not considered to impede adult upstream migration and would require no additional resting structures. All Lower Snake breach locations provide velocities between 2 to 3 feet per second and flow depths around eight feet for total river flows of 15,000 cfs. As total river flows increase, so do velocities and flow depths. While velocities in the breach area at flows greater than 170,000 cfs could be in ranges that may impede movement even with structures, upstream migration does not occur during these high flows. The high flow periods occur in the spring when spring-run Chinook salmon, sockeye salmon, and some steelhead migrate upstream through the lower Snake River.

In any breached areas where velocities are predicted to be above 5 ft/s at flows less than 170,000 cfs, channel enhancement features would be installed to assist fish in migrating upstream in steps. Where overbank velocities exceed 5 ft/s, channel enhancement features such as precast 6-foot boulders would be placed to provide energy dissipation along the bank to provide resting locations. The spacing of these features ranges from about 200 feet at 5 ft/s to 10 feet for 12 ft/s. The location and extent of channel enhancement features would be detailed in future hydraulic modeling efforts.

Snake River Steelhead

*Summary of Key Effects*

Quantitative model estimates show that MO3 may result in higher juvenile Snake River steelhead survival, reduced travel times and decreased powerhouse passage events. Because the lower Snake projects would be breached, juvenile fish transportation would be eliminated. Steelhead kelts and overwintering steelhead moving downstream in the breached section of the Snake should also experience higher survival rates and faster travel times. The model estimates for both CSS and COMPASS presented in this section are based on a combination of hatchery and wild fish. The CSS model also produced similar estimates using wild fish only; but because those estimates still assume that hatchery fish are present and migrating concurrently with the natural origin fish, those estimates are not representative of a wild fish only migration. This does not capture what would occur if Lower Snake River Compensation hatchery production was reduced or eliminated post-dam breach. The wild fish specific estimates from CSS are contained in Appendix E for reference.

*Juvenile Fish Migration/Survival*

For Snake River steelhead, the COMPASS and CSS models estimate that MO3 would increase juvenile survival and reduce travel time, elevated TDG, and powerhouse encounters (Table 3-90).

**Table 3-90. Multiple Objective Alternative 3 Juvenile model metrics for Snake River Steelhead**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 42.7% | 52.7% | +10% | +23% |
| Juvenile Survival (CSS) | 57.1% | 83.1% | +26.0% | +46% |
| Juvenile Travel Time (COMPASS) | 16.4 days | 9.0 days | -7.4 days | -45% |
| Juvenile Travel Time (CSS) | 16.2 days | 11.0 days | -5.2 days | -32% |
| % Transported (COMPASS) | 39.7% | 0 | -39.7 | -100% |
| % Transported (CSS) | Unknown | 0 | N/A | N/A |
| Transport: In-River Benefit Ratio (CSS) | 1.41 | No Transport | N/A | N/A |
| Powerhouse Passages (COMPASS) | 1.73 | 0.42 | -1.31 | -76% |
| Powerhouse Passages (CSS) | 1.96 | 0.46 | -1.5 | -77% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 109.4% TDG | -5.5% TDG | -5% |

The COMPASS and CSS modeling results indicate that survival rates would increase between 23 and 46 percent relative to the No Action Alternative and that travel times would decrease between 32 and 45 percent relative to the No Action Alternative. However, potential reductions of hatchery fish may also reduce numbers of juvenile Snake River steelhead as discussed above for Chinook salmon. This potential reduction in the number of hatchery fish would likely result in a reduction of these predicted survival rates of steelhead because of increased predation rates since the two stocks currently migrate downstream together. The dam breach measures in MO3 would eliminate juvenile Snake River steelhead transportation.

For Snake River steelhead, the UW/CBR TDG modeling estimated that the Lower Granite to Bonneville Dam reach-average TDG exposure index would decrease by about 5 percent.

*Adult Fish Migration/Survival*

For Snake River steelhead, the CSS cohort model estimates that MO3 would produce a substantial increase (178 percent) in SAR relative to the No Action Alternative. The CSS model estimated an absolute SAR of 5.0 percent. There are no LCM model estimates available for this DPS (Table 3-91).

**Table 3-91. Multiple Objective Alternative 3 Adult Model Metrics for Snake River Steelhead**

| Metric (Model) | NAA | MO3 | Change from NAA | % Change |
|---|---|---|---|---|
| SARs LGR-LGR (CSS) | 1.8 | 5.0 | +3.2 | +178% |

Higher spill levels at the lower Columbia projects during April should result in higher survival rates for adult Snake River steelhead falling back through dams and kelts migrating downstream. Fewer adults use powerhouse passage routes when a spill route is available and overall downstream passage increased when surface passage was available (Normandeau et al. 2014; Ham et al. 2012).

Steelhead kelts and overwintering steelhead moving downstream in the breached section of the Snake River should experience both higher survival rates and faster travel speeds. It is challenging to estimate additional mortality rates due to dam passage for kelts compared to a free-flowing river environment because mortality is naturally high following spawning. Keefer et al. (2017) used radio telemetry to estimate survival and travel speeds of adult steelhead upstream to spawning tributaries in the Snake River, and the return migration to the ocean. Approximately 85 percent of steelhead died after reaching their natal tributary but before initiating the kelt migration through the hydrosystem. Outmigration survival was a minimum of 31 to 39 percent past the four lower Snake dams and a minimum of 13 to 20 percent past all eight dams. English et al. (2006) compared kelt migration speeds through the middle Columbia and four undammed rivers in British Columbia and found travel speed for kelts was substantially faster in the free-flowing rivers however, water velocity and gradient were not closely correlated with fish travel time.

<u>Snake River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon as a surrogate for juvenile Snake River coho salmon and Snake River fall-run Chinook as a surrogate for adult Snake River coho salmon.

*Summary of Key Effects*

Overall, MO3 would reduce juvenile coho salmon travel time, powerhouse encounters, and TDG while increasing juvenile survival.

*Juvenile Fish Migration/Survival*

See Snake River spring/summer-run Chinook salmon as a surrogate for juvenile Snake River coho salmon.

*Adult Fish Migration/Survival*

Long-term effects of MO3 on Snake River adult coho would include a lower risk of delay and fallback because four of the dams would be breached. Temperatures would be reduced during adult migration with the total number of days where temperatures are over 20°C at Ice Harbor Dam. Susceptibility to disease would also diminish with lower migration temperatures. All of these effects would improve long-term survival and spawning success of Snake River coho salmon.

Short-term effects under this alternative include elevated suspended sediments and depleted DO levels during breaching that if not mitigated could lead to major losses of adult coho salmon.

<u>Snake River Sockeye Salmon</u>

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile Snake River sockeye salmon.

*Summary of Key Effects*

Key long-term effects of MO3 would improve downstream and upstream migration survival through the lower Snake River due to breaching the four dams. Benefits would accrue through faster downstream travel time, fewer powerhouse encounters, lower predation, and reduced TDG effects.

Significant short-term effects could occur due to the large amount of suspended sediment and reduced DO due to breaching the dams. There would be the potential for large-scale mortality for any fish in the river during this construction work.

*Juvenile Migration/Survival*

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for Snake River sockeye salmon.

*Adult Migration/Survival*

The percent of days over 18°C between June 21 and July 31 would be 87.3 percent, which is three additional days over 18°C compared to the No Action Alternative. This means Snake River sockeye might have slightly greater thermal stress than under the No Action Alternative. However, breaching of the four lower Snake River dams is expected to reduce delays in upstream migration and decrease the time fish are exposed to the slightly warmer water temperatures. Additionally, sockeye would not have the transportation effects that can increase straying and fallback and prolong their exposure to thermal stress.

MO3 would eliminate temperature differences between the river and the fish ladders at the dam locations. In addition, breaching the four lower Snake River dams would result in moderate decreases in elevated TDG in the Snake River compared to the No Action Alternative.

Another water quality parameter important during upstream migration is the amount of suspended sediment in the water. The typical sediment load is around 2 mg/L of total suspended solids. Excavation for the dam breach measure of MO3 would cause a large sediment plume each year and potentially during runoff of the following 2 to 7 years. The estimates are nearly 25,000 mg/L during excavation for each breach and 30 mg/L after breach. Approximately 27 days would have suspended sediment over 5,000 mg/L. In the conceptual design proposed for analysis, the timing of dam breaching would occur at the tail end of the adult sockeye migration through the lower Snake River. Therefore, only the latest few fish in the run for two consecutive years of construction would experience the high turbidity levels in the river. The estimated severity of the sediment pulse indicates mortality between 20 and 40 percent of fish downstream of these dams. However, the vast majority of Snake River sockeye would have passed upstream from the dams by the time these levels are reached; therefore, MO3 would have minor increases in mortality of these fish compared to the No Action Alternative.

Under MO3, breaching the four Lower Snake River dams would cause DO levels to drop to approximately 2 mg/L throughout the Little Goose and Lower Monumental pool areas in the year of construction. Sockeye salmon need around 5 mg/L of DO for survival. Sockeye salmon become stressed at lower levels and can suffocate with prolonged lack of oxygen. There may be some loss of late migrating sockeye in these two pools during the peak of sediment release, which is the primary cause of the drop in DO in the water; however, almost all of the adult sockeye would have already passed upstream prior to construction.

Under MO3, the lack of juvenile transportation would reduce the fallback and straying. Straying may still occur but would be at the natural levels for this population. This would improve homing compared to the No Action Alternative and would reduce risk of incidental catch in the middle Columbia River fisheries. Reductions in delay, fallback, and straying are likely under MO3.

<u>Snake River Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

Key long-term effects of MO3 for fall-run Chinook would be the major increase in available spawning habitat. Other major improvements would include the downstream migration survival through the lower Snake River due to breaching the four dams. Benefits would accrue through faster downstream travel time, fewer powerhouse encounters, substantially less predation, and reduced TDG.

Major short-term effects would occur due to the large amount of suspended sediment during dam breaching. There is the potential for large-scale mortality for any fish in the river during this construction work.

*Larval Development/Juvenile rearing*

Breaching the four lower Snake River Dams is estimated to increase the available spawning habitat for fall-run Chinook from 226 acres to 3,521 acres, an increase of 15 times the area available today (Corps 2002). The mean depth of water would be reduced, but fall-run Chinook use a wide range of depths for spawning and would be expected to take advantage of the new area available due to dam breaching. MO3 would lead to large increases in spawning habitat and improved conditions for spawning.

Under MO3, juvenile fall-run Chinook may move downstream to use McNary and John Day reservoirs for rearing. One of the long-term effects is that the portion of the fish that overwinter in reservoirs for their first year is expected to be smaller in MO3 compared to the No Action Alternative.

*Juvenile Migration/Survival*

The mean water temperature for May through July is estimated to be slightly warmer than in the No Action Alternative with a higher percentage of days over 20°C (35.6 percent in MO3 compared to 26.6 percent in the No Action Alternative). This represents a minor increase in temperatures and days over 20°C compared with the No Action Alternative. However, the cold water flow augmentation from Dworshak is expected to be more effective with the smaller cross-sectional breached areas to cool down in July and August compared to the No Action Alternative. Major decreases in travel times would substantially reduce predation risk.

An increase in nesting habitat is expected in lower Ice Harbor pool area after dam breaching. Only those islands that would not be inundated in spring flows are suitable habitat. Although a small area of nesting habitat may increase, the risk of bird predation would likely decrease as outmigrating Chinook travel times decrease and turbidity increases under MO3; these factors would reduce exposure to bird predators.

One of the long-term effects of dam breaching is a higher sediment load through the free-flowing reach of river. Under MO3, the Snake River is expected to carry approximately 30 mg/L on average. Outmigrating fall-run Chinook would experience a minor decrease in predation risk under MO3 because of the decreased visibility for the predators.

*Adult Migration/Survival*

The dam breach measure of MO3 would reduce the delays to migration caused by temperature differential between the river and the ladders. This would be a benefit to upstream migrating fall-run Chinook.

Temperatures at Ice Harbor would experience a moderate decrease with only 29.2 percent of all adult migration days over 20°C compared to 54.3 percent in the No Action Alternative. Straying and migration delays, as well as susceptibility to disease, would be reduced in MO3. All of these effects would improve survival and spawning success.

Based on sediment movement analysis (see Section 3.3), excavation for the dam breach measure of MO3 would cause a large sediment plume for a long duration, that may reoccur for two to seven years after excavation. In the conceptual design proposed for analysis, the timing of dam breaching would occur during the adult fall-run Chinook migration through the Lower Snake River. Two consecutive years of construction would cause fish in this population to experience the high turbidity levels in the river. The estimated severity of the sediment pulse indicates the potential for mortality between 20 and 40 percent of fish downstream of these dams. This could result in a major short-term loss to the population, but the Snake River fall-run Chinook population would be expected to recover due to the benefits from dam breaching. Further design and mitigation measures would be developed to minimize the short-term losses.

Under MO3, breaching the four Lower Snake River dams and elevated suspended sediments is estimated to cause DO levels to drop to approximately 2 mg/L throughout the Little Goose and Lower Monumental pool areas in the year of construction. Chinook salmon need over 5 mg/L of DO for survival; they become stressed at levels below this and can suffocate with prolonged lack of oxygen. If not mitigated, these levels of DO could cause the loss of major portions of migrating adult fall-run Chinook in these two pools during the peak of sediment release.

MO3 would eliminate juvenile fish transportation. Scientists expect reductions in delay, fallback, and straying under MO3.

***Lower Columbia River Salmon and Steelhead***

<u>Lower Columbia River Chinook Salmon</u>

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for lower Columbia River Chinook salmon.

*Summary of Key Effects*

Juvenile survival and travel time would be similar to the No Action Alternative under MO3, with the possible exception that the fall run of Lower Columbia River Chinook salmon, which could experience higher outmigration survival through Bonneville Dam with lower spill in August.

Adult migration and survival would be lower for spring-run fish due to increased spill and TDG, while fall-run fish may experience less fallback and delay. Dam breach measures in MO3 would not affect Lower Columbia River Chinook salmon.

*Juvenile Fish Migration/Survival*

Five of the 32 populations of Lower Columbia River Chinook salmon pass Bonneville Dam on their downstream outmigration to the ocean. Modeling was not available for this ESU; however, juvenile survival at Bonneville Dam of Snake River spring/summer-run Chinook salmon was used as a surrogate. COMPASS modeling predicts juvenile survival would have negligible increases (+0.4 percent) higher than the No Action Alternative. Much lower spill at Bonneville in August could have a minor increase in juvenile survival for fall-run Lower Columbia Chinook as powerhouse passage at powerhouse number one has a higher survival than spillway routes.

Effects of outflows from March through September for all runs of Lower Columbia River Chinook salmon would be similar to the No Action Alternative. At The Dalles, water quality modeling indicates higher TDG in April through June with increased spill above the threshold of 120 percent TDG for 76 days, compared to 33 under the No Action Alternative. The small proportion of this ESU that passes above Bonneville Dam may experience increased incidence of GBT during outmigration (spring-run and late-fall-run) and rearing (all runs) between The Dalles and Bonneville. Reduction of spill in August would reduce TDG to levels well below the No Action Alternative levels at this time; fall-run fish outmigrating at this time would not be affected, though they would experience the increased TDG during juvenile rearing. Below Bonneville Dam, modeling indicates the TDG would be slightly higher in the spring and considerably lower in August than the No Action Alternative, with 68 days exceeding the water quality standard compared to 61 days in the No Action Alternative.

*Adult Fish Migration/Survival*

Structural measures such as modifying the upper ladder serpentine sections at Bonneville Dam are expected to reduce delay associated with upstream passage. Fallback rates may decrease for fall-run and late-fall-run fish with decreased spill in August, but increase for spring-run adults. Similarly, TDG would be higher in April through June, but lower in August, so adult spring-run fish would also experience higher TDG exposure. All runs would experience higher TDG exposure for juvenile rearing. Hydrology and water quality modeling predicts flows and temperatures that could affect lower Columbia River Chinook salmon adult migration and survival would be similar to the No Action Alternative.

<u>Lower Columbia River Steelhead</u>

Refer to Snake River steelhead analysis as a surrogate for lower Columbia River steelhead.

*Summary of Key Effects*

Juvenile survival in MO3 would be similar to the No Action Alternative, with modeled dam survival similar to the No Action Alternative. Faster travel times with higher spill would be expected for fish that pass Bonneville Dam, but reduced flows would also slow travel time for other Lower Columbia River steelhead and potential increased TDG effects. Adult migration of a portion of the winter run could be decreased slightly with higher winter flows. Survival of kelts would be higher in spring and early summer, but lower in winter with reduced spill, and increase TDG may affect adults.

*Juvenile Fish Migration/Survival*

Modeling for juvenile Snake River steelhead was used as a surrogate of juvenile survival for Lower Columbia steelhead that pass Bonneville Dam. These results predict there would be no discernable difference in juvenile survival between MO3 and the No Action Alternative. TDG exposure to the fish that pass upstream of Bonneville would be higher with 43 more days above the water quality standard, and below Bonneville they would experience seven more days over the standard.

*Adult Fish Migration/Survival*

Structural measures such as modifying the upper ladder serpentine sections at Bonneville Dam are expected to have minor reductions in delay associated with upstream passage. Under MO3, higher spill levels during May could increase fallback and delay of a portion of winter-run steelhead. Spill reduction in August would generally reduce adult fallback and delay. Temperatures would be similar to the No Action Alternative, and adult fish would generally experience higher TDG as described for juveniles.

<u>Lower Columbia River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile Lower Columbia River coho salmon and Snake River fall-run Chinook salmon as a surrogate for adult Lower Columbia River coho salmon.

*Summary of Key Effects*

Lower Columbia River coho salmon would have minor increases in juvenile survival and negligible impacts to adult salmon upstream migration under MO3, relative to the No Action Alternative.

*Juvenile Fish Migration/Survival*

Using the surrogate approach, CRS operational changes in MO3 may slightly increase survival rates for Lower Columbia River juvenile coho passing Bonneville Dam by as much as 1 percent. Refer to Snake River spring-run Chinook for surrogate information in Section 3.5.2.5.

*Adult Fish Migration/Survival*

Upstream migration and survival of adult Lower Columbia River coho salmon would have negligible impacts under MO3 compared to the No Action Alternative using surrogate information. Refer to Snake River fall-run Chinook for surrogate information in Section 3.5.2.5.

Lower Columbia River Chum Salmon

Refer to Snake River spring/summer-run Chinook salmon analysis as a surrogate for Columbia River chum salmon.

*Summary of Key Effects*

MO3 is expected to result in minor increases in juvenile chum survival through Bonneville Dam and Reservoir relative to the No Action Alternative, while incubating chum sac fry would be exposed to minor increases in TDG.

*Juvenile Fish Migration/Survival*

As there is no direct estimate of Bonneville Dam survival specific to juvenile chum, juvenile Snake River spring-run Chinook are used as a surrogate. Under MO3, COMPASS modeling indicates that CRS operational changes are expected to result in minor increases in juvenile chum survival relative to the No Action Alternative. There is no dam-specific survival estimate available from CSS.

Under MO3, chum flow operations would be met slightly more often (1 percent more) than the No Action Alternative. In years when additional releases from Grand Coulee for chum would be needed, the average additional volume needed would be 0.08 Maf.

Maintaining TDG levels of 105 percent or less from November 1 to April 30 appears to provide a sufficient level of protection to chum salmon eggs and sac fry incubating in the gravel downstream of Bonneville Dam in the Ives/Pierce Island Complex, using 3 percent per foot depth compensation. In the No Action Alternative, chum sac fry are exposed to TDG above 105 percent in 4 out of 80 years and those exceedances are all in the mid- to late April timeframe.

*Adult Fish Migration/Survival*

Most chum spawn downstream of Bonneville. Migration of chum into the Columbia River is in October and November. Adult migration and survival under MO3 would likely be similar to the No Action Alternative.

**Other Anadromous Fish**

***Pacific Eulachon***

Summary of Key Effects

Eulachon would continue to migrate into the Columbia River from November through March, with specific dates of migration and spawning based on a variety of environmental factors including temperature, high tides, and ocean conditions (NMFS 2017). Modeled data for MO3 (based on the period of record for Bonneville tailwater temperatures) indicate that temperatures would not be substantially different from the No Action Alternative. Average monthly temperatures in the winter months would be about 0.2 to 0.3 degree Fahrenheit cooler. Spawning locations and substrate conditions would not be expected to differ from the No Action Alternative.

Compared to the No Action Alternative, MO3 would have no change in the time between the peak spawning runs, egg development, and larval emergence. The spring freshet that disperses larvae to adequate food sources would continue to be highly variable, with an average of 166 days between spawning temperature triggers and peak flows (158 days in high flow years, and 157 days in low flow years).

Spring flow rates would be expected to be about 1 percent to 2 percent lower during outmigration compared to the No Action Alternative. Decreased flow can affect the chemical and physical processes of the estuary-plume environment, which affects primary productivity (NMFS 2017). The relationship between Bonneville outflow and the estuary plume is not certain, but a reduction could result in slightly less distribution of larvae.

Bird predation risk can be influenced by flow rates. Higher flows are linked to higher predation rates on eulachon, whereas at lower flows birds tend to switch to marine prey. Under MO3, there would be relatively little change (1 to 4 percent) in all months and water year types (the change is low enough to be likely immeasurable). Slightly higher flows in December could increase predation risk. The early portion of the eulachon run comes in during November and December and may be more subject to predation

Operation of the CRS system under MO3 would result in very similar turbidity levels in spring.

***Green Sturgeon***

Summary of Key Effects

The Columbia River use by green sturgeon is primarily foraging habitat for adults and subadults. Key effects of MO3 are focused on how flows and temperatures influence the cues for entering the Columbia River as well as the availability and distribution of food sources. Overall, the estuary would continue to provide good foraging and rearing habitat for green sturgeon, but there could be a minor decrease in summer foraging habitat under MO3 compared to the No Action Alternative.

Adult Fish Migration/Survival

Green sturgeon migrate seasonally along the West Coast, foraging in bays and estuaries during the summer and fall months, including the Columbia River estuary (as far upstream as Longview). Both southern DPS and northern DPS occur in the Columbia River, but the majority are southern DPS. The Columbia River estuary provides important foraging and rearing habitat for green sturgeon. MO3

Under MO3, green sturgeon would continue to arrive in June and leave in September or October (variation compared to the No Action Alternative is one day or less in arrival/departure date). This date range would be expected to continue supporting adequate rearing conditions.

Under MO3, there could be a slight decrease in summer flows (1 percent to 3 percent from June through September), but overall the estuary would continue to provide good foraging habitat for green sturgeon, but there could be a minor decrease in summer foraging habitat under MO3 compared to the No Action Alternative.

***Pacific Lamprey***

Summary of Key Effects

MO3 has several measures that are designed specifically to benefit lamprey. These measures are proposed structural improvements that include changing extended-length submersible bar screens, expanding the network of Lamprey Passage Structures, changing the design for turbine cooling water strainers, replacing turbines for safer fish passage, to reduce fish injury and mortality.

As described for the No Action Alternative, upstream and downstream passage at the mainstem Columbia River and Snake River dams has been the greatest influence on population decline and reduced distribution of Pacific lamprey. The most substantial benefit of MO3 would be the breaching of the four Lower Snake River Dams. This would reduce mortality to lamprey during the downstream migration phase and would substantially improve the ease of upstream migration. Other key benefits would accrue through the improvements to get fish to enter the fish ladders this would occur through expanding the network of Lamprey Passage Structures and modifying fish ladders to incorporate lamprey passage criteria into the structural modifications.

Larval Development/Juvenile Rearing

MO3 has no measures that would either benefit or harm juvenile lamprey during the rearing stage. All ramping rates and dewatering issues would be the same in MO3 as for the No Action Alternative.

Juvenile Fish Migration/Survival

Under MO3, several structural measures would improve passage conditions, increase survival, and reduce injuries. Proposed actions include the following:

- Changing the extended-length submersible bar screens to a screen material that would substantially reduce mortality due to impingement.
- A new design of structure for exclusion of juvenile lamprey from cooling water strainer intakes would reduce or eliminate this pathway of mortality.
- Additional powerhouse surface passage at McNary projects to change the dynamics of lamprey passage. A higher percentage of lamprey would be expected to pass via the safer surface routes instead of the turbines in relation to the No Action Alternative.
- Replacing turbines at John Day Project with improved fish passage turbines that would improve conditions for fish passage and increase lamprey survival.

Because of the high degree of uncertainty surrounding how many juvenile lamprey are lost or injured on their downstream migration, it is difficult to quantify the improvement represented by all of the measures. For fish that encounter multiple dams on their migration downstream, reducing the total number of hazards would increase their probability for survival.

Adult Fish Migration/Survival

Each structural measure in MO3 that targets lamprey is intended to increase their dam passage efficiency either by getting fish to enter rather than turn back from the fishway, or to increase successful upstream passage. Effectiveness of the measure would vary by dam.

The most substantial benefit from MO3 would occur in the Snake River basin with breaching of the four Lower Snake River Dams. In the proposed conceptual-level designs, the river would run through the excavated earthen embankments and become free flowing in which lamprey could migrate upstream without encountering ladders or other barriers. However, hydraulic analysis shows that high velocity barriers could form at the concrete corners of the abandoned dams during high flows and early season migrants could see velocities above their burst speeds. Substrate along each of the breaches would be riprap to prevent erosion and lamprey would be expected to use burst-speed swimming over riprap.

Breaching of the four lower Snake River Dams would result in faster heating and cooling of river water compared to what would occur in reservoirs in the No Action Alternative. This means the water would be warmer in early June and July, but cooler in August and September.

Fluctuations would occur on diel basis (i.e., water temperatures warm up through the day and cool down at night). The fish would experience cooling in the evenings, which would lessen the overall impact to lamprey. Exposure may be reduced with faster migration times from dam breaches. July temperatures are highest when lamprey peak migrations occur.

Approximately 44 percent of adult lamprey that reach Bonneville Dam pass to upstream areas, while 68 percent of those that pass Bonneville Dam will also pass The Dalles Dam (Keefer et al. 2012). If the proposed structural measures were implemented at Bonneville, moderate improvements in fish passage efficiency would occur. Similar improvements at John Day ladders to improve lamprey entrance into the fishway resulted in increased passage efficiency from 46 percent to 83 percent (Clabough et al. 2015). Because dynamics at each dam are very different, the improvements from the increased passage efficiency cannot be directly inferred across projects, but lamprey would see improvements in overall dam passage efficiency with improvements in ladder entrance efficiency.

At John Day, lamprey passage was estimated at 67.5 percent (Keefer et al. 2019). Additional work for the Lamprey Passage Structures on the south fishway and extension on the north fishway would continue to moderately improve overall dam passage efficiency incrementally.

The overall expected improvements in lamprey passage efficiency should decrease susceptibility to physical stress and mortality. These structural measures for lamprey are expected to provide a major benefit to the population size and distribution of Pacific lamprey in the Columbia Basin, and especially in the Snake River Basin due to breaching of the four lower Snake River Dams.

#### ***American Shad***

Summary of Key Effects

No long-term change is anticipated to juvenile shad in the lower Columbia because plankton communities and shoreline habitat are not changing in the lower Columbia in MO3. The lack of reservoirs in the lower Snake reach would make that reach less suitable for shad than under the No Action Alternative, so an overall decrease in shad under MO3 is anticipated.

Juvenile Fish Migration/Survival

Plankton communities and shoreline habitat are not expected to change in the lower Columbia reservoirs relative to the No Action Alternative. However, plankton communities may be depressed in the lower Columbia reservoirs after the lower Snake dam breaches until a new plankton community equilibrium is established. During the period when plankton communities are depressed, juvenile shad are likely to face minor food reductions and may decline because their diet is almost exclusively plankton.

Adult Fish Migration/Survival

The proportion of adult shad counted at Bonneville Dam that migrate upstream past McNary Dam is not expected to change due to change in temperatures relative to the No Action Alternative. The breach of the lower Snake dams would facilitate upstream expansion of shad in terms of passage.

## RESIDENT FISH

### Region A

#### *Kootenai River Basin*

Summary of Key Effects

MO3 would have the same key effects as the No Action Alternative. Current discharges from Libby Dam have detrimental effects to fish species in the Kootenai River downstream of Libby Dam. Spring water temperatures would continue to be too cold for the development of many aquatic species. Spring flows would also continue to increase at a rate less than normalized, thereby delaying and reducing productivity associated with inundated riparian and varial zone habitats. These reduced flow rates would also continue to limit productivity and may adversely impact food sources for resident fish downstream of Libby Dam.

Cottonwood seedlings would continue to have variable survival depending on timing, stage and duration of spring flows, along with winter stage during the ensuing winter. In addition, the discharge regime from Libby Dam would not provide for successful burbot recruitment, and spring water temperatures would be too cold to allow for proper larval development.

Habitat Effects Common to This Fish Community

MO3 would not change water temperatures in the spring from those under the No Action Alternative. However, similar to MO1 and MO2, MO3 would provide deeper end-of-December drafts than the No Action Alternative, with deep drafts of 11 feet in the wet years, and thus may enhance reservoir warming during the spring and early summer.

MO3 would have a lower rate of flow increase from Libby Dam in the spring compared to the No Action Alternative. This decrease in flow rate under MO3 would result in a greater delay in spring productivity than under the No Action Alternative.

MO3 would decrease the potential for cottonwood and willow seeding and recruitment compared to the No Action Alternative. Under MO3, there would be less area for seeding establishment than under the No Action Alternative. On average, there would be no habitat available under MO3 that is not flooded by winter scour flows compared to one foot of elevation above these flows in the No Action Alternative.

MO3 would have a similar rate of recession of river stage at Bonners Ferry during the seeding seasons than the No Action Alternative.

Bull Trout

Effects of MO3 to bull trout that differ from the No Action Alternative include lower flows below Libby Dam and increases in usable habitat for juvenile and adult bull trout.

Under MO3, Lake Koocanusa would be above elevation 2,450 feet for two more days during the summer productivity period than under the No Action Alternative. The expected result would be minor increases in productivity and an increased food web under MO3. In addition, fall water levels would be higher, on average, than under the No Action Alternative.

The minimum elevation of Lake Koocanusa under MO3 would be 7 feet lower, while the maximum elevation would be 1 foot higher than under the No Action Alternative. The expected result would be greater variability in water levels and more frequent annual dewatering and decreased benthic insect production, which may result in a decrease in bull trout growth and/or survival.

MO3 would have slightly lower discharges than the No Action Alternative, but would provide more usable habitat for juvenile (day and night) and adult bull trout than the No Action Alternative.

Kootenai River White Sturgeon

MO3 would provide an estimated one less day of peak discharge than provided by the No Action Alternative. This reduction in the ability to maximize the number of days flow exceeds 30 kcfs at Bonners Ferry relative to the No Action Alternative is negligible.

MO3 would provide a deeper end-of-December draft than the No Action Alternative, with drafts up to 11 feet deeper in wet years. These deeper drafts would likely lead to slightly lower productivity at Lake Koocanusa.

Other Fish

The median minimum elevation of Lake Koocanusa under MO3 would be 11 foot lower than under the No Action Alternative, while the maximum elevation would be 1 foot higher than the No Action Alternative. These conditions would have the same effects identified in the discussion above for bull trout.

Under MO3, there would be fewer days when Libby Dam would provide a discharge of 20 kcfs or greater when compared to the No Action Alternative. These flows would be insufficient to mobilize or reshape tributary deltas that can prevent bull trout access during the fall spawning season.

MO3 would have slightly lower discharges from Libby Dam from May 15 to September 30 than the No Action Alternative, but would provide slightly more usable habitat for juvenile and adult redband rainbow trout than the No Action Alternative, which may result in increased growth and/or survival of all life stages of redband rainbow trout.

Effects to burbot under alternative MO3 include lower and cooler winter flows during spawning. Median flows under Alternative MO3 as measured at Bonners Ferry between January 1 and April 30 would be lower than No Action Alternative. Median flows under Alternative MO3 would be more likely than the No Action Alternative to provide the low and stable flows to imitate pre-dam hydrographs during burbot spawning and incubation, and thus most conducive to successful burbot recruitment. In addition, these lower flows would cool more readily than higher flows and help induce successful spawning.

***Hungry Horse/Flathead/Clark Fork Fish Communities***

Summary of Key Effects

The measures that affect project operations at Hungry Horse Reservoir are the same as MO1. The only difference between MO1 and MO3 is that MO3 includes the *Ramping Rates for Safety* measure, which removes ramping rate restrictions that were put in place to minimize effects. The key operational effects of MO3 (same as MO1) are largely biological responses to changes in Hungry Horse Reservoir elevations and outflows to provide additional water supply. Lower elevations through the summer would decrease food supply for fish with slight reductions in plankton production and surface area for summer terrestrial insects. Benthic insect production important to fish would be decreased under MO3. Lower surface elevations could also increase rates of predation and harvest as fish are more vulnerable in shallower water as they migrate into and out of tributaries to fulfill their life cycles. Increased outflows in summer would likely result in increased entrainment of zooplankton and fish out of Hungry Horse reservoir. Increased flows in the South Fork Flathead River would be attenuated with flows from the mainstem Flathead River but would still result in higher summer flows that would decrease native fish habitat suitability in that reach. MO3 would have negligible effects on Flathead Lake, lower Flathead River, or Clark Fork River fish.

Habitat Effects Common to This Fish Community

Habitat effects due to Hungry Horse Reservoir elevations would be the same as MO1. See that alternative for detailed descriptions.

Because the elevation follows the same summary hydrograph as in MO1, the following parameters would also be similar:

- End of month volume of reservoir available to produce zooplankton would be 1 to 3 percent lower in summer.
- Magnitude and rate of drawdowns in reservoir elevation affecting benthic aquatic insect production. Benthic habitat reduced by at least 3 to 4 percent, with higher magnitude of effect in headwater bays.
- End of month surface area influencing available surface area for terrestrial insect feeding in summer and the distance from the water surface from the terrestrial vegetation, which influences what proportion of non-flying terrestrial insects drop to the water surface to be available for fish.

See Section 3.5.3.4, Multiple Objective 1, Resident Fish, Region A for detailed analyses of these relationships.

Outflow patterns from Hungry Horse Reservoir would also be very similar to MO1, with higher summer flows for additional water supply and lower spring, fall, and winter flows. Therefore, flows on down the system in the South Fork Flathead River, mainstem Flathead River, Flathead Lake, lower Flathead River, and Clark Fork River would also all be the same as MO1. See Section 3.5.3.4, Multiple Objective 1, Resident Fish, Region A for detailed analyses.

The key difference between MO1 and MO3 is that MO3 includes the measure to remove ramping rate restrictions that have been implemented over time to reduce fish effects from ramping rates. Increased ramping rates would increase effects on aquatic insect production and potential stranding of fish. This measure is also in MO2 and habitat effects are described in Section 3.5.3.5, Multiple Objective 2, Resident Fish, Region A. One other difference is MO3 outflows are lower for about two weeks in February.

<u>Bull Trout</u>

As described in the physical environment, MO3 conditions would slightly (1 to 2 percent) reduce the summer production of zooplankton that fuels the food web and surface area available for summer terrestrial insect feeding and substantially lower the benthic insect production, compared to the No Action Alternative. Reservoir elevations would be 3 to 4 feet lower in the late summer and fall in most years when bull trout migrate into tributaries and spawn, resulting in increased varial zone effects and potential tributary habitat blockage. This effect would be up to 12 feet in extremely dry years. Bull trout entrainment would be 9 to 21 percent higher due to increased outflows in late summer. Zooplankton entrainment would also be 9 to 21 percent higher than the No Action Alternative so there would be more plankton available in the South Fork Flathead River, but increased flows would decrease habitat available for transitory bull trout use. Summer median flows in the mainstem Flathead River would be 2 to 11 percent higher in summer than the No Action Alternative, further exacerbating issues with habitat suitability. Operations of Seli'š Ksanka Qlispe' Dam (Flathead Lake) would be similar to the No Action Alternative, and the bull trout habitat use and life history functions in Flathead Lake, the Lower Flathead River, and Clark Fork River would be similar to the No Action Alternative. See Section 3.5.3.4, Multiple Objective 1, Resident Fish, Region A for more detailed analyses.

<u>Other Fish</u>

Many effects described for bull trout would also apply to all of the native fish species in Hungry Horse Reservoir. Slight decreases in zooplankton, decreased macroinvertebrates, and reduced summertime feeding of terrestrial insects could reduce food supply slightly (1 to 2 percent) in summer. Compared to the No Action Alternative, Westslope cutthroat trout and other spring-spawning native fish would experience greater varial zone effects on their way upstream as adults, and could encounter some tributary blockages, but the delta formation of these tributaries is not known. Under MO3 operations, the modeled April and May elevations would be 5 feet and 3 feet, respectively, lower than the No Action Alternative. Juveniles typically outmigrate in June when the effects would be similar to the No Action Alternative. Entrainment from the reservoir would also continue at unquantified levels and could increase nine to 21 percent in the summer months with increased outflows. Habitat suitability described for bull trout would be similar for other native fish (Muhlfield et al. 2011), with higher summer flows in MO3 resulting in decreased amount of suitable habitat for them in summer. Effects to fish in Flathead Lake, the lower Flathead River, and Clark Fork Rivers would be similar as described in the No Action Alternative. See Section 3.5.3.4, Multiple Objective 1, Resident Fish, Region A for detailed analyses.

***Lake Pend Oreille (Albeni Falls Reservoir)/Pend Oreille River***

Summary of Key Effects

The key effects of MO3 for all resources in the Pend Oreille basin would be the same as those found under the No Action Alternative.

Habitat Effects Common to All Fish

Common habitat effects of MO3 would be the same as those identified for the No Action Alternative.

Bull Trout

Key effects to bull trout under MO3 are not different from the No Action Alternative.

Other Fish

Effects of MO3 would be the same as those identified under the No Action Alternative.

**Region B**

***Lake Roosevelt/Columbia River from U.S.-Canada Border to Chief Joseph Dam***

Summary of Key Effects

Flow, elevations, and water quality affect the quality of habitat for various resident fish species above, in, and downstream of Lake Roosevelt. The Columbia River from the U.S.-Canada border would continue to support a white sturgeon population that spawns successfully but primarily relies on fish manager intervention to survive a recruitment bottleneck; conditions for natural recruitment may be further diminished in a small proportion of years. In Lake Roosevelt, retention time is a key metric for most fish species in Lake Roosevelt, driving the food web that supports the fish as well as influencing how many are entrained and would be lower in November and December than the No Action Alternative. Lake elevations under MO3 would be similar to the No Action Alternative related to risk of impeded tributary habitat access and egg desiccation/stranding for redband rainbow trout. The portion of kokanee that spawn in tributaries would continue to have access in fall similar to the No Action Alternative. The effect of egg desiccation under MO3 would remain the same for burbot and kokanee. MO3 would continue to support both wild and hatchery-raised kokanee, redband rainbow trout and hatchery rainbow trout as well as non-native warmwater game species such as walleye, smallmouth bass, and northern pike. Northern pike would likely continue to increase and invade downstream and pike suppression efforts would be at similar levels as the No Action Alternative. Rufus Woods Lake would continue to provide habitat for fish entrained from Lake Roosevelt and from limited production of shoreline spawning by some species; entrainment could increase in winter and decrease in summer months. TDG would be similar or less than the No Action Alternative.

Habitat Effects Common to This Fish Community

The No Action Alternative would begin a shallow drop in early January where MO3 would hold steady through January and then drop into the winter draft in February. Initiation of refill would depend on the basin's water conditions but typically would begin in early May similar to the No Action Alternative in most years except the draft may be about a foot deeper in dry years. Elevation would then rise until mid-May where they would be the same as the No Action Alternative for the rest of the water year, reaching a target full pool of about 1,289 feet by July 4.

Median peak outflows follow the same pattern as the No Action Alternative with slightly reduced peaks in early June and July. The MO3 median flows in early spring through September would be about 2 percent to 5 percent lower than the No Action Alternative. November and December median flows would be about 2 percent to 4 percent higher than the No Action Alternative, while January flows would be 5 percent lower. These peak outflows can influence the rate of entrainment from Lake Roosevelt into Rufus Woods Lake. TDG in the Grand Coulee tailwater is also a concern for fish in Rufus Woods Lake. Under the MO3 TDG would be lower than the No Action Alternative.

Retention time of water through the reservoir is a driving metric for the food web in Lake Roosevelt and influences the populations of several fish species.

Generally speaking, under MO3 median retention time would be similar to or slightly higher than the No Action Alternative in late spring, summer, and fall. In all year types, retention time under MO3 would be 2 percent to 5 percent lower in November and December. In wet years, it would be slightly lower than the No Action Alternative (one percent to three percent) in spring. In wet years is when retention time is lowest because more water is moving through the system, and MO3 would reduce spring retention times even further in these years.

Kokanee, redband rainbow trout, juvenile burbot, larval sturgeon, and many prey species rely directly on the food source provided by the zooplankton production and higher-level predators such as bull trout prey on these fish. Zooplankton are more widespread, more plentiful, and larger body size when retention times are higher, and tend to be smaller bodied, swept out of the reservoir faster, and more concentrated near Grand Coulee dam with lower retention time. With lower retention times under MO3 in winter and spring, when retention times are already fairly low, there would be less food available to fish, and they would also tend to follow the food source and crowd down towards the dam, becoming more susceptible to entrainment.

<u>Bull Trout</u>

Bull trout are temperature sensitive and would continue to use this reach for FMO habitat until temperatures reach stressful levels, which would be the same as the No Action Alternative. Bull trout in Lake Roosevelt could continue to move to cooler locations in the reservoir and these refuges would remain similar to the No Action Alternative. High flow years would continue to influence bull trout distribution through flushing more of them from the river near the U.S.-Canada border down into Lake Roosevelt. Similar to MO1, peak flows at the U.S.-Canada border were modeled showing a decrease of about 1 percent to 2 percent under MO3, which would likely be a negligible change to bull trout distribution. Increased outflows in November and December could potentially increase entrainment of bull trout, but this is negligible because of the scarcity of bull trout in Lake Roosevelt.

Bull trout prey base would continue to fluctuate as the fish they eat are sensitive to changes in productivity and location of zooplankton in Lake Roosevelt. Productivity and location are influenced by the retention time of water in the reservoir, which would be adversely affected by lower retention times in winter under MO3. Bull trout are also sensitive to contaminants that are found in this region and would continue to bioaccumulate contaminants as a top predator. Reservoir operations that would increase the exposure of shorelines and contaminant uptake and fluctuation events would be the same as the No Action Alternative.

<u>Other Fish</u>

In the Columbia River reach from the U.S.-Canada border to Lake Roosevelt, white sturgeon are typically able to spawn as evidenced by capture of young of the year larvae (Howell and McLellan 2018), but rarely experience successful recruitment from larvae to juvenile sturgeon, and only in extremely high water years. Successful recruitment, as documented in 1996, 1997, and 2011, appears to be dependent on a combination of flows exceeding 200 kcfs and water temperatures of about 14°C for 3 to 4 weeks in late June/early July (Howell and McLellan 2011 and Howell and McLellan 2014). Under MO3, these flows would slightly lower than the No Action Alternative. These slightly reduced flows at the U.S.-Canada border would result in potentially decreased recruitment window. The timing of these flows coinciding with lower reservoir levels can also increase recruitment ability with the longer riverine habitat provided by a lower reservoir. MO3 reservoir levels would be the same as the No Action Alternative. Recruitment window for sturgeon reproduction would be slightly reduced overall. Other factors that would continue to influence sturgeon include predation by fish that are favored by reservoir conditions if larvae are flushed into the Lake Roosevelt. Slightly lower flows in spring could slightly reduce the risk of larvae entering Lake Roosevelt. The uptake of contaminants such as copper closer to the U.S.-Canada border being flushed downstream into the reservoir by high flows would also be slightly lower. Under MO3, recruitment of white sturgeon would continue to be a rare event with slightly reduced recruitment. It would continue to be supplemented by hatchery propagation, as larval sturgeon are captured and raised in hatcheries until they are past the window where recruitment has been shown to fail at a high rate. Once these juveniles are released back into the reservoir they continue to grow and survive well. The reservoir would continue to provide good conditions for growth and survival of these fish.

Wild production of native fish such as burbot, kokanee and redband rainbow trout would continue to provide valuable resources in Lake Roosevelt. As described in the common habitat effects, these fish are the most sensitive to the effects of changing retention times. Under the No Action Alternative an estimated average of over 400,000 fish annually would be entrained, with 30 to 50 percent of them being kokanee, primarily of wild origin and rainbow trout the second most entrained species. Under MO3 operations, increased entrainment would be expected in November and December as the outflows increase over the No Action Alternative and retention times would be 2 percent to 5 percent lower. Previous entrainment studies (LeCaire 2000) indicated winter being a period relatively low entrainment; however, the prolonged drawdown period is expected to increase entrainment during this time. In wet years, entrainment would also be slightly higher in March to May (one percent to two percent lower retention time) which could increase entrainment slightly. Increased entrainment of zooplankton would decrease food availability that is key to winter survival and growth of several fish species including kokanee, juvenile burbot, and other juvenile fish.

For tributary spawning species such as redband rainbow trout and a portion of the wild production of kokanee, tributary access at the right time of year is important. Reservoir drawdown in the spring creates barren tributary reaches through the varial zone, which directly and indirectly impedes migration to and from tributaries and the reservoir. A lake elevation under MO3 would be sufficient to protect the access for the portion of kokanee that spawn in tributaries. Redband rainbow trout need access tributaries in the spring. Under MO3, reservoir elevations would be nearly the same as the No Action Alternative levels in the critical spawning migration time of April-May in wet years when varial zone effects are the highest due to deepest drawdowns.

Species such as kokanee and burbot that spawn on shorelines in Lake Roosevelt are susceptible to egg desiccation if reservoir levels drop while eggs are still in the gravel. Kokanee spawn on shoreline gravels September 15-October 15 and eggs incubate through February. Burbot tend to spawn successfully in depths provided by the MO3 in the Columbia River and in Lake Roosevelt on shorelines near the Colville River in winter with eggs incubating through the end of March (Bonar et al. 2000). MO3, compared to the No Action Alternative, would reduce the desiccation of eggs slightly because the reservoir holds slightly longer January in average years. Dry years could see minor changes with January levels in this 20 percent of years expected to drop slightly lower than the No Action Alternative, as well as a short-term reduction in levels during late November.

Burbot spawn later in the winter and would have similar effects as the No Action Alternative, except for the slight improvement noted in average years in January. Burbot spawn in the Columbia River above Lake Roosevelt and in reservoir towards the upper end; the river spawning fish would not be as susceptible to reservoir fluctuations and would be similar to the No Action Alternative.

Kokanee are very sensitive to water temperature, and during summer are found at depths below 120m to find suitably cool water. Under the No Action Alternative, Lake Roosevelt is very weakly stratified but does have suitably cool water at this depth along with suitable levels of dissolved oxygen. Lake whitefish and mountain whitefish also likely use this cool water in the summer.

Non-native warmwater gamefish, such as walleye, northern pike, smallmouth bass, sunfish, crappie, and others, as well as the prey fish that they eat (such as shiners, dace, and sculpins) all tolerate a wide range of environmental conditions and would continue to contribute to the fishery community under the MO3, and continue to adversely impact native species via predation. The invasion downstream by northern pike is of concern, and the Lake Roosevelt Co-Managers are actively suppressing pike populations using gillnets set by boats as soon as they can get on the water in the spring until the boat ramp becomes unusable at elevation of 1,235 feet. Under the No Action Alternative this occurs on April 15 in wet years, boat ramps remain useable in dry and average years. This would be the same in MO3. It should be noted that is only one boat ramp, but the middle of Lake Roosevelt area becomes inaccessible earlier, at lake elevation 1,245’. Additionally, outflows and retention time would continue to influence the entrainment and downstream invasion of non-native gamefish below Chief Joseph Dam where ESA-listed anadromous salmonids would be susceptible to predation by them. During the time when pike juveniles would be most susceptible to entrainment (May to August), retention time under MO3 would be similar or slightly higher so entrainment risk for pike would be similar to the No Action Alternative or slightly lower.

Once released, the net pen fish that supplement the rainbow trout fishery in Lake Roosevelt would experience similar effects as their native counterparts except for spawning and early rearing effects. In addition, the net pen locations are situated where the water quality can be affected by changes in reservoir elevations; these fish are sensitive to temperature and TDG, and their eventual recruitment to the fishery can be affected by retention time coupled with reservoir elevation at the time of their release (McLellan et al. 2008), which is typically in May. Under the MO3, the water quality at these locations would be similar to the No Action Alternative, and the retention time in May would be either similar or slightly higher so entrainment risk would be the same as the No Action Alternative or slightly less. The net pen operators strive to release these fish to coincide with the initiation of reservoir refill when outflows are reduced, which under MO3 would be the same as the No Action Alternative, so these fish would continue to be release when water quality conditions would be suitable.

The fish in Rufus Woods Lake would continue to be supplemented by entrained fish out of Lake Roosevelt to a large extent, with fish mostly entrained during the spring freshet and winter drawdown periods. The increased flows and shorter retention times in November and December may increase entrainment and boost populations in Rufus Woods Lake, where decreased outflows in August and September likely would decrease entrainment. This lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. High flows during late spring and early summer would continue to flush eggs and larvae from protected rearing areas similar to the No Action Alternative, but slightly lower magnitude. Median peak outflows occur in early June and would be about 3 percent lower than the No Action Alternative. TDG in the Grand Coulee tailwater is a concern for fish in Rufus Woods Lake; modeling showed TDG would be lower than the No Action Alternative.

***Chief Joseph to McNary Dam***

Summary of Key Effects

Key effects under MO3 that differ from those of the No Action Alternative would be the long-term restoration of fragmented populations of white sturgeon. There would be slight reductions in flows and minor reductions in productivity in the McNary reservoir for two to seven years following the breaching of the four lower Snake River dams. Connectivity of the Columbia River with the Snake River would increase. Increased white sturgeon spawning and recruitment, minor increases in turbidity below the Snake and Columbia River confluence, and slight reductions in smallmouth foraging success are also expected.

Habitat Effects Common to All Fish

Under MO3, the breaching of the four lower Snake River dams would lead to an increase in spring sediment levels in the McNary pool below the confluence of the Snake and Columbia Rivers. There would be a substantial increase in connectivity of the Columbia River with mainstem riverine habitats on the lower Snake River.

Bull Trout

Key effects to bull trout under MO3 would not differ from those of the No Action Alternative.

Other Fish

Effects to white sturgeon from MO3 are similar to those of the No Action Alternative. However, under this alternative there would be slight reductions in high flows of May and June, potentially leading to minor reductions in white sturgeon spawning success. In addition, white sturgeon require large sections of riverine habitat for successful spawning and recruitment. Under MO3, there would be a major increase in connectivity of riverine habitats for white sturgeon. Populations in the McNary pool and Hanford reach would have access to hundreds of miles of the lower Snake River, up to Clearwater River and the Hells Canyon complex.

Key effects to fish species in this reach under MO3 would include a slight reduction in productivity of the McNary pool downstream from the Snake River confluence for two to seven years. Deposition of sediments in McNary pool following the breaching of the four lower Snake River dams would increase. There is a potential reduction in foraging success of smallmouth bass due to increased turbidity during breaching and during runoff and heavy rain events. Following the breaching of the four lower Snake River dams there would be a reduction in downstream drift of small fish and aquatic invertebrates that would reduce forage for resident fish from two to seven years. While breaching, and during high runoff or rain events shortly following breaching, large quantities of sediment would be deposited in the McNary pool just below the confluence of the Snake and Colombia River. This sediment would alter these habitats by silting in gravel coble habitats and reducing the benthic organisms that depend on them. Increased turbidity is associated with reduced foraging success of smallmouth bass and other visual feeders. Under MO3, there would be an increase in seasonal turbidity in the McNary pool from sources upstream in the Snake River. Smallmouth bass foraging success would be reduced by some unknown amount during runoff and heavy rainfall events.

**Region C**

***Snake River Basin***

Summary of Key Effects

Key effects to resident species under MO3 can be broken into short and long-term effects. Short term effects include high sediment and low oxygen concentrations that would likely lead to the loss of most of the fish in this reach during breaching, reduced forage and productivity for 2 to 7 years following breaching, and potential migration barriers at tributaries that may become perched during reservoir drawdown. Long-term effects would likely include changes in water temperature regimes with warmer water temperatures in the spring and cooler water temperatures in the fall, changes in resident fish communities from reservoir to riverine species, improved fish passage and habitat connectivity, major reductions in TDG, and improved spawning habitat of river spawning species.

Habitat Effects Common to All Fish

Under MO3, habitats would change considerably. Water velocities in the lower Snake River would increase nearly tenfold shifting the fish community to one dominated by riverine species. Substrates would revert to more cobble gravel and less silt and sand, and water levels (river stage) would have greater seasonal variation.

Bull Trout

The breaching of the four lower Snake River dams under MO3 would result in short- and long-term changes to bull trout use in the lower Snake River as compared to the No Action Alternative. Low numbers of bull trout would continue to use the lower Snake River as a migration corridor and for foraging and overwintering from November through June. However, breaching of the dams would allow for easier passage and better connectivity between populations. High suspended sediment levels and very low DO levels during dam breaching and the years following would adversely affect bull trout. Any bull trout in the river at that time may experience elevated levels of mortality. Overall water temperatures following dam breaching would be cooler for much of the year. However, May and June water temperatures would be higher.

Because breaching would occur about a month before bull trout would be entering the mainstem Snake River in the fall, potential passage effects from construction may be reduced. In the short term, passage into the tributaries may be adversely affected as sediment deposits may prevent bull trout from re-ascending tributaries in the spring.

Bull trout would no longer be entrained at the dams and would not need to use fish ladders to move upstream. High flows in the river may cause seasonal velocity barriers for bull trout at the dam sites when water reaches velocities over 12 feet per second as it passes through the breached portion of the dams. However, the remaining dam structures may provide foraging areas for bull trout as they overwinter and during migrations.

Because the volume of water would be reduced, water temperatures would change faster in response to environmental inputs (i.e., warmer air temperatures or cold snowmelt). Water temperatures are expected to warm sooner in the spring, and cool earlier in the fall. Daily water temperature fluctuations would be larger as well. Overall, yearly water temperatures would be cooler and more suitable for bull trout, resulting in reduced stress and improved survival. However, water temperatures would be higher in June and July and may induce bull trout to migrate from to cooler tributary habitats earlier in the year. Under MO3, TDG levels would be reduced to 104 to 105 percent year-round. This reduction in TDG would benefit bull trout.

Immediately following breaching of the lower Snake River dams, suspended sediment loads in the Snake River would be greatly increased and DO decreased relative to the No Action Alternative. DO levels in the river at that time would be low enough that any bull trout in the mainstem could experience increased levels of mortality. As suspended sediment levels decrease, DO levels would return to normal levels that would support bull trout. Long-term effects of MO3 would include elevated sediment during the spring freshet the year following dam breaching. These conditions may adversely affect bull trout.

Unlike the No Action Alternative, under MO3 there would likely be a temporary reduction in forage for bull trout. As river flows clean the sediment from embedded cobble and gravel, invertebrate populations would expand and productivity would increase. This reduced productivity is estimated to be about 2 to 7 years. Forage fish and invertebrates would be expected to increase over time. The change of the food base from zooplankton to macroinvertebrates in the river would benefit sub-adult bull trout.

<u>White Sturgeon</u>

The breaching of the four lower Snake River dams under MO3 would increase connectivity between McNary Reservoir, Hells Canyon, and spawning habitat in the lower Snake River. Short-term effects would include high levels of suspended sediment and very low DO levels during dam breaching. Any white sturgeon in the river at that time may experience increased levels of mortality.

Spawning of white sturgeon in the Snake River basin under MO3 would change relative to the No Action Alternative. The breaching of the four lower Snake River dams would increase the amount of spawning habitat available in this reach and produce higher water velocities that would induce spawning. Suitable spawning substrates would expand from an estimated 226 to 3,521 acres under a breach scenario. Modeling shows that average velocities in a breached scenario would reach between 6 and 8 ft/sec during the spring runoff compared to less than 1 ft/sec under the No Action Alternative. These conditions would lead to more successful spawning and recruitment for white sturgeon.

Water temperatures in the lower Snake River under MO3 would change from those of the No Action Alternative. Water quality modeling shows that water temperatures would likely be 2 to 4 degrees Fahrenheit warmer in June and July and 2 to 4 degrees Fahrenheit cooler in September through December under this alternative. Earlier warming may induce adults to spawn earlier and reduce any adverse effects. Water temperatures in the lower Snake River would continue to be suitable for egg incubation under MO3. However, more days would likely exceed optimum temperatures for egg incubation than under the No Action Alternative.

The ability of the Snake River to provide rearing habitat for the yolk sac larvae and juvenile white sturgeon under MO3 would be different in both the short and the long term from that under the No Action Alternative. In the short term, release of sediments during dam breaching would temporarily cover cobble and gravel substrates with silt and sediment, reducing hiding cover for sturgeon sac fry and invertebrates that provide forage for juvenile sturgeon. The substrate would be scoured clean in two to seven years and would likely improve habitat for both spawning and rearing long term. River mechanics modeling (see Section 3.3) shows that following dam breaching, currently existing sediment deposits would likely be scoured to the original riverbed.

Migration of white sturgeon through the lower Snake River would improve in the long term under MO3. Breaching of the four dams would reconnect white sturgeon populations from McNary Reservoir to Hells Canyon. Movement between populations would be unrestricted and spawning habitat would increase. Recruitment would also likely increase. In the short term, there would be no upstream passage, as water quality conditions during dam breaching may not support sturgeon passage.

TDG levels would be greatly reduced under MO3 relative to the No Action Alternative. Under this alternative, TDG conditions would be ideal for most of the lower Snake River as there would be no spill at the four dams to raise TDG levels. Modeling shows under MO3 TDG levels would not exceed 110 percent at any time during the year, and that the highest TDG level would be approximately 104 percent. No adverse effects from TDG on white sturgeon are expected under MO3.

The effects of suspended sediment loads in the Snake River reservoirs on white sturgeon under MO3 would be very different from those under the No Action Alternative. During, and immediately following, breaching of the lower Snake River dams, suspended sediment loads in the Snake River would increase up to 25,000 mg/l for a short period of time and loads of about 5,000 mg/l for may extend for 18 to 26 days following each of the dam breaching events. These sediment concentrations would result in a 20 to 40 percent mortality of white sturgeon.

Further, chemical and biological oxygen demands associated with dam breaching and the increased suspended sediment could lower DO levels in the river to 2 ppm. Short-term effects to white sturgeon could result in periods of significant mortality. The loss of mature adult fish would be a major adverse effect. As suspended sediment levels decrease, DO levels would return to normal levels that would support white sturgeon.

The breaching of the Snake River dams under MO3 would have a much greater potential to affect contaminant levels in the river than the No Action. Dam breaching would re-entrain dormant sediments that may contain elevated concentrations of heavy metals, pesticides, and other chemicals of concern. These chemicals of concern would have an unknown impact on white sturgeon

<u>Other Fish</u>

Effects to resident fish from MO3 that differ from those of the No Action would include the loss of fish and invertebrates during and shortly following dam breaching, an increase in mean water velocity, the conversion of reservoir habitats to riverine habitats, a reduction in TDG levels, an increase in spawning habitat for riverine species, and changes in water temperature regimes.

Effects from MO3 can be broken into short- and long-term effects. Short-term effects to resident fish species from dam breaching would include elevated sediment concentrations and reduced oxygen levels. Sediment levels may reach 25,000 mg/l for short periods of time and over 5,000 mg/L for 18 to 20 days. Similar to bull trout, these levels of suspended sediment may induce mortality rates between 20 and 60 percent for resident fish depending on the species. Chemical and biological oxygen demands associated with dam breaching and the increased suspended sediment could lower DO levels in the Snake River to approximately 2 ppm. These reduced oxygen concentrations could result in significant levels of mortality in the lower Snake River. Short-term effects could also include the loss of macroinvertebrate or significant reductions to populations that provide forage for most of the resident fish community. This reduced forage base is expected to last between two and seven years as flows from a new river scour embedded substrates that would house invertebrate populations.

Long-term effects from MO3 would include large decreases in TDG concentrations and altered water temperature regimes throughout the lower Snake River. Under MO3 TDG is not expected to reach 105 percent and risk of GBT to resident fish would be reduced. Water temperatures under this alternative would be 2 to 4 degrees Celsius warmer in spring and 2 to 4 degrees Celsius cooler in the fall. These changes in temperature may alter spawn timing and success for resident fish species.

Under MO3 there would be major changes in aquatic habitats available to resident fish species. Large reductions in slow water habitats would occur with major shifts to riverine habitats. One important metric to measure these changes is water velocity. Mean annual water velocity would increase from less than 0.5 ft/sec under the No Action Alternative to about 4 ft/sec under MO3. This increase in velocity would alter the fish community such that reservoir-dependent species would be reduced and riverine species would increase. Relative abundance of walleye, crappie, and northern pikeminnow would decline under MO3, while concentrations of smallmouth bass would remain the same or increase slightly and the abundance of white sturgeon would increase. Changes in habitat would include increased spawning habitats for riverine species while slow water rearing habitats would be reduced to backwater and side channel areas.

The change from reservoir to riverine habitats under MO3 would also alter the productivity and forage base for resident fish species. Forage resources would convert from a zooplankton-dominated reservoir to an insect-dominated river. Zooplankton are expected to drop to less than 10 percent of the current biomass and would be replaced, in time, with macroinvertebrates. Productivity is expected to be reduced during the dam breach but would slowly return over time.

**Region D**

***Mainstem Columbia River from McNary Dam to the Estuary***

<u>Summary of Key Effects</u>

Bull trout would continue to use the Columbia River in limited numbers and seek cold water refuge available at the mouths of tributaries. White sturgeon would continue to successfully reproduce in years with adequate flow and temperature conditions.

<u>Habitat Effects Common to this Fish Community</u>

Outflows from McNary Reservoir influence some of the fish relationships described in this section. Peak spring flows affect habitat maintenance for some species. Modeled median outflows for MO3 indicate that outflows would be within 3 percent of the No Action Alternative (no discernable change).

Other flow parameters referred to in this section refer to outflows of McNary Dam, which are indicative of flows on downstream through the other Projects.

<u>Bull Trout</u>

Bull trout are known to use the mainstem Columbia River to move between tributaries and have been observed at Bonneville Dam and McNary Dam in the spring and summer (Barrows et al. 2016). Water temperature is the most important habitat factor for bull trout in the mainstem Columbia. Under MO3, bull trout would continue to use the mainstem Columbia for migration between tributaries, as well as tributary mouths for passage and thermal refugia.

Adult bull trout move downstream during fall and overwinter in reservoirs (October to February; Barrows et al. 2016). Although bull trout successfully move between areas on the mainstem, their migration can be delayed at the dams. MO3 includes structural measures for additional spillway passage at McNary Dam. This measure would be in operation from March 1 through August 31, and could slightly improve bull trout downstream passage, but the majority of adult bull trout would have moved out of the mainstem by the time this surface passage route would be in use.

Passage through turbines can cause injury or mortality MO3 includes turbine replacement with IFP turbines, which would improve survival (Deng et al. 2019). At John Day, turbine replacement would provide safer passage for any bull trout that move through the dam.

Bull trout would continue to be subject to bird predation.

<u>Other Fish</u>

Under MO3, white sturgeon spawning and recruitment would be similar to the No Action Alternative. In low flow years, it is likely that there is very little spawning and recruitment, but overall conditions would be similar to the No Action Alternative.

Model results indicate suitable spawning temperatures would be similar to the No Action Alternative. In years of low flow conditions, water temperatures could increase beyond the suitable range by early June, resulting in little or no recruitment.

White sturgeon spawning generally occurs in areas with fast-flowing waters over coarse substrates (Parsley et al. 1993). Dam breaching upstream under MO3 could result in some amount of sediment increase downstream.

Lack of effective upstream white sturgeon passage for all age classes decreases the connectivity of the population (Parsley et al. 2007). Under MO3, a measure to improve fish passage at Bonneville Dam would likely improve potential passage for sturgeon. The vertical slot fishway could make it easier for sturgeon to pass upstream.

Turbine units at dams can cause injury and mortality in juvenile and adult sturgeon. Under MO3, improvements to turbines at John Day would reduce injuries and mortality of sturgeon (Deng et al. 2019).

White sturgeon larvae are adversely affected by TDG. Studies have shown high rates of altered buoyancy at 118 percent TDG, and 50 percent mortality at 131 percent TDG (Counihan et al. 1998). Adults are more able to compensate for increased TDG by moving to lower depths, but larvae in shallow water would be more adversely affected. Under MO3, TDG rates would be less than the No Action Alternative at McNary and Bonneville Dams in August but would be higher at The Dalles and Bonneville from mid-April through mid-June. Since the earlier spring months are when larvae would be more likely to be present, overall this would be a represent a minor increase in adverse effects compared to the No Action Alternative.

Under MO3, pool elevations could be about 1 foot higher in the John Day pool, which provides more habitat for juveniles, but subsequent drops in elevation could lead to juvenile stranding. MO3 may result in increased sediment transport through the lower Columbia River and increase sedimentation in these reservoirs.

Under MO3, no changes to resident fish communities would be expected. As shown above, outflow rates below McNary Dam would be very similar to the No Action Alternative. Water quality and food availability would also be similar to the No Action Alternative.

Conditions that promote lower water temperatures and higher spring flows tend to lower the survival rates of warmwater game fish, potentially lowering populations of predators on salmon and steelhead. MO3 would be expected to continue supporting warmwater game fish at levels similar to current conditions.

**MACROINVERTEBRATES**

Below is a discussion of the macroinvertebrates in Regions A, B, C, and D under MO3. For more detailed information on the effects of MO3 on aquatic invertebrates and implications on food web interactions see the Habitat Effects section of these respective fish community analyses in the Resident Fish section under the applicable region.

**Region A**

Project operations under MO3 would affect the aquatic environments provided by Hungry Horse Reservoir, South Fork Flathead River, Flathead River, Flathead Lake, lower Flathead River, Clark Fork River, Lake Pend Oreille, Pend Oreille River, Lake Koocanusa, and the Kootenai River. Hungry Horse Reservoir and Albeni Falls Reservoir operations would both be the same under MO3 as MO1 and effects to aquatic macro-invertebrates would be the same (see Section 3.5.2.3 for a discussion of the macroinvertebrate effects under MO1).

Hungry Horse reservoir would experience increased dewatering of insects through the summer because of reduced varial zone habitat. Lower summer elevations would also result in decreased summer zooplankton production, and increased release of zooplankton out of the reservoir and into the South Fork Flathead River with higher outflows. South Fork Flathead River flows could increase zooplankton levels and wetted area for macroinvertebrate production in the South Fork Flathead River but could also flush more out of this area with higher velocities. MO3 operations would result in negligible changes to Flathead Lake, the lower Flathead River, and the Clark Fork River. These habitats would continue to support the macroinvertebrates described in the affected environment.

The operations of Albeni Falls Project would be very similar to the No Action Alternative and MO1 operations and would not result in appreciable changes to Lake Pend Oreille or the Pend Oreille River, nor the macroinvertebrate communities in those habitats.

In the Kootenai basin, MO3 operations would diverge from the No Action Alternative with deeper, steeper drafts in winter. Summer elevations would be similar to MO1. Lake Koocanusa would be held above elevation 2450 from one to two more days than the No Action Alternative, which would result in similar overall productivity of zooplankton and macroinvertebrates in the system.

**Region B**

The Columbia River from Canada to Lake Roosevelt would continue to produce benthic aquatic insects such as stonefly, caddisfly, and mayfly larvae. The river elevation in this reach is influenced by Lake Roosevelt operations and inflows so is somewhat variable, which would constrain benthic production to some degree.

MO3 river stage at the U.S.-Canada border and downstream into Lake Roosevelt would be the same as the No Action Alternative. Macroinvertebrate habitat would not be affected. In Lake Roosevelt, the elevations would also be the same as under the No Action Alternative, with the minor exception that the winter elevation would be held level about two weeks longer than under the No Action Alternative, just prior to the winter draft. This would be a slight benefit to aquatic invertebrate production.

In Lake Roosevelt, the production, distribution and persistence of zooplankton is highly variable and sensitive to how long the water stays in the reservoir (retention time), which is a function if inflows, reservoir volume, and outflows. Longer water retention times allow for more and larger-bodied zooplankton to be more widely distributed throughout the reservoir. Lower retention times result in fewer and smaller-bodied zooplankton that get concentrated near the dam, where they would be subject to high rates of entrainment. Generally speaking, under MO3 median retention time would be similar to or slightly higher than the No Action Alternative in late spring, summer, and fall. In all year types, retention time under MO3 would be 2 percent to 5 percent lower in November and December. In wet years it would be slightly lower than the No Action Alternative (1 percent to 3 percent) in spring. In wet years retention time is generally lowest because more water is moving through the system, and MO3 would reduce spring retention times even further in these years.

Downstream of Grand Coulee Dam, Rufus Woods Lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. Aquatic insect production and desiccation, river stage at RM 594 in Rufus Woods Lake would follow the same pattern and magnitude changes under MO3 as the No Action Alternative. The stage would be slightly lower (less than a half of a foot) through the spring, but the change to macroinvertebrate habitat would likely be negligible.

**Region C**

Dworshak Reservoir elevations would be the same as the No Action Alternative. Benthic production in the reservoir would continue to be low due to the extensive variation in water surface elevation, near-shore wave action that causes erosion, and the lack of aquatic plants along the shoreline. Likewise, outflows would be the same as the No Action Alternative. Benthic communities in the Clearwater River below Dworshak Reservoir would continue to be limited by unsuitably high flows in summer and late winter.

The breaching of the four lower Snake dams would result in a shift to macroinvertebrate communities. Organisms in the rivers downstream of breach sites would likely experience substantial mortality in the short-term immediately following breach due to elevated suspended sediment and major reductions in dissolve oxygen that would move downstream (see Section 3.4, *Water Quality*). Over time, as the river reached a state of equilibrium, conditions would be shifted from reservoir habitats to more natural riverine habitats. Species richness would likely increase over time. Opossum shrimp and Siberian prawns would likely be reduced in numbers as they favor slow-moving lake habitats. The rock and riprap substrate that provide crayfish habitat would be reduced as dam sites and other structures would be dewatered. As the river flows cleared out accumulated sediments over the course of several years, there would be a shift from more soft sediment habitat dominated by worms to more hard habitats with a higher diversity of aquatic macroinvertebrates. Mussels, clams, and snails that prefer lake habitats would be reduced.

**Region D**

MO3 would result in only minor changes to flows or temperatures that could affect macroinvertebrate communities in the lower Columbia River. Very little benthic macroinvertebrate information is available for the lower Columbia River. Lake habitats in the impounded reaches would continue to support a low diversity of worms, benthic insects, and mollusks. The breach of Snake River dams could result in increased sedimentation in some areas of the lower Columbia River, possibly resulting in a species shift of more worms, mollusks, etc. that prefer soft substrates in these localized areas. The run of river dams would continue to be operated at stable elevations that would continue production of these aquatic macroinvertebrates.

**SUMMARY OF EFFECTS**

**Anadromous Fish**

Model results indicate that the breaching of the four lower Snake River projects is expected to have major beneficial effects on juvenile outmigration and adult upstream migration. This MO would end juvenile transportation from the Snake River and would likely lead to a transition in hatchery mitigation tied to those dams as described in the mitigation measures in Chapter 5.

Under MO3 there is a slight increase predicted in upper Columbia spring Chinook salmon in-river survival and no change to steelhead relative to the No Action Alternative. These changes are primarily due to increased spill levels in the lower Columbia River. CSS model results were not available (no model results were able to be produced) for upper Columbia River species in this EIS. Results from the NOAA LCM indicate that the level of improvement to upper Columbia spring Chinook SARs is dependent on the level to which latent mortality affects this stock. If increased spill in the lower Columbia River does not improve ocean survival, (i.e. reduce latent mortality) the LCM model predicts negligible to minor improvements in SARs (one percent relative increase). Larger reductions in latent mortality would result in larger predicted increases in both SARs and abundance for Upper Columbia stocks (4 to 147 percent relative increase in abundance).

Quantitative model results from both the CSS and LCM were available indicated a range of potential long-term outcomes largely due to how the models address latent mortality. The CSS models predict that outmigrants from Lower Granite that return to Lower Granite (SARs) would increase by 170 percent relative to the No Action Alternative. The NOAA LCM predicted that SARs from Lower Granite to Bonneville would improve by 14 percent relative to the No Action Alternative. The CSS model predicted similar improvements for Snake River steelhead. NOAA did not produce LCM model estimates for Snake River steelhead.

MO3 is also expected to provide a long-term benefit to species that spawn or rear in the mainstem Snake River habitats, such as fall Chinook. By breaching the four lower Snake River dams, major short-term adverse impacts to fish, riparian and wetland habitat in the Snake River and confluence of the Columbia River would occur, associated with the initial breaching the dams, drawing down the reservoirs, and time for the river to move sediment and stabilize. These effects are expected to diminish over time. MO3 also includes structural modifications to infrastructure at the dams to benefit passage of adult salmon, steelhead, and Pacific lamprey.

Maximum summer water temperature would increase slightly; water temperature variability would increase; and water temperatures would not stay cool as long into the spring and would cool earlier in the fall with the removal of the thermal inertia of the lower Snake dam reservoirs. In general, anadromous species not migrating to or from the Snake River may see minor changes in passage through the lower Columbia River, while effects to Snake River species are expected to be major and beneficial once short term adverse effects associated with dam removal have subsided.

**Resident Fish**

Habitat effects outside of the Snake River would remain minor and similar to those in MO1. In Region A, higher lake elevations under MO3 would result in higher productivity at areas such as Lake Koocanusa, while effects at Hungry Horse would be similar to MO1 (minor to moderate adverse due to reduced food productivity in summer and lower lake elevations). In Region B, the effects to Lake Roosevelt are expected to be minor when compared to the No Action Alternative. Winter drawdown is expected to increase entrainment, but the varial zone/tributary access impacts are comparable to the No Action Alternative. In Region C, long-term effects would likely include changes in water temperature regimes with warmer water temperatures in the spring and cooler water temperatures in the fall, changes in resident fish communities from reservoir to riverine species, improved fish passage and habitat connectivity, major reductions in TDG, and improved spawning habitat of river spawning species. Short term effects include high sediment and low oxygen concentrations that would potentially lead to the elevated mortality for fish in this reach during breaching, reduced forage and productivity for 2 to 7 years following breaching, and potential migration barriers at tributaries that may become perched during reservoir drawdown. These adverse short-term effects and beneficial long-term effects in the Snake River are expected to be major. Effects in Region D would be minor adverse to negligible.

**Macroinvertebrates**

Habitat effects outside of the Snake River would remain minor and similar to those in MO1. All organisms in the rivers downstream of breach sites would likely experience substantial mortality in the short-term immediately following breach due to the pulses of sediment traveling downstream. At Libby Dam, high flows would decrease the potential for cottonwood and willow seeding and recruitment. Structural changes at McNary and John Day would improve passage for bull trout and other species. Over time, as the river reached a state of equilibrium, conditions would be shifted from the reservoir habitat to more natural riverine habitats. Species richness would likely increase over time, with a shift toward species preferring riverine habitats. These adverse short-term effects and beneficial long-term effects in the Snake River are expected to be major.

### *3.5.3.7 Multiple Objective Alternative 4*

**ANADROMOUS FISH**

**Salmon and Steelhead**

Several different ESU/DPS units of salmon and steelhead share a similar life cycle and experience similar effects from the MOs, but also have ESU/DPS specific traits that specifically drive effects differently from one another. Common effects analyses across all salmon and steelhead are discussed first, and then those ESU/DPS specific effects are displayed.

***Effects Common Across Salmon and Steelhead***

<u>Summary of Key Effects</u>

MO4 includes several structural and operational measures intended to improve juvenile salmon and steelhead migration and survival, including incremental improvements in powerhouse surface passage routes and improved survival of fish that go through the turbines. Increases in spill, drawing down lower river reservoirs, and additional flow augmentation in dry years are expected to decrease the travel time of in-river fish, and decrease powerhouse encounter rates, but TDG exposure would increase. Fewer smolts would be transported. Adult migration would be enhanced by structural measures to reduce delays in the Snake River projects, and steelhead kelt survival would be improved with the addition of spillway weir notch inserts, but adult delays and fallback may be increased with more spill. In the balance between survival benefits of transporting fish compared to increasing the speed and survival of in-river fish, MO4 leans towards less transport and increasing the number of fish migrating in-river. The overall benefits to abundance of returning salmon and steelhead would depend on the degree to which latent mortality affects ocean survival of in-river fish. Unless otherwise noted, quantitative results from COMPASS and the Life Cycle Model (LCM) are based on a combination of hatchery and natural origin fish. This applies for both juvenile and adult results.

Juvenile Fish Migration/Survival

There are two structural measures in MO4 that may affect juvenile migration and survival. These are also in MO1 and are described in more detail there, but are summarized here:

- **Construct additional powerhouse surface passage routes** at Lower Granite, Little Goose, Lower Monumental, Ice Harbor, McNary, and John Day Dams: This would route additional juvenile fish away from turbine passage routes to spillway or spillway-like routes, likely decreasing travel times and increasing survival. See MO1 Common Effects for details. As discussed in MO1, even with the most optimistic 30 percent passage efficiency assumption in place, the effect of these powerhouse surface passage structures on in-river survival and subsequent adult returns was minor. This is especially relevant in MO4, which employs spill up to the 125 percent TDG cap at all eight fish passage dams. These structures could potentially be more effective at influencing population level dynamics at lower spill levels than those included in MO4, but powerhouse passage is estimated to be so low under 125 percent spill levels there were not enough fish passing via the powerhouse to have a meaningful impact.
- **Install IFP turbines at John Day Dam** would improve juvenile survival of the juveniles that pass through this turbine route. See MO1 Common Effects for details.

Additionally, MO4 includes a measure that was designed to improve overwintering adult steelhead and kelt survival but may also improve juvenile migration.

- **Adding spillway weir notch gate inserts** at Lower Granite, Little Goose, Lower Monumental, Ice Harbor, McNary, and John Day Dams would allow the attraction of smolts and overwintering steelhead later into the season, and would allow the attraction using one fourth of the water. An increase in the total number of fish passing via surface routes is expected. See adult survival and migration section below for more details about this measure.

Several operational measures warrant discussion here individually, regarding effects to juvenile fish. Measures that would result in changes to spill, flows, passage routes, or temperatures were incorporated into the fish models. Others could not be incorporated into modeling for effects analysis, or are modeled but may be difficult to separate from other factors; effects of these measures are discussed qualitatively.

- MO4's spill to 125 percent TDG increases the proportion of spill at each of the lower Columbia and lower Snake projects compared to the No Action Alternative. The higher spill has the net effect of routing greater numbers of juvenile salmon and steelhead into spill routes and fewer through powerhouse routes such as the juvenile fish bypasses and turbine routes. For juvenile salmon and steelhead, quantitative fish modeling was used when available to estimate the effects of these spill changes on fish.
- Drawing down the lower Columbia River projects to at, or near, MOP elevations will reduce water travel time to some degree relative to the No Action Alternative. At the same time,

these drawdowns in the John Day pool would expose additional nesting habitat on Blalock Island and likely increase the risk of avian predation in this area for all species.

- Holding contingency reserves within juvenile fish passage spill is likely to have little effect on juvenile migration. These measures were both included in the 80-year modeling datasets.
- The McNary Dam flow target measure is intended to provide additional spring flow augmentation in dry years to improve juvenile outmigration. More water in the Columbia River in dry years could increase survival of outmigrating juveniles by reducing in-river travel times. The effects of this measure were estimated by the primary fish models.
- Several measures in MO4 affect juvenile fish transportation rates and effects of these changes differ by ESU/DPS. Overall, the higher spill in MO4 decreases the proportion of juvenile salmon and steelhead available for transport. In addition, juvenile transport would be suspended from June 15 to August 15, when it would be re-initiated and extended until November 15 at the three lower Snake collector dams.
- Operating turbines above 1 percent peak efficiency could affect juvenile Snake River spring-run/summer-run Chinook direct survival. This measure is also in MO2 and MO3; see those alternatives for more details.

The full suite of operational measures would change flow patterns in the Lower Columbia River with decreases in monthly average flows of 1 to 3 percent from April to June and a decrease of 2 to 4 percent in month average flow in August. In the driest years, monthly average flows in May would be 12 percent higher than the No Action Alternative. Similar to the spill changes, fish modeling was used when available to estimate the effects of these flow changes on juvenile fish.

Overall, MO4 is distinct compared to the No Action Alternative from a TDG perspective. There is substantially higher spill during the March-August period that generates higher and more prolonged elevated TDG relative to the No Action Alternative. UW/CBR TDG modeling, separate from COMPASS and CSS in-river survival estimates, estimated higher reach average exposure to TDG indices.

There may be decreases in fish injury under MO4 with the lower number of powerhouse passages relative to the No Action Alternative and further reduced to some degree by installation of improved fish passage turbines at John Day Dam. Turbidity is not anticipated to change under MO4 relative to the No Action Alternative, as forebay drawdowns to near minimum operating pool elevations in the lower Columbia may temporarily have minor total suspended solids/turbidity effects, but they are expected to be minor given the size of large reservoirs. There may be an overall decrease in juvenile fish predation exposure under MO4 due to these factors relative to the No Action Alternative, but the magnitude is uncertain. In some reservoirs, predation rates could potentially increase if poor tailraces conditions (e.g. eddies or other confusing flow patterns) are created by high spill levels. Changes in operations of Grand Coulee Dam under MO4 could increase entrainment of northern pike, hastening the invasion of this predator downstream where salmon and steelhead are found, thus increasing their predation exposure.

Adult Fish Migration/Survival

There are several operational and structural measures in MO4 that may affect adult salmon and steelhead. Two of these structures are in MO1 so are described in detail there and summarized here:

- **Improve adult ladder passage** through modification of adult fish trap at Lower Granite Dam would reduce delays in migration through Lower Granite Dam.
- **Installing pumping systems** to provide deeper, cooler water if available in adult fish ladders at Lower Monumental and Ice Harbor dams would decrease the temperature differential in fish ladders that can delay adult migration when surface waters are warm.

Additionally, MO4 includes a unique measure not in any other alternative, which was designed to improve overwintering steelhead and kelt survival:

- **Add spillway weir notch gate inserts at Lower Granite, Little Goose, Lower Monumental, Ice Harbor, McNary, and John Day Dams.** During the late fall and early winter adult steelhead that have overshot their natal streams, may overwinter in mainstem habitats. In the spring, some steelhead that have spawned (kelts) are attempting to return to the ocean and often pass downstream of project dams on the Snake and Columbia rivers prior to juvenile spill operations. Historically, spill operations through spillway weirs and normal spillbays have ceased at this time of year and these fish have only turbine routes available for downstream passage. Water flows are at their lowest at this time of year and can be as low as 20 kcfs in the Snake River. Using this water for spillway weir operation can take a large portion of remaining water flows. Spillway weir notch gates use about one quarter the flow of normal weirs and allow the weir to continue operating at very low flows. However, additional design modifications to the existing weir may be required to avoid the potential for additional injuries from adult sized fish impacting the concrete chute of the spillway.

Fallback rates and passage blockages/delays of adult salmon and steelhead may increase under MO4. Fallback has been associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). Increased travel time of adults between Lower Monumental and Lower Granite Dams caused by blocked or delayed adult passage has been consistently observed when Little Goose spill percentages are above 30 percent. It is important to note that regional managers attempt to use in-season adaptive management to identify and remedy any excessive fallback or delays in passage. The effect of TDG on adult salmon and steelhead was not modeled for MO4, but an increase in reach average exposure to TDG is anticipated relative to the No Action Alternative.

Temperatures in the lower Snake River and the lower Columbia River would be similar to the No Action Alternative. In the Columbia River, a general analysis indicated the overall number of days water temperatures in the McNary tailrace that exceed 20°C would not change relative to the No Action Alternative. A site- and timing-specific analysis of water temperature model results indicates slightly warmer conditions in July of low water years, when temperatures would be most stressful to fish. At McNary Dam, outflow temperature would exceed 20°C in 57 days of low flow, high temperature year types (years like 2015), compared to 22 days in the No Action Alternative. Furthermore, the number of days that adult ladder temperature differentials exceed 2 degrees Celsius would slightly increase from 2.8 percent (No Action Alternative) to 3.8 percent (MO4), which may slightly increase delay in dam passage for adult fish (Caudill et al. 2013).

In the balance between survival benefits of transporting juvenile fish with increasing the speed and survival of in-river fish, MO4 is expected to result in less transport and increased numbers of juveniles migrating in-river. This has the potential to shift the overall benefits to abundance of returning salmon and steelhead. This would depend on the degree to which decreased latent mortality would improve ocean survival of in-river fish. Based on the timing of when transported smolts reach the ocean compared to their in-river counterparts, NWFSC modeling predicts increased ocean survival for earlier arriving fish. Since more smolts would travel in-river and arrive below Bonneville Dam later compared to the No Action Alternative, the NMFS COMPASS and LCM models show generally lower abundances of returning Snake River adults without adding any factor for latent mortality. Adult returns to the Snake River are predicted by the NMFS models to be lower for spring migrating stocks unless ocean survival can be increased by 10 percent or more (i.e. a 10 percent or greater reduction in latent mortality). In contrast, CSS modeling predicts increased survival of juvenile salmon and steelhead moving downstream, as well as increased ocean survival, and therefore more returning adults. If CSS model predictions are accurate, SARs and adult abundance would be higher than the No Action Alternative. See the "Comparison of COMPASS and CSS Models" discussion in section 3.5.3.1 for more detail on the two models.

***Upper Columbia River Salmon and Steelhead***

Upstream of McNary Dam, upper Columbia salmon and steelhead migrate past as many as five non-federal dams and reservoirs, which also impact the survival and passage of these species. The federal agencies do not dictate generation or spill levels at the PUD projects so metrics such as powerhouse encounter rate are not directly affected but are influenced by river flow levels coming through the upper Basin. The timing and volume of flow levels affected by CRS operational decisions are reflected in model analysis. COMPASS and LCM estimates of powerhouse encounter rate and SARs include passage effects from a combination of federal and PUD dam passage (Rock Island Dam to Bonneville Dam). CSS model results are not available for upper Columbia stocks.

<u>Upper Columbia Spring-Run Chinook Salmon</u>

*Summary of Key Effects*

Structural and operational measures in MO4 are expected to increase juvenile survival of upper Columbia River spring-run Chinook salmon by 1.5 percent. Travel time and powerhouse encounters would be decreased, but increased exposure to TDG could offset some of the survival improvement. Adult upstream migrants could see additional delays and increased fallback with higher spill as well as increased TDG levels. Life cycle modeling indicated about a three percent increase in abundance. Increases could be higher if lower powerhouse encounters were to decrease delayed mortality in the ocean.

*Juvenile Fish Migration/Survival*

Juveniles in this ESU migrate through the Columbia River downstream past the four lower CRS projects in addition to up to five non-federal dams. Structural and operational measures described in the Common Effects section that describe changes from the No Action Alternative at McNary, John Day, The Dalles, and Bonneville Projects would apply to these fish. Based on the combination of structural improvements, higher spill, and reservoir drawdowns, COMPASS modeling estimates that MO4 is expected to result in a 1.5 percent increase in average juvenile survival for upper Columbia River spring-run Chinook salmon. Relative to the No Action Alternative, a 13 percent decrease in average juvenile travel time from McNary to Bonneville Dam, and a 23 percent decrease in the number of powerhouse passage events from Rock Island to Bonneville Dam (includes passage past three non-federal dams). TDG exposure would be higher for upper Columbia River spring-run Chinook salmon with reach average exposure nearly 120 percent TDG. Increased mortality due to TDG could offset some of the increase in overall juvenile survival from operations and configurations under MO4. CSS cohort modeling for upper Columbia River spring-run Chinook was not available for this ESU. Table 3-92 displays a summary of these model metrics.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in these predators would likely increase predation on juvenile Chinook and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish

**Table 3-92. Multiple Objective Alternative 4 Juvenile Model Metrics for Upper Columbia River Spring-Run Chinook Salmon**

| Metric (Model) | NAA | MO4 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) (McNary to Bonneville) | 69.5% | 71.0% | +1.5% | +2% |
| Juvenile Travel Time (COMPASS) (McNary to Bonneville) | 6.1 days | 5.3 days | -0.8 days | -13% |
| % Transported | No upper Columbia River spring-run Chinook transported | | | |
| Powerhouse Passages (COMPASS) (Rock Island to Bonneville) | 3.29 | 2.53 | -0.76 | -23% |
| TDG Average Exposure (McNary to Bonneville) | 115.9% TDG | 119.3% TDG | 3.6% TDG | 3% |

*Adult Fish Migration/Survival*

Neither of the adult structural measures in MO4 would provide benefits to upper Columbia River spring-run Chinook salmon because they are both in the Snake River basin. Increased spill and higher TDG in the lower Columbia River would likely reduce adult migration success to some extent.

NWFSC LCM results predict abundance of the Wenatchee population, indicative of this ESU, would increase about 3 percent, assuming latent mortality was the same as in the No Action Alternative. CSS modeling was not available for this population, but the methods in CSS modeling suggest that fewer powerhouse encounters would reduce latent mortality and can be considered here. If the 23 percent lower powerhouse encounter rate were to reduce latent mortality and subsequently increase ocean survival, abundance could increase by more than 3 percent. See Table 3-93 for details.

**Table 3-93. Model Metrics Related to Adult Survival and Abundance of Upper Columbia River Spring-Run Chinook Salmon under Multiple Objective Alternative 4**

| Metric (Model) | NAA | MO4 | Change from NAA | % Change |
|---|---|---|---|---|
| SARs (NWFSC LCM) Rock Island to Bonneville | 0.94% | 0.96% | +.02% | +2% |
| Abundance of Wenatchee population, representative of the upper Columbia River Spring Chinook salmon ESU (NWFSC LCM)[1] | 498 | 513 (0%)<br>673 (10%)<br>901 (25%)<br>1308 (50%) | +15 (0%)<br>+175(10%)<br>+403 (25%)<br>+810 (50%) | +3% (0%)<br>+35% (10%)<br>+81% (25%)<br>+163% (50%) |

[1] NWFSC LCM does not factor latent mortality due to the hydrosystem into the SARS or abundance output. For discussion purposes, potential increases in ocean survival of 10 percent, 25 percent, and 50 percent are shown. The value for 0 percent is the actual model output, the 10 percent, 25 percent, and 50 percent values represent scenarios of what SARs, or abundance hypothetically could be under the increased ocean survival if changes in the alternative were to decrease latent mortality by that much.

Upper Columbia River Steelhead

*Summary of Key Effects*

Measures in MO4 may result in a negligible increase in average juvenile survival for upper Columbia River steelhead, no change in average juvenile travel time, and a 15 percent decrease in the number of powerhouse passage events from McNary to Bonneville Dam. Exposure to TDG would be higher than the No Action Alternative. Similar numbers and arrival timing of juveniles to the ocean, coupled with increased survival of upstream migrants, would likely result in similar abundances of returning adults. If latent mortality in the ocean were to decrease due to fewer powerhouse encounters, there could be a higher increase in abundance.

*Juvenile Fish Migration/Survival*

Juveniles from this DPS migrate through the Columbia River downstream past the four lower CRS projects in addition to up to five PUD dams. Operations at upstream reservoirs that affect seasonal flow patterns downstream influence travel time and survival at the PUD owned projects. Structural and operational measures described in the Common Effects section, including Additional Powerhouse Surface Passage at McNary and John Day and increased spill, would route more fish away from powerhouse routes and likely increase survival. COMPASS modeling estimates predict that from McNary Dam to Bonneville Dam, juvenile survival would increase by 0.3 percent and that travel time would be the same as the No Action Alternative. Powerhouse passages from Rock Island to Bonneville would decrease 15 percent, but TDG exposure would be increased to nearly 120 percent average exposure throughout juvenile migration. Table 3-94 summarizes juvenile model metrics for MO4.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Steelhead are particularly susceptible to predation by Caspian terns. Increases in these predators would likely increase predation on juvenile steelhead and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish.

**Table 3-94. Multiple Objective Alternative 4 Juvenile Model Metrics for Upper Columbia River Steelhead**

| Metric (Model) | NAA | MO4 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) (McNary to Bonneville) | 65.8% | 66.1% | +0.3% | +0% |
| Juvenile Travel Time (COMPASS) (McNary to Bonneville) | 6.6 days | 6.6 days | 0 days | 0% |
| % Transported (COMPASS) | No transport of upper Columbia steelhead | | | |
| Powerhouse Passages (COMPASS) (Rock Island to Bonneville) | 2.72 | 2.31 | -0.41 | -15% |
| TDG Average Exposure (TDG Tool) (McNary to Bonneville) | 116% TDG | 119.6% TDG | +3.6% TDG | 3% |

*Adult Fish Migration/Survival*

Steelhead that go past their natal (birth) stream typically move downstream in October through March before the start of spring spill, while steelhead kelts move downstream throughout spring, both before and after the start of spill. Adults passing downstream after the start of spill are expected to have a slightly decreased rate of powerhouse passage events. In an adult passage study at McNary Dam, survival rates through turbines at McNary Dam averaged 90.7 percent while survival through the spillway weir averaged 97.7 percent (Normandeau 2014). Steelhead are typically surface oriented and when a surface weir is available, a large fraction of adult migrants use the route (Ham et al. 2012).

Life cycle abundance modeling was not available for upper Columbia River steelhead. However, insights from both the CSS and NWFSC LCM models can be considered when evaluating potential affects to abundance. The NWFSC LCM relies heavily on date of arrival below Bonneville Dam to estimate ocean survival and does not initially consider any increases or decreases in latent mortality. Based on COMPASS modeling, travel time and juvenile survival would be similar to the No Action Alternative, meaning a similar number of juveniles would arrive at the ocean with timing similar to the No Action Alternative. Because arrival timing would be similar, adult abundance could also be similar to the No Action Alternative.

Haeseker et al. (2018) evaluated natural origin steelhead populations from the Entiat and Methow using CSS Snake River steelhead relationships, based on the CSS finding that upper Columbia River steelhead populations have similar responses to fresh water migration conditions (powerhouse passage experiences, flow) and marine conditions as their Snake River counterparts (DeHart 2019/CRSO-47). While their analysis did not model all the MO4 measures, spill to 125 percent TDG at the four lower Columbia projects was estimated to produce a 3.7 percent SAR for the Entiat/Methow steelhead (personal communication, DeHart 2019). The increased SAR was a 28 percent increase relative to the baseline condition[5] used by CSS modelers (Haeseker et al. 2018; DeHart 2019/CRSO-47), which may be similar to the No Action Alternative. Presumably, this increase would be a result of decreased latent mortality in the ocean.

<u>Upper Columbia River Coho Salmon</u>

See Upper Columbia spring-run Chinook salmon analysis as a surrogate for juvenile Upper Columbia coho salmon and Upper Columbia fall Chinook salmon analysis as a surrogate for adult Upper Columbia coho salmon.

*Summary of Key Effects*

Juvenile upper Columbia River coho survival would be similar to upper Columbia River spring-run Chinook, with structural measures and spill increases potentially increasing juvenile survival. Conditions for upstream migrating adults would include similar thermal regime, though higher temperature differential in fish ladders could hamper migration success. Overall, increases in juvenile survival and potentially higher survival due to lower powerhouse encounters and shorter travel times may result in higher returns of adult upper Columbia River coho salmon.

*Juvenile Fish Migration/Survival*

See upper Columbia River juvenile spring Chinook MO4 analysis for surrogate information of juvenile upper Columbia River coho salmon.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in these predators would likely increase predation on juvenile coho and reduce survival of these fish.

---

[5] A comparison of CRSO No Action Alternative and MO4 H&H datasets and the CSS modeling assumptions from the Haeseker et al. (2018) analysis has not been completed. Hydrology and operations modeling in the lower Columbia may not be consistent with the rest of the CRSO modeling analyses in MO4. Inputs to the models would need to be compared.

The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish

*Adult Fish Migration/Survival*

Adult migration conditions would be similar to upper Columbia River Fall Chinook salmon, which were analyzed in a workshop using water quality and hydrology outputs. MO4 water quality modeling showed no change in the frequency of water temperatures exceeding 20°C relative to the No Action Alternative, when adult upper Columbia coho salmon would be migrating upstream. Upper Columbia River coho adults migrate August/September (early run) and October/November (late run). McNary Dam outflows would be 5 to 10 percent lower than the No Action Alternative in September and October. See upper Columbia River Fall Chinook for surrogate information of adult upper Columbia coho salmon.

<u>Upper Columbia River Sockeye Salmon</u>

Refer to the upper Columbia River Chinook salmon analysis as a surrogate for Upper Columbia River sockeye salmon.

*Summary of Key Effects*

The changes with the greatest effect in MO4 would be the increase in TDG and minor increases in water temperature on dry years when augmentation flows are depleted. Both of these changes would have adverse effects on adult upstream migrating fish survival.

*Juvenile Migration/Survival*

Operational changes for MO4, would increase the number of days with TDG over 120 and 125 percent at Bonneville and McNary dams, but no difference at Chief Joseph Dam. This change is substantial enough that MO4 could have greater adverse effects from TDG compared to the No Action Alternative. Refer to the upper Columbia River Chinook salmon analysis, as a surrogate for Upper Columbia River sockeye salmon juvenile and adult fish migration and survival metrics.

Table 3-95 shows the comparison between MO4 and the No Action Alternative of percent of days with TDG over 120 and 125 percent. These increases could cause an increase in occurrence of GBT for juveniles and adults.

**Table 3-95. Percent of Days with TDG above 120 Percent and 125 Percent in the No Action Alternative and in Multiple Objective Alternative 4**

| Project | NAA % of days above 120% TDG | MO4 % of days above 120% TDG | NAA % of days above 125% TDG | MO4 % of days above 125% TDG |
|---|---|---|---|---|
| Bonneville Dam | 10.8 | 25.8 | 3.3 | 3.7 |
| McNary Dam | 6.8 | 13.3 | 2.1 | 3.0 |
| Chief Joseph Dam | Less than 0.1 | Less than 0.1 | 0.0 | 0.0 |

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in these predators would likely increase predation on juvenile sockeye and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would, therefore, have no difference in the risk of predation from other fish.

*Adult Migration/Survival*

Neither of the adult structural measures in MO4 would provide benefits to upper Columbia River sockeye salmon because they are both in the Snake River basin. Increased spill and higher TDG in the lower Columbia River would likely reduce adult migration and success to some extent. Refer to the upper Columbia River Chinook salmon analysis, as a surrogate for Upper Columbia River sockeye salmon, for additional information in modeled adult fish migration and survival metrics.

MO4 would result in increased temperatures in July of low-flow years from Chief Joseph Dam to McNary Dam. For upper Columbia River sockeye, a ten percent increase (25 to 35 percent) in the number of days over 18°C at Chief Joseph Dam was noted. This increase would induce thermal stress for upstream migrating adult sockeye. The water temperature at Chief Joseph Dam influences sockeye that use the nearby tributary of Okanogan River. Okanogan sockeye arrive at the confluence of the Okanogan River with the Columbia River when water temperatures are warmer than 21°C, and then hold in the mainstem Columbia River. From around July 1 until the end of August, sockeye hold in the mainstem of the Columbia River until they get a temperature break in the Okanogan River and are then able to move upstream toward their spawning areas. Earlier runs of fish are more successful. The experience of moving up through warm water in the Columbia River, then warm water at the confluence of the Okanogan River Confluence where they hold, means that the cumulative stress is likely to decrease adult fish survival and their gamete viability.

Increased returns of adults would be expected at Bonneville Dam from the increased juvenile survival, which would result in more juveniles arriving to the ocean. Challenges to upstream migration and survival could decrease those gains to some extent, but life cycle modeling was not completed for sockeye salmon. Furthermore, MO4 could provide potential increases of upper Columbia River sockeye salmon abundance if lower powerhouse encounter rates were to increase ocean survival compared to the No Action Alternative.

<u>Upper Columbia summer/fall-run Chinook salmon</u>

*Summary of Key Effects*

Overall, there may be a decrease in reservoir habitat supporting upper Columbia summer/fall-run Chinook salmon, but the magnitude of this decrease is uncertain. There may be slightly greater adult migration delay due to slightly higher incidence of adult ladder temperature differentials above $2^{o}C$.

*Juvenile Fish Migration/Survival*

No change is anticipated in McNary and John Day Reservoir plankton communities or juvenile rearing habitat below Bonneville Dam under MO4, relative to the No Action Alternative (see Section 3.4, *Water Quality*, and the Resident Fish subsection of Section 3.5.2.5 for additional information). However, shoreline habitat in the John Day pool is expected to decrease relative to the No Action Alternative due to the drawdown measures. Overall, there may be a decrease in reservoir habitat supporting upper Columbia summer/fall-run Chinook, but the magnitude is uncertain.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in these predators would likely increase predation on juvenile Chinook and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish

*Adult Fish Migration/Survival*

As described in common effects, water temperatures in the Columbia River from Chief Joseph to McNary Dam may be warmer than the No Action Alternative in hot, dry years, resulting in additional migration delay, fallback, or susceptibility to disease. The number of days that adult ladder temperature differentials exceed 2°C would slightly increase from 2.8 percent (No Action Alternative) to 3.8 percent (MO4), which may slightly increase delay in dam passage for adult fish (Caudill et al. 2013).

Specific to Okanogan upper Columbia summer/fall-run Chinook, there is a slight increase in number of days the mainstem would be 20°C or higher at the confluence of the Okanogan River (1.1 percent), relative to the No Action Alternative (0 percent) when adults hold in the mainstem. This means that there may be a slight decrease anticipated in the ability of the Okanogan fish to hold in the mainstem until water temperatures in the Okanogan River are cool enough that adults can move up from the mainstem without having to migrate through water temperatures typically considered lethal for salmon and steelhead (Ashbrook et al. 2009).

The frequency of meeting the Vernita Bar Agreement to protect the prolific fall-run Chinook spawning in and around the Hanford Reach of the Columbia River in Washington is not expected to change under any MOs relative to the No Action Alternative. Other operational changes under MOs are likewise not anticipated to affect upper Columbia summer/fall-run Chinook spawning from the tailrace of Chief Joseph Dam to Bonneville Dam in terms of changes in flows, water temperatures, or TDG generated under the MOs.

***Middle Columbia River Salmon and Steelhead***

<u>Middle Columbia River Chinook Salmon</u>

See Upper Columbia River spring-run Chinook analysis as a surrogate for Middle Columbia River Spring-Run Chinook Salmon.

*Summary of Key Effects*

Using the surrogate species of upper Columbia River spring-run Chinook salmon, MO4 may result in minor increases in middle Columbia River Chinook salmon average juvenile survival from the McNary Dam to the Bonneville Dam tailrace, reduce travel times, and decrease the average number of powerhouse passage events. Other effects of MO4 are similar to those generally seen across all salmonids, and are discussed in the *Effects Common Across Salmon and Steelhead* under Section 3.5.3.7.

*Juvenile Fish Migration/Survival*

Under MO4, CRS operational changes may result in increased survival, lower travel times, and decreased powerhouse passage events on juvenile middle Columbia River Chinook. See Upper Columbia River spring-run Chinook analysis as a surrogate for juvenile Middle Columbia River Spring-Run Chinook Salmon.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in these predators would likely increase predation on juvenile Chinook and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish

*Adult Fish Migration/Survival*

Effects to middle Columbia River Chinook salmon would be similar to upper Columbia River spring-run Chinook salmon, except they would not experience the increased temperatures in the upper Columbia River reach between Chief Joseph Dam to McNary Dam. Water quality modeling indicated this temperature effect would be attenuated by the time the water would get to McNary Dam, where temperatures would be similar to the No Action Alternative. Increased juvenile survival and shorter travel times would likely result in better ocean survival and more returning adult fish. Further improvements could be realized if lower powerhouse encounter rates were to decrease ocean mortality even further. See Upper Columbia River spring-run Chinook analysis as a surrogate for adult migration and survival of Middle Columbia River Spring-Run Chinook Salmon.

<u>Middle Columbia River Steelhead</u>

Refer to Upper Columbia River steelhead analysis as a surrogate for Middle Columbia River steelhead.

*Summary of Key Effects*

Juvenile survival of middle Columbia River steelhead would increase slightly, though travel time would be similar to the No Action Alternative. Fewer powerhouse encounters would be expected for these fish. A notched spillway weir and higher spill considered in MO4 would increase kelt survival, but higher spill would decrease upstream migrant success. Overall, similar or higher returns of middle Columbia River steelhead would be expected.

*Juvenile Fish Migration/Survival*

Under MO4, CRS operational changes would result in minor increases in juvenile survival, negligible reductions in travel times, and decreased powerhouse passage events on middle Columbia River steelhead. Powerhouse encounters would likely be lower due to increased spill and other measures, as described in Common Effects. Refer to Upper Columbia River steelhead analysis as a surrogate for Middle Columbia River steelhead.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Steelhead are particularly susceptible to predation by Caspian terns. Increases in these predators would likely increase predation on juvenile steelhead and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish

*Adult Fish Migration/Survival*

The addition of a notched spillway weir at McNary Dam with 2 kcfs of spill in October and November should increase survival of steelhead for the portion that pass McNary Dam and fallback in the fall. See the common effects section for more details. Increased spill would increase survival of kelts in the spring as well, but may increase straying and fallback of upstream migrants. Refer to Upper Columbia River steelhead analysis as a surrogate for Middle Columbia River steelhead for additional information.

Life cycle abundance modeling was not available for steelhead. However, insights from both the CSS and NWFSC LCM models can be considered in discussing abundance, as described for upper Columbia River steelhead.

***Snake River Salmon and Steelhead***

<u>Snake River Spring/Summer-Run Chinook Salmon</u>

*Summary of Key Effects*

The COMPASS and CSS modeling results predict that compared to the No Action Alternative, juvenile survival rates associated with MO4 from the lower Snake River to below Bonneville Dam would increase, though the magnitudes varied from less than one percentage point to almost 6 percent, depending on the model. Relative to the No Action Alternative, travel time would decrease between eight to 14 percent. The most notable changes would be about an 80 percent relative reduction in powerhouse encounter rates, a major reduction in proportion of fish transported, and TDG exposure of almost 120 percent average through a smolt’s migration.

Adult passage impacts such as fallback or passage delays like those observed at Little Goose dam at spill levels greater than 30 percent could increase under MO4. Adults migrating upstream would also experience substantially elevated average TDG levels compared to the No Action Alternative.

The resulting predicted change in SARS and abundance depends on model assumptions and drivers. The two models used in this analysis predict significantly different smolt-to-adult return rates in the absence of latent mortality. NWFSC LCM predicted a decrease in SARS and abundance if latent mortality was the same as in the No Action Alternative. If decreased powerhouse encounters were to decrease latent mortality by more than 10 percent and therefore increase ocean survival, the SARS and abundance would show an increase. CSS predicts major increases in both SARS and abundance. The two models also predict significantly different smolt-to-adult return rates.

*Juvenile Fish Migration/Survival*

This ESU migrates through the Snake and Columbia Rivers downstream past the eight CRS projects, four on the Snake River, and four on the lower Columbia River. Structural and operational measures described in the Common Effects section that describe changes at all of these dams would apply to these fish.

MO4 would result in an increase in spill, a minor decrease in travel time; a reduction in the proportion of fish going through powerhouses at the projects, fewer juvenile Chinook salmon transported and increased juvenile in-river survival. Increased augmentation flows under MO4 are expected to result in a slightly faster migration times for juvenile Chinook in low water years.

For Snake River spring/summer-run Chinook salmon, the COMPASS model estimates that MO4 would increase juvenile survival from Lower Granite dam to Bonneville Dam by less than one percent, and travel time would decrease by a day and a half (eight percent relative reduction). CSS modeling predicts a larger improvement, with survival 5.9 percent higher and travel time 14 percent lower. However, high spill levels (especially during low river flow conditions) can create large and persistent eddies downstream of each dam. These eddies can adversely affect downstream travel time and in-river survival and are not accounted for in the models during low flow conditions. Consequently, to some degree both models may have the potential to overestimate improvements in juvenile survival, travel time, and SARs.

Data suggests that juvenile Snake River Chinook salmon are migrating earlier in the season with some fish migrating as early as mid-March (DART 2020). Under MO4, spill would begin on March 1st to encompass these early migrants. However, current models are not calibrated to this early spill date and effects from early spill are as yet uncertain. Early spill could benefit early migrants by reducing migration delays and improving survival but river conditions in March can be very different that April and May (lower flows, cooler water temperature). The effects of spill may be much different in early spring compared to later.

Both models predict that the combination of structural measures, increased spill, drawing down the lower Columbia River reservoirs to MOP, and additional flow augmentation in this alternative would be expected to decrease powerhouse encounters. The models predict a decrease in powerhouses encounters that range from 78 percent (COMPASS) to 84 percent (CSS) relative to the No Action Alternative. Spill levels in MO4 lead to increased exposure to TDG, which would increase from about 115 percent up to 120 percent average exposure to a smolt during outmigration. Both models also predict a substantial decrease in the number of smolts transported each year. These changes in TDG exposure and reduced transport could offset some of juvenile survival and life cycle benefits gained with higher spill.

For Snake River spring/summer-run Chinook salmon, the COMPASS and CSS models estimate that MO4 would have the following effects compared to operations under the No Action Alternative, described below in Table 3-96.

**Table 3-96. Multiple Objective Alternative 4 Juvenile Model Metrics for Snake River Spring/Summer-Run Chinook Salmon**

| Metric (Model) | NAA | MO4 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 50.4% | 50.7% | +0.3% | +1% |
| Juvenile Survival (CSS) | 57.6% | 63.5% | +5.9% | +10% |
| Juvenile Travel Time (COMPASS) | 17.7 days | 16.2 days | -1.5 days | -8% |
| Juvenile Travel Time (CSS) | 15.8 days | 13.6 days | -2.2 days | -14% |
| % Transported (COMPASS) | 38.5% | 7.3% | -31.2% | -81% |
| % Transported (CSS) | 19.2% | 6.9% | -12.3% | -64% |
| Transport: In-River Benefit Ratio (CSS) | 0.86 | 0.56 | -0.30 | -35% |
| Powerhouse Passages (COMPASS) | 2.25 | 0.49 | -1.76 | -78% |
| Powerhouse Passages (CSS) | 2.15 | 0.34 | -1.81 | -84% |
| TDG Average Exposure (TDG Tool) | 115.1% TDG | 119.7% TDG | +5.1% TDG | 4% |

Several measures in MO4 affect juvenile Snake River spring/summer-run Chinook fish transportation rates. The higher spill in MO4 would substantially decrease the proportion of smolts transported during the spring spill season because fewer fish would be passing through the juvenile fish bypasses (a higher proportion would pass via spillways) and thus not available for transport. Juvenile fish transportation would be suspended on June 14 through August 15, then reinitiated and continued through November 15. Stopping transport in mid-June may affect the tail end of the Snake River spring/summer-run Chinook outmigration. Although there may be few fish still migrating downstream, late spring benefits from transportation are typically high, so this could lower juvenile migration success for those late migrating spring Chinook. The re-initiation of juvenile fish transportation after mid-August would occur after the Snake River spring/summer-run outmigration has ended and is not anticipated to affect this ESU. The life cycle implications of these juvenile experiences are discussed further in adult survival.

The proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in bird predators could increase predation on juvenile fall Chinook salmon and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish.

*Adult Fish Migration/Survival*

Several structural measures in MO4 are anticipated to benefit adult Snake River spring/summer-run Chinook passage upstream and these include: modifying the adult trap and bypass loop at Lower Granite dam reducing delay) and installing pumping systems at Ice Harbor and Lower Monumental ladders to reduce ladder temperature differentials if cool water is available in order to reduce delay.

However, fallback rates, as well as passage delay or blockage, of Snake River spring/summer-run Chinook may increase under MO4. Fallback for this ESU has been associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). The fish that fell back were less likely to reach their spawning areas compared to fish that never fell back. When looking at PIT-tag data from Bonneville Dam during 2006–2011, a mean of 9.6 percent of spring/summer-run Chinook salmon that fell back reascended (NMFS 2019). Thus, the MO4 higher spill operation would increase the fallback of Snake River spring/summer-run Chinook salmon adults as they migrate upstream.

Adult passage delay and/or blockages may also increase under MO4. Substantial delays and decreases in adult passage rates at Little Goose have been frequently observed when spill levels exceed proportions greater than 30 percent of total river flow. This challenge could occur at other projects under the spill levels that would be implemented as part of MO4. Other operational effects discussed in common effects would also apply to this ESU. It is important to note that regional managers use in-season adaptive management to identify and remedy any excessive fallback or delay. Therefore, while the average survival for Snake River spring/summer-run Chinook salmon adults may decrease from the recent averages of about 89 percent between Bonneville and McNary Dam, and 84 percent between Bonneville and Lower Granite Dam under the No Action Alternative, increased challenges with adult passage may or may not have a large effect under this alternative.

Due to differing assumptions and drivers in the models, and possibly also due to the different populations modeled, the primary life cycle models produced widely differing results for Snake River spring/summer-run Chinook salmon SARS and abundance. The NWFSC LCM indicated a 12 percent decrease in SARS and an average 32 percent decrease in abundance of adult returns to spawning grounds relative to the No Action Alternative. CSS, on the other hand, predicts MO4 would increase SARS by 75 percent and nearly double the abundance of adult returns. These metrics are displayed in Table 3-97.

**Table 3-97. Multiple Objective Alternative 4 Adult Model Metrics for Snake River Spring/Summer-Run Chinook Salmon**

| Metric (Model) | NAA | MO4 | Change from NAA | % Change |
|---|---|---|---|---|
| LGR-BON SARs (NWFSC LCM)[1] | 0.88% | 0.77% (0%)<br>0.84% (10%)<br>0.94% (25%)<br>1.12% (50%) | -0.11% (0%)<br>-0.04% (10%)<br>+0.06% (25%)<br>+2.4% (50%) | -12% (0%)<br>-4% (10%)<br>+8% (25%)<br>+27% (50%) |
| LGR-BON SARs (CSS) | 2.0% | 3.5% | +1.5% | +75% |
| Abundance of south fork Salmon and middle fork salmon river representative populations (NWFSC LCM) | 2,351 | 1,590 (0%)<br>1,944 (10%)<br>2,489 (25%)<br>3,586 (50%) | -761 (0%)<br>-407 (10%)<br>+138 (25%)<br>+1,235 (50%) | -32% (0%)<br>-17% (10%)<br>+6% (25%)<br>+53% (50%) |
| Abundance (CSS)[2] | 6114 | 12159 | +6045 | +99% |

[1] NWFSC LCM does not factor latent mortality due to the hydrosystem into the SARS or abundance output. For discussion purposes, potential increases in ocean survival of 10 percent, 25 percent, and 50 percent are shown. The value for 0 percent is the actual model output, the 10 percent, 25 percent, and 50 percent values represent scenarios of what SARs, or abundance hypothetically could be under the increased ocean survival if changes in the alternative were to decrease latent mortality by that much.

[2] CSS provided results for six populations in the Grande Ronde/Imnaha Major Population Group. The absolute values represent those populations only; the percent change is considered indicative of the Snake River ESU for the purpose of comparing between MOs.

The differences in model assumptions and the results returned can lend additional understanding to MO4 effects on Snake River spring/summer-run Chinook salmon, as well as infer understanding of other ESU/DPSs of salmon and steelhead as well.

The CSS model predicts that in-river survival of juvenile spring Chinook salmon will increase above a threshold of roughly 60 percent, which is the point where the model predicts that transportation no longer provides a benefit compared to in-river migration. Because average survival is expected to be 63.5 percent, CSS results predict that reduced latent mortality more than offsets the reduction in the number of transported fish and therefore predicts major improvements in the abundance of returning Snake River spring Chinook salmon.

The NMFS LCM uses input metrics from COMPASS results, such as juvenile survival and travel timing. The ocean survival of fish that survive to below Bonneville Dam are then estimated by a separate ocean model. The LCM model then uses an adult migration module based on adult fish returning from the ocean and have reached Bonneville Dam, and then computes expected survival for migration upstream to spawning grounds in the upper Snake River Basin.

It is important to note that the juvenile survival indicated in the COMPASS metrics in the juvenile survival table applies to in-river traveling smolts only. Based on prior research, transported smolts are assumed to have a survival rate of 98 percent from Lower Granite to Bonneville Dam, compared to roughly 50 percent survival of in-river smolts. MO4 spill levels reduce the proportion of transported fish and increase the number of smolts experiencing the lower survival rate of the in-river travel. In-river migrants typically arrive below Bonneville Dam later than transported fish, which can decrease ocean survival in the model. The result would be fewer juveniles make it to the ocean under optimal timing resulting in lower overall survival to adulthood. There are also seasonal changes to the relative effect of transport each year. Generally-speaking, fish transported later in the spring season experience better SARs than in-river fish, while earlier in the season there is more benefit to in-river travel. This could be driven by challenges to in-river survival due to factors such as predation and thermal stress, which tend to increase from April to June. MO4 would cease transport in mid-June, when the survival benefit of being transported would be greatest. The lower rate of transported smolts could result in fewer adults straying to different populations than their origin.

Another difference between the models is how ocean survival is accounted for. CSS models incorporate data that links increases or decrease in ocean survival to the hydrosystem experience of each smolt (i.e. latent or delayed mortality from CRS passage is expressed in changes to ocean survival). For MO4, ocean survival was predicted to increase from 3.6 percent under the No Action Alternative to 5.7 percent in MO2 (a 60 percent increase in ocean survival). Factors such as fewer powerhouse encounters and decreased travel time are assumed to increase survival in the ocean due to decreased latent mortality from a smolt's experience through the CRS projects, which would in turn increase the abundance of returning adults to the Columbia River.

While ocean survival is not directly tied to the CRS passage experience in the NMFS LCM models, as a sensitivity analysis, factors of potential change in ocean survival were applied to the results. The model predicts an abundance increase under MO4 if ocean survival can be increased by more than 10 percent. The model run with increased ocean survival of 50 percent indicates an increase of 53 percent more adults than the No Action Alternative. However, the LCM model runs predict that if latent mortality is not reduced by more than 10 percent than the measures associated with MO4 would lead to a decrease in SARS for Snake River spring Chinook salmon and reduced adult abundance of the South Fork Salmon and Middle Fork Salmon River representative populations.

<u>Snake River Steelhead</u>

*Summary of Key Effects*

Both models indicate moderate improvement to the juvenile metrics of survival, travel time, and powerhouse passage events, though the magnitude of estimated survival varies. The two models also predict significantly different smolt-to-adult return rates.

*Juvenile Fish Migration/Survival*

This ESU migrates through the Snake and Columbia Rivers downstream past the eight CRS projects, four on the Snake River, and four on the lower Columbia River. MO4 would result in a substantial increase in spill, a decrease in travel time, a reduction in the proportion of fish going through powerhouses at the projects and fewer juvenile steelhead transported. Increased augmentation of river flows under MO4 are expected to result in a slightly faster migration times for juvenile steelhead in low water years.

Structural and operational measures described in the Common Effects section that describe changes at all of these dams would apply to these fish. The combination of several measures is predicted to decrease travel time and powerhouse encounters, as well as increase survival. This includes a measure to increase Columbia River flows on dry years downstream of Chief Joseph Dam. COMPASS modeling indicates 0.4 percent increase in average juvenile Snake River steelhead survival; whereas CSS indicates the increase would be 16.6 percent, a major increase in survival (30 percent improvement relative to the No Action Alternative). Both models agree travel time would decrease by approximately a day and a half (8 percent (COMPASS) to 10 percent (CSS) reduction relative to the No Action Alternative). However, high spill levels (especially during low river flow conditions) can create large and persistent eddies downstream of each dam. These eddies can adversely affect downstream travel time and in-river survival and are not accounted for in the models during low flow conditions. Consequently, both models may overestimate improvements in juvenile survival, travel time, and SARs.

There is evidence that juvenile Snake River steelhead are migrating earlier in the season with some fish migrating as early as late March (DART 2020). Under MO4, spill would begin on March 1st to encompass these early migrants. However, current models are not calibrated to this early spill date and effects from early spill are as yet uncertain. Early spill could benefit early migrants by reducing migration delays and improving survival but river conditions in March can be very different that April and May (lower flows, cooler water temperature). The effects of spill may be much different in early spring compared to later.

The combination of structural measures, increased spill, drawing down the lower Columbia River reservoirs to MOP, and additional flow augmentation in this alternative would be expected to decrease powerhouse encounters. The models predict a decrease of 80 percent (COMPASS) to 86 percent (CSS) relative to the No Action Alternative. While powerhouse passage is expected to decrease, exposure to TDG would increase from about 115 percent up to 120 percent average exposure to a smolt during outmigration. This exposure could potentially offset some of juvenile survival and life cycle benefits gained. The COMPASS model also predicts a substantial decrease in the number of smolts transported each year. Table 3-98 displays the juvenile model metrics for Snake River steelhead under MO4.

**Table 3-98. Multiple Objective Alternative 4 Juvenile Model Metrics for Snake River Steelhead**

| Metric (Model) | NAA | MO4 | Change from NAA | % Change |
|---|---|---|---|---|
| Juvenile Survival (COMPASS) | 42.7% | 43.1% | +0.4% | +1% |
| Juvenile Survival (CSS) | 57.1% | 73.7% | +16.6% | +30% |
| Juvenile Travel Time (COMPASS) | 16.4 days | 15.1 days | -1.3 days | -8% |
| Juvenile Travel Time (CSS) | 16.2 days | 14.6 days | -1.6 days | -10% |
| % Transported (COMPASS) | 39.7% | 7.2% | -32.5% | -82% |
| % Transported (CSS) | Not reported | | | |
| Transport: In River benefit ratio (CSS) | 1.41 | 0.79 | -0.62 | -44% |
| Powerhouse Passages (COMPASS) | 1.73 | 0.35 | -1.38 | -80% |
| Powerhouse Passages (CSS) | 1.96 | 0.28 | -1.68 | -86% |
| TDG Average Exposure (TDG Tool) | 115.4% TDG | 119.8% TDG | +5.1% TDG | 4% |

Several measures in MO4 would affect juvenile Snake River steelhead transportation rates. Juvenile fish transportation would be suspended on June 14. This may affect the tail end of the juvenile Snake River steelhead outmigration. Early season transport is most beneficial for steelhead, particularly for natural origin steelhead (Gosselin et al. 2018). Because over 95 percent of the Snake River steelhead DPS has passed McNary Dam before mid-June (DART) reducing transport on June 14 should not decrease these benefits. The re-initiation of juvenile fish transportation from August 16 to November 15 would be after the juvenile Snake River steelhead outmigration and is not anticipated to affect this DPS.

The higher spill in MO4 would substantially increase the number of juveniles passing via spillways and thus not able to be collected in juvenile fish bypasses for transport. COMPASS modeling predicts transportation would change from an average of 40 percent of the wild fish transported under the No Action Alternative to about 7 percent under MO4, an 82 percent relative decrease. The proportion transported in any given year could vary with hydrologic and operational conditions. Transported juvenile steelhead have an expected rate of 98 percent survival to below Bonneville Dam compared to the in-river juvenile survival of 43 percent. Because of this survival differential unless significant increases to in-river survival, similar to those predicted by the CSS model, fewer juveniles overall would survive the trip from Lower Granite to Bonneville Dam based on the COMPASS analysis. Further implications of transport are discussed in the Adult Survival section below.

Proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Steelhead are particularly susceptible to predation by Caspian terns. Increases in these predators would likely increase predation on juvenile steelhead and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish.

*Adult Fish Migration/Survival*

Several structural measures in MO4 are anticipated to benefit adult Snake River steelhead passage upstream, including modifying the adult trap and bypass loop at Lower Granite Dam and installing pumping systems at Ice Harbor and Lower Monumental ladders intended to reduce ladder temperature differentials and migration delays. Other operational effects discussed in common effects would also apply to this ESU. Higher spring spill levels should result in higher survival rates for adult steelhead falling back through dams and kelts migrating downstream, as fewer adults used powerhouse passage routes when a spill route was available and overall downstream passage increased when surface passage was available (Normandeau et al. 2014). However, increases in fallback rates, adult passage delay and/or blockages may also increase under MO4 and are generally an adverse impact on adult survival and spawning success. Substantial delays and decreases in adult passage rates at Little Goose have been frequently observed when spill levels exceed proportions greater than 30 percent of total river flow. This challenge could occur at additional projects under the spill levels that are proposed as part of MO4.

Based on CSS model results (see Table 3-99), major increases in adult returns would be expected. For Snake River steelhead, the CSS cohort model predicted that the Lower Granite to Bonneville Dam smolt to adult return rate would be 1.8 percent under the No Action Alternative, and 3.1 percent under MO4. This represents a 72 percent increase in adult returns back to Bonneville Dam per smolt passing Lower Granite Dam. This result assumes that fish passage improvements at the CRS projects will reduce latent mortality affects and improve ocean survival.

**Table 3-99. Multiple Objective Alternative 4 Adult Model Metrics for Snake River Steelhead**

| Metric (Model) | NAA | MO1 | Change from NAA | % Change |
|---|---|---|---|---|
| SARs LGR-BON (CSS) | 1.8% | 3.1% | +1.3% | +72% |

There are no LCM results for Snake River steelhead but based on NMFS modeling results for Snake River spring Chinook salmon, MO4 may actually result in a major decrease in adult returns of Snake River steelhead compared to the No Action Alternative. As described in the juvenile effects section, transportation rates would be much lower earlier.

Typically, transportation provides a larger benefit to steelhead than spring Chinook. Because, like with spring Chinook, both CSS and COMPASS models predict large declines in transportation, it is reasonable to assume that LCM results would also show a decline in overall SARs in the absence of any latent affects like those predicted by CSS modeling.

<u>Snake River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon as a surrogate for juvenile Snake River coho salmon and Snake River fall-run Chinook as a surrogate for adult Snake River coho salmon.

*Summary of Key Effects*

Juvenile Snake River coho salmon survival may see a moderate increase in MO4, with faster travel time, lower powerhouse encounters, but higher TDG exposure. The proportion of fish transported would be lower than the No Action Alternative. Structural measures would improve adult upstream migration. The overall abundance of returning adults is uncertain, depending on how lower transport rates, higher in-river juvenile survival, and lower powerhouse encounters interact with ocean survival.

*Juvenile Fish Migration/Survival*

MO4 would result in an increase in spill, a minor decrease in travel time, a reduction in the proportion of fish going through powerhouses at the projects and fewer juvenile coho salmon transported. Increased augmentation flows under MO4 are expected to result in a slightly faster migration times for juvenile coho in low water years.

Structural and operational measures described in the common effects section would apply to juvenile Snake River salmon, and most of these would be expected to increase juvenile survival.

Juvenile survival of Snake River coho salmon is estimated using juvenile modeling results for Snake River spring/summer-run Chinook salmon as a surrogate. See Snake River spring/summer-run Chinook salmon quantitative results as a surrogate for Snake River coho salmon.

The proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in bird predators could increase predation on juvenile fall Chinook salmon and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish.

*Adult Fish Migration/Survival*

Structural measures in MO4 would reduce adult passage delays and increase adult Snake River coho salmon upstream migration success (e.g., modified adult trap and bypass loop at Lower Granite Dam, and pumping systems at Ice Harbor and Lower Monumental ladders to reduce ladder temperature differentials). Changes in fish spill would not affect upstream migration because they migrate after fish spill would end. See adult Snake River Chinook analysis as a surrogate for Snake River coho.

Abundance of returning adults was not modeled for Snake River coho salmon, but some inferences can be made from life cycle modeling of Snake River spring/summer-run and fall-run Chinook salmon. In general, fewer coho salmon would be transported as juveniles in MO4, and more would travel in-river. Based on surrogate results, if decreased powerhouse encounters were to increase ocean survival, there could be a major increase in adults. If ocean survival would not be affected by changes in powerhouse encounters, then abundance could see a moderate decrease due to the overall later arrival of smolts to the ocean.

<u>Snake River Sockeye Salmon</u>

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for Snake River sockeye salmon.

*Summary of Key Effects*

Notable effects of this alternative include increased nesting habitat for birds that puts outmigrating juvenile sockeye at greater risk of predation as well as greater TDG exposure. TDG exposure could be balanced somewhat by the faster travel time that may increase juvenile survival. A major beneficial effect for upstream migrating adults would occur due to much less transport of those fish as juveniles.

*Juvenile Migration/Survival*

MO4 would result in an increase in spill, a decrease in travel time, a reduction in the proportion of fish going through powerhouses at the projects and fewer juvenile sockeye salmon transported. Increased augmentation flows, under MO4, are expected to result in a slightly faster migration times for juvenile sockeye in low water years based on surrogate species, Snake River spring/summer-run Chinook salmon. Additional results for surrogate, juvenile Snake River spring/summer-run Chinook, showed that minor reductions in travel time would occur when compared to the No Action Alternative. Faster travel times generally result in increased survival rates.

The proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in bird predators could increase predation on juvenile sockeye salmon and reduce survival of these fish. The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish.

Operational changes for MO4 would cause a major increase in the number of days with TDG over 120 and 125 percent at Bonneville, McNary, and Lower Granite projects. This change is substantial enough that MO4 could have greater adverse effects from TDG compared to the No Action Alternative. Table 3-100 shows the comparison between MO4 and the No Action Alternative of percent of days with TDG over 120 and 125 percent. This could cause an increase in occurrence of GBT for juveniles and adults.

**Table 3-100. Percent of Days with TDG above 120 Percent and 125 Percent in the No Action Alternative and in Multiple Objective Alternative 4**

| Project | NAA % of days above 120% TDG | MO4 % of days above 120% TDG | NAA % of days above 125% TDG | MO4 % of days above 125% TDG |
|---|---|---|---|---|
| Bonneville Dam | 10.8 | 25.8 | 3.2 | 3.7 |
| McNary Dam | 6.8 | 13.3 | 2.1 | 3.0 |
| Lower Granite Dam | 2.7 | 22.6 | 1.3 | 12.9 |

*Adult Migration/Survival*

Under MO4, downstream transport of juvenile sockeye would be decreased; based on surrogate species, Snake River spring/summer-run Chinook salmon analyses expect major reduction in transportation. Decreased transportation could also result in an overall decrease in the amount of fallback and straying related to transport. Straying may still occur, but would be much closer to the natural levels for this population

Adult sockeye migrate upriver in late summer and early fall when flows are low and water temperatures can be high. High spill levels under these conditions can cause migration delays as fish search for entrances to fish ladders. These delays are expected to occur at Little Goose Dam and may occur at other projects. This population travels far inland and adults have little excess energy reserves for migration. Delays for these fish may reduce fitness and the probability of successfully spawning.

The summer water temperatures in the river during the upstream migration would not change. However, this alternative is estimated to have 58.9 percent of all days with a greater than 2-degree temperature difference between the river and the fish ladders compared to 50 percent of all days in the No Action Alternative. Having substantially more days with a greater than 2-degree temperature differential between river water and the fish ladders would cause a greater risk of delay at the dams. Installation of pumps to provide cool water in the ladders may reduce the number of days with large differentials in temperature.

The increase in TDG could have adverse effects for adult migrating salmon. The other important water quality parameters of suspended sediment and DO would have no change compared to the No Action Alternative.

Abundance of returning adults was not modeled, but some inferences can be made from life cycle modeling of surrogate Snake River spring/summer-run Chinook salmon. Fewer sockeye salmon would be transported as juveniles, and more smolts would travel in-river. Similar to the surrogate species, if decreased powerhouse encounters were to increase ocean survival, there could be a major increase in adults. If ocean survival would not be affected by changes in powerhouse encounters, then abundance changes are much harder to predict for this species.

<u>Snake River Fall-Run Chinook Salmon</u>

*Summary of Key Effects*

The most notable effect of MO4 for Snake River fall-run Chinook would be the risk of delays for adults trying to migrate up the fish ladders. MO4 would have more days with a temperature differential of more than 2 degrees Celsius warmer water in the fish ladders. A minor beneficial effect for upstream migrating adults would be the reduction in straying that could occur because fewer fish would be transported as juveniles.

*Larval Development/Juvenile Rearing*

None of the measures under MO4 would change the substrate sizes or distribution in the spawning areas or expand suitable spawning areas; therefore, this alternative is expected to have the same larval development and juvenile rearing habitat conditions as the No Action Alternative. The same would be true for river depths in the spawning areas; no change is anticipated for eggs incubating in the gravel. Additionally, there would be no change in the reservoirs that provide rearing habitat for overwintering fall-run Chinook.

*Juvenile Migration/Survival*

MO4 would result in an increase in spill, a decrease in travel time, a reduction in the proportion of fish going through powerhouses at the projects and fewer juvenile fall Chinook salmon transported. Increased augmentation flows under MO4 are expected to result in negligible decreases in migration travel times for juvenile fall chinook in low water years.

The proposed MOP operations at projects would reduce pool elevations and increase nesting habitat for Caspian terns and gulls at Blalock Island in the John Day pool. Increases in fish eating birds could increase predation on juvenile fall Chinook salmon and reduce survival of these fish.

The mean water temperature is expected to be the same as the No Action Alternative and would therefore have no difference in the risk of predation from other fish.

Turbidity effects in MO4 would have no expected change relative to the No Action Alternative in the Snake River, but would have effects in the McNary Dam tailrace because of forebay elevation manipulations at John Day Dam. The *Drawdown to MOP* measure may have minor turbidity effects, but effects are not expected to be great in large reservoirs.

Some operations can produce hydraulic conditions within the tailrace that increase fish vulnerability to predation by extending the amount of time they spend in the tailrace. These conditions can also increase the time juvenile fish are exposed to elevated levels of dissolved gas. High spill under MO4 would likely create these conditions at Snake River dams. High spill levels can lead to large eddies and have been known to draw fish from spillway outflow into the slower flows of the powerhouse and circulate them in predator holding areas. These eddies can even pull fish from the bypass facilities into these predator rich areas. Under MO4, juvenile fish would experience an increased risk of predation because of these hydraulic conditions.

The benefits of transport for fall Chinook increase in the summer and fall (Smith et al. 2018). Consequently, the termination of transport from July 1 through August 15 may potentially reduce juvenile survival and adult returns for this species and would require adaptive management.

*Adult Migration/Survival*

Under MO4, downstream transport of juvenile fish would be reduced compared to the No Action Alternative. Because stray rates of transported fish are approximately 5 percent greater than for fish left in river during migration (Bond et al. 2017), there would be a minor decrease in the numbers of fish that stray to other tributaries. Straying may still occur but would be reduced.

River water temperatures during the upstream migration period are expected to be the same as in the No Action Alternative, which would mean the same rate of delay and fallback would continue to occur. Likewise, there would be no change to sediment concentrations or DO levels from any measures in MO4 during the adult migration period.

The temperature differential between the river and the fish ladders would be worse than in the No Action Alternative. MO4 would have 58.6 percent of all days in August and September with more than 2 degree Celsius differential compared to 50.1 percent in the No Action Alternative. This would have a slight increase in risk of delay under MO4 due to approximately five more days with warmer water in the ladders. Installation of ladder cooling pumps at Lower Monumental and Ice Harbor dams would reduce number of days at these dams where temperatures differences between the river and fish ladders would deter migration.

No life cycle modeling is available for Snake River Fall Chinook salmon, but some inferences can be made from life cycle modeling of Snake River Spring/Summer Chinook salmon. Fewer salmon would be transported as juveniles, and more would travel in-river. The relative SAR of transported fall Chinook is on average lower than that of in-river fish in June and early July, while the benefits of transportation on SAR are highest in August and September (Gosselin et al. 2018). Similar to Snake River spring/summer-run Chinook salmon, if decreased powerhouse encounters were to increase ocean survival, there could be a major increase in adults. If ocean survival would not be affected by changes in powerhouse encounters, then abundance could see a moderate decrease due to the overall later arrival of smolts to the ocean. Fewer fish in late transport would result in reduced adult returns.

***Lower Columbia River Salmon and Steelhead***

Lower Columbia River Chinook Salmon

Refer to the Snake River spring/summer-run Chinook salmon analysis as a surrogate for lower Columbia River Chinook salmon.

*Summary of Key Effects*

Juvenile Lower Columbia River Chinook salmon survival would be decreased slightly under MO4 due to modeled conditions such as spill, and likely be further decreased due to exposure to high TDG during outmigration. Adult migration would likely be less successful with increased fallback, delays, and TDG effects.

Results (and change from the No Action Alternative) for metrics for lower Columbia River Chinook salmon:

- Negligible decrease in juvenile project survival at Bonneville Reservoir and Dam (see Snake River spring-run/summer-run Chinook used as a surrogate) = (-0.8 percent)
- Bonneville Dam median outflows, April to June = (0 percent to -2 percent most years)
- Bonneville Dam outflows, August to September = (-4 percent to -7 percent)
- Spill, Bonneville = Spill, Bonneville Dam = March (+71 percent) April-Jul (+10 percent to +26 percent)
- Temperature, The Dalles Dam, days exceeding state standard = 72 days (+1 day)
- Temperature, Bonneville Dam, days exceeding state standard = 57 days (-1 day)
- TDG, The Dalles Dam, days exceeding state standard = 127 days (+94 days)
- TDG, Bonneville Dam, days exceeding state standard = 113 days (+52 days)

*Juvenile Fish Migration/Survival*

Five of the 32 populations of Lower Columbia River Chinook salmon pass Bonneville Dam on their downstream outmigration to the ocean. Modeling was not available for this ESU so juvenile survival at Bonneville Dam of Snake River spring/summer-run Chinook salmon was used as a surrogate of juvenile survival. COMPASS modeling predicts juvenile survival of 88.2

percent through the Bonneville Project, including the reservoir and the dam, or 0.8 percent lower than the No Action Alternative. It is important to note this model result does not incorporate any effects from TDG exposure, which would be much higher in MO4. The number of days that would exceed the state water quality standard for TDG at The Dalles and Bonneville tailwater would be 90 percent and 180 percent higher, respectively.

Outflows can influence juvenile outmigration if changes in flows are enough to noticeably affect travel time, and therefore survival. Increased spill also decreases travel time. Hydrology modeling predicts spring-run and late-fall-run fish would experience outflows about 1 to 2 percent lower in April through August than the No Action Alternative in most years, but flow augmentation in dry years could improve migration speed for the portion of all runs that outmigrate in May and June and sometimes July. Increased spill in April through July would also decrease travel time. Fall-run fish outmigrate in late summer and may see flows up to 4 to 7 percent lower in August through September than the No Action Alternative, but with higher spill. This decrease in late summer flows could affect the ability of these juveniles to outmigrate and use habitats in the estuary. Water quality modeling indicated there would not be a perceptible change in temperature in the lower river with MO4 operations.

*Adult Fish Migration/Survival*

There are no structural measures in MO4 that would increase adult passage and survival. Fallback rates for spring-run would likely increase with higher spill in April under MO4 as fallback is associated with higher flow and higher spill levels at many dams (Boggs et al. 2004; Keefer et al. 2005). However, regional managers use in-season adaptive management to identify and remedy any excessive fallback. Hydrology and water quality modeling predicts flows and temperatures would be similar to the No Action Alternative, except for slightly lower fall flows could increase adult migration of fall-run and late-fall-run fish. Higher TDG described for juvenile fish would also affect adult migrating fish. Although TDG would be higher throughout spring and summer than the No Action Alternative, the biggest difference would be in March and April where TDG would typically be below the state standard in the No Action Alternative (about 112 percent in March) but over 120 percent TDG in MO4. This would increase TDG-related effects to spring-run adults.

Lower Columbia River Steelhead

Refer to Snake River steelhead analysis as a surrogate for lower Columbia River steelhead.

*Summary of Key Effects*

Juvenile Lower Columbia River steelhead survival would be decreased slightly due to modeled conditions such as spill and flows, as well as high TDG. In dry years, juvenile survival would be improved with additional flow augmentation. Adult upstream migration would likely be less successful with increased fallback, delays, and TDG effects; however, kelt survival would be improved with higher spill.

*Juvenile Fish Migration/Survival*

Survival would be decreased slightly due to modeled conditions such as spill, and likely be further decreased due to exposure to high TDG during rearing and outmigration.

MO4 results (and change from the No Action Alternative) for metrics for Lower Columbia River Steelhead:

- Negligible decrease in juvenile project survival, Bonneville Reservoir and Dam (Snake River steelhead used as a surrogate) = (-0.6 percent)
- Bonneville Dam outflows, April to June = (0 percent to -2 percent most years.
- Bonneville Dam outflows, August to October = (-4 percent to -7 percent) otherwise (+/- 0 to 2 percent)
- Spill, Bonneville Dam = March (+71 percent) April-Jul (+10 percent to +26 percent)
- Temperature, The Dalles Dam, days exceeding state standard = 72 days (+1 day)
- Temperature, Bonneville Dam, days exceeding state standard = 57 days (-1 day)
- TDG, The Dalles Dam, days exceeding state standard = 127 days (+94 days)
- TDG, Bonneville Dam, days exceeding state standard = 113 days (+52 days)

Modeling juvenile survival of Snake River steelhead, used as a surrogate for the Lower Columbia River steelhead, through the Bonneville project (reservoir and dam), predicts under MO4 negligible lower survival than the No Action Alternative. Among the fish that pass Bonneville Dam, higher spill in the spring would slightly decreased dam passage survival, although it would also reduce travel time and result in faster transitions through the project area. In dry years, additional flow augmentation would help move juveniles out more quickly than the No Action Alternative. Temperatures would be similar to the No Action Alternative. It is important to note this model result does not incorporate any effects from TDG exposure, which would be much higher in MO4. The number of days that would exceed the state water quality standard for TDG at The Dalles and Bonneville tailwater would be 90 percent and 180 percent higher, respectively. TDG would be higher than the water quality standard for most of the juvenile outmigration season.

*Adult Fish Migration/Survival*

There are no structural measures in MO4 for increased adult upstream passage. Under MO4, higher spill levels during upstream migration periods should result in higher survival rates for adult steelhead falling back through dams and kelts migrating downstream, but may increase fallback and delay of upstream migrants. Lower flows in August through October may increase the migration speed and success of the tail end of the summer run.

Temperatures would be similar to the No Action Alternative, and adult fish would generally experience higher TDG as described for juveniles. Higher TDG described for juvenile fish would affect adult migrating fish as well. Although TDG would be higher throughout spring and summer than the No Action Alternative, the biggest difference would be in March and April where TDG would typically be below the state standard in the No Action Alternative (about 112 percent in March) but over 120 percent TDG in MO4. This would increase TDG-related effects to the winter run. Summer steelhead would experience much higher TDG throughout their upstream migration period.

<u>Lower Columbia River Coho Salmon</u>

See Snake River spring/summer-run Chinook salmon analysis as a surrogate for juvenile Lower Columbia River coho salmon and Snake River fall-run Chinook salmon as a surrogate for adult Lower Columbia River coho salmon.

*Summary of Key Effects*

Overall, a negligible decrease in juvenile passage survival for Lower Columbia River coho is expected due to increased spillway passage and water temperatures under MO4, relative to the No Action Alternative. An increase in fish ladder temperature differentials would also decrease adult migration success.

*Juvenile Fish Migration/Survival*

Lower Columbia River coho salmon passing Bonneville Dam under MO4, based upon project survival of Snake River spring/summer-run Chinook salmon as a surrogate, would result in negligible decreases in survival (approximately 0.9 percent). Refer to Snake River spring-run Chinook for surrogate information in Section 3.5.2.6. Generally speaking, higher spill at Bonneville Dam results may result in lower survival through the dam.

*Adult Fish Migration/Survival*

Lower Columbia River coho salmon adults are similar in upstream migration characteristics to Snake River fall-run Chinook salmon and were used as a surrogate for adult Lower Columbia River coho salmon. Snake River fall-run Chinook salmon were analyzed in workshops using modeled water quality and hydrology data; MO4 operational changes could result in fewer days when lower Columbia water temperatures in reservoirs would exceed 20°C, and water temperatures around Bonneville Dam specifically may be slightly cooler under all of the MOs compared to the No Action Alternative. However, MO4 analysis showed more days when lower Columbia fish ladder temperature differentials would exceed 2 degrees Celsius. This change in ladder temperature differentials may cause an increase in adult salmon to stop or delay migration relative to the No Action Alternative. For additional information on the surrogate species, Snake River fall-run Chinook, refer to Section 3.5.2.5.

<u>Columbia River Chum Salmon</u>

Refer to Snake River spring/summer-run Chinook salmon analysis as a surrogate for Columbia River chum salmon.

*Summary of Key Effects*

MO4 operations would result in more difficulty in meeting chum flows downstream of Bonneville Dam, with an increase of 12 percent of years, compared to the No Action Alternative, where the flows could not be met without additional drafting of Grand Coulee. Juvenile outmigration could be slower due to decreased outflows in March, and the small proportion of juvenile chum salmon that pass Bonneville Dam would experience negligible increased survival at the dam. Adult migration and survival would likely be similar to the No Action Alternative.

MO4 is expected to result in a 1 percent decrease in juvenile chum survival relative to the No Action Alternative from spawning sites directly downstream of Bonneville Dam, with the decision to either abandon chum or draft additional water from Grand Coulee in 20 percent of years. Incubating chum sac fry would be exposed to TDG above 105 percent in 30 out of 80 years, which is higher than the modeled exposure rate in the No Action Alternative (four out of 80 years).

*Larval Development/Juvenile Rearing*

How operations under MO4 affects the ability of Grand Coulee to provide winter flows to protect chum redds and provide sufficient access to habitat was calculated using hydrology modeling. Chum flows may also be impacted by changes to carryover at storage projects and how they impact inflows to Grand Coulee reservoir; the water supply measure will reduce carryover in all years, and the McNary Flow Objective measure will substantially reduce carryover in dry years. Under MO4, chum flows would be met in 80 percent of years, compared to 92 percent of years in the No Action Alternative. In years when additional releases from Grand Coulee for chum would be needed, the average additional volume needed would be 0.24 Maf. This would be a moderate decrease to the success of chum rearing and decision-makers would have to decide whether to increase risk to chum eggs or reduce spring augmentation flows for spring migrating juvenile salmon.

Maintaining water saturation of 105 percent TDG or less from November 1 through April 30303030 appears to provide a sufficient level of protection to chum salmon eggs and sac fry incubating in the gravel downstream of Bonneville Dam in the Ives/Pierce Island Complex. In MO4, chum sac fry would be exposed to TDG above 105 percent in 30 out of the 80-year record modeled, all in the mid- to late April timeframe. This is 25 more years out of 80 (or 31 percent more often) than the No Action Alternative where this TDG threshold would be exceeded.

*Juvenile Fish Migration/Survival*

Chum salmon only encounter one CRS project, Bonneville Dam; therefore, none of the structural measures described in common effects would apply to these fish, and only a small proportion of spawning occurs above Bonneville Dam. As there is no direct estimate of Bonneville Project survival specific to juvenile chum, juvenile model metrics for Snake River spring/summer-run Chinook salmon are used as a surrogate to estimate any change in juvenile survival for the portion that pass Bonneville Dam. Under MO4, COMPASS modeling for the surrogate species indicates that CRS operational changes are expected to result in negligible decreases in juvenile passage survival compared to the No Action Alternative. MO4 would not change the outmigration conditions for juvenile chum that spawn below Bonneville Dam, other than they may experience higher TDG than under the No Action Alternative. Bonneville Dam outflows would be similar to the No Action Alternative when chum juveniles begin outmigration.

*Adult Fish Migration/Survival*

Most chum spawn downstream of Bonneville. Migration of chum into the Columbia River is in October and November. Bonneville Dam average monthly outflows would be about 1 to 3 percent lower than the No Action Alternative and would be a negligible effect on adult migration under MO4.

**Other Anadromous Fish**

***Pacific Eulachon***

<u>Summary of Key Effects</u>

Eulachon would continue to migrate into the Columbia River from November through March, with specific dates of migration and spawning based on a variety of environmental factors including temperature, high tides, and ocean conditions (NMFS 2017). Temperature, spawning locations, and substrate would be the same as the No Action Alternative.

In most water year types, MO4 would have little change in the time between the peak spawning runs, egg development, and larval emergence. In extremely dry years (the lowest 1 percent), the freshet would begin a couple of days earlier, but would be sustained longer. During the driest 10 percent of years, the discharge duration would be sustained about 8 percent to 9 percent higher in May and June, which could increase larval dispersal downstream in very low water years.

Spring flows for juvenile outmigration would be a negligible change from the No Action Alternative in March and April, and a 10 percent increase in May in the driest 1 percent of years that would be a minor benefit to juvenile outmigration in those years. Higher flows are linked to higher predation rates on adults, but the minor increase in flows in extreme dry years would likely be a negligible effect on adult predation in those driest years.

***Green Sturgeon***

<u>Summary of Key Effects</u>

The Columbia River use by green sturgeon is primarily foraging habitat for adults and subadults. Key effects of MO4 would be similar to the No Action Alternative in most years. Hydrology modeling indicated in dry years (lowest 25 percent of years) there may be a variation between the months of July when flows would be 4 percent higher than the No Action Alternative and August when flows would be 5 percent lower than the No Action Alternative. This change of flows (when flow augmentation would cease) could cause forage sources to move further upstream in July and then downstream in August, but sturgeon would likely be able to continue foraging effectively and this would be a negligible effect.

***Pacific Lamprey***

<u>Summary of Key Effects</u>

MO4 has several measures that are designed specifically to benefit lamprey. These measures are proposed structural improvements that would include converting extended-length submersible bar screens to submersible bar screens, expanding the network of Lamprey Passage Structures to bypass impediments in fish ladders, changing the design for turbine cooling water strainers, replacing turbines for safer fish passage, among other physical modifications to reduce fish injury and mortality.

The most substantial benefit of MO4 would be the improvements to get fish to enter the fish ladders; this would occur through expanding the network of Lamprey Passage Structures and modifying fish ladders to incorporate lamprey passage criteria into the structural modifications. Adults migrating upstream in July would experience higher water temperatures in the Columbia River from Chief Joseph Dam to McNary Dam that would likely lower their survival and migration success.

<u>Larval Development/Juvenile Rearing</u>

Hydrosystem operations affect larval lamprey rearing in shallow waters due to elevation fluctuations that can dewater larvae rearing in sediment. Rates that lower the water level less than 10 cm per hour are natural, but faster than that can strand lamprey. In MO4, drawdowns in late March could dewater larval lamprey rearing in sediment. Most fine sediments at tributary junctions host lamprey. This alternative could reduce the amount of habitat available for larval lamprey (reference to be added prior to final). Although it is difficult to quantify, the effect is anticipated to be minor to moderate.

As juveniles are rearing, temperature affects outmigration: juveniles move out of the system faster in warmer temperatures. This alternative would have no change in the Snake and Lower Columbia Rivers, but the middle Columbia reach would have minor increases in July during low flow years. It has not been quantified what influence this may have on number of lamprey or intensity of effect. If juveniles are triggered to migrate earlier compared to the No Action Alternative, they would likely be slightly smaller and therefore slightly less fit for the long journey down river.

<u>Juvenile Fish Migration/Survival</u>

A substantial amount of injuries and mortality can occur for outmigrating juveniles on their downstream migration including impingement on screens.

These measures are also in MO1 and their effects are described in more detail in the lamprey section in that alternative. Briefly, the measures and their anticipated effects would be:

Converting the extended-length submersible bar screens to submerged traveling screens would substantially reduce mortality due to impingement.

- A new design of structure for exclusion of juvenile lamprey from cooling water strainer intakes would substantially reduce or eliminate this pathway of mortality.
- Additional powerhouse surface passage would change the dynamics of lamprey passage. A higher percentage of lamprey would be expected to pass via the safer surface routes instead of the turbines in relation to the No Action Alternative.
- Replacing turbines at John Day Project with a newer design of turbine would improve conditions for fish passage and reduce the injury rate for lamprey.
- The hydraulic analysis shows an increased hydrograph in May/June in low water years, which could benefit lamprey from upper river areas as it could increase outmigration triggers and speed.
- Reservoir drawdown to MOP to speed up outmigration travel time would benefit juvenile outmigrating lamprey.
- American lamprey lack a swim bladder and are considered less susceptible to barotrauma than salmonids (Colotelo et al. 2012).

Because of the high degree of uncertainty surrounding how many juvenile lamprey are lost or injured on their downstream migration, it is difficult to quantify the improvement represented by all of the measures. For fish that encounter multiple dams on their migration downstream, reducing the total number of hazards would increase their probability for survival to adult life stage.

Adult Migration/Survival

Similarly, there are measures in MO4 that were also in MO1 that improve adult lamprey passage; they are described and analyzed in detail in the lamprey section of MO1 and summarized here:

- Expanding the network of lamprey passage structures would improve lamprey passage.
- Modifying the upper ladder serpentine flow control ladder sections at Bonneville Dam would reduce migration delays caused by baffles in this section.
- Adding cooler water in the fish ladders at Lower Monumental and Ice Harbor would be expected to benefit lamprey because this has been successful at Little Goose and Ice Harbor.
- Modifications to Lower Monumental include diffuser grate plating. This modification has been completed at all other ladders in the CRS, except Lower Monumental, and has resulted in slight benefits to lamprey passage.
- Johnson et al. (2012) found that lamprey passage is inhibited when ladder velocities are too high and when attraction flow to a lamprey entrance is hard to distinguish from nearby discharges such as spillway or turbines.

The overall expected improvements in lamprey passage efficiency should decrease susceptibility to physical stress and mortality, and shorter holding time would be beneficial to the fish. These structural measures for lamprey are expected to provide a substantial benefit to the population size and distribution of Pacific lamprey in the Columbia Basin. Compared to the No Action Alternative, all proposed structural measures to reduce losses would have benefits to the population and recruitment to the next generation. The combined effect of all proposed structural modifications would be a substantial improvement for lamprey survival and fitness.

A site- and timing-specific analysis of water temperatures indicates slightly warmer conditions in July of low water years, when temperatures would be most stressful. At McNary Dam, outflow temperature would exceed 20°C in 57 days of low flow, high temperature year types (similar to 2015), compared to 22 days in the No Action Alternative. This would result in lower migration success and survival of adult lamprey.

***American Shad***

<u>Summary of Key Effects</u>

No change is anticipated to plankton communities, but shoreline habitat is expected to decrease under MO4, so there may be a minor decrease in juvenile shad. The proportion of shad moving upstream of McNary Dam in low flow years may increase under MO4, so an overall decrease in shad abundance is anticipated relative to the No Action Alternative but the magnitude of that change is uncertain.

<u>Juvenile Fish Migration/Survival</u>

Plankton communities and shoreline habitat are not expected to change in the lower Columbia reservoirs relative to the No Action Alternative, so no changes are anticipated for juvenile shad. Shoreline habitat would decrease due to the lower Columbia River drawdowns to near minimum operating pool elevations, but the lower Snake River shoreline habitat area is not anticipated to change.

<u>Adult Fish Migration/Survival</u>

In low flow years under MO4, the proportion of adult shad counted at Bonneville Dam that migrate upstream past McNary Dam may increase due to concomitant minor increases in summer water temperatures in the John Day pool in this alternative, relative to the No Action Alternative. However, the average monthly flows for in MO4 would be higher than the No Action Alternative in some months (for example, July), and lower in other months, so overall the proportion of adult shad passing McNary Dam would likely be mixed or no effect due to this variability in temperatures and flows.

## RESIDENT FISH

### Region A

#### *Kootenai River Basin*

<u>Summary of Key Effects</u>

Key effects to resident fish resources under MO4 would include decreases in reservoir productivity in wet years and a delay in summer productivity in the Kootenai River below Libby Dam. Conversely, MO4 would have a greater potential for cottonwood establishment and riparian regeneration, but flows would provide the least usable habitat for bull trout, redband rainbow trout, and westslope cutthroat trout of all the MOs.

<u>Habitat Effects Common to This Fish Community</u>

MO4 would have a lower rate of flow increase from Libby Dam between mid-March and mid-May than the No Action Alternative. Under MO4, the rate of flow increase would be less than the No Action Alternative. This decrease in flow rate under MO4 would also result in a greater delay in commencement of river productivity than under the No Action Alternative.

MO4 would increase the potential for cottonwood and willow seeding and recruitment compared to the No Action Alternative. Under MO4, there would be nearly three times the number of days when the winter peak stage would not exceed 1753 feet at Bonners Ferry, which is a generic surrogate for the previous year's seeding peak stage. There would also be a greater difference river elevation between the winter and spring peak stage at Bonners Ferry when compared to the No Action Alternative. MO4 would have the greatest potential of all the MOs for riparian regeneration. However, steadily increasing median flows in late summer would adversely impact varial zone productivity (i.e. inundation of previously non-wetted river margins and shifting photic zone would reduce productivity potential), but these effects could possibly be mitigated with real-time operation considerations. MO4 would have a lower rate of recession of river stage at Bonners Ferry during the seeding seasons than the No Action Alternative. This lower recession rate of MO4 would better promote cottonwood establishment than the rate under the No Action Alternative.

<u>Bull Trout</u>

Effects of MO4 to bull trout that differ from the No Action Alternative include large reductions in reservoir productivity, lower minimum and maximum water levels at Lake Koocanusa, large decreases in reservoir elevations at Libby Dam, and decreases in usable habitat for juvenile and adult bull trout.

Under MO4, Lake Koocanusa would above elevation 2,450 feet for 33 days during the summer productivity period (June 15-September 15) compared to 44 days under the No Action Alternative. In dry years there would be no days with lake elevations above 2,450 feet. This would lead to reductions in maximum surface productivity potential in all but the wettest years, and especially in dry years. Primary and secondary food production would be reduced, which would likely adversely affect bull trout growth and/or survival.

The median minimum and maximum elevation of Lake Koocanusa under MO4 would be the same as No Action Alternative, though drier years as measured at The Dalles would result in further decreased minimum elevations than No Action Alternative. The expected result would be more frequent annual dewatering and decreased benthic insect production, which may result in a decrease in bull trout growth and/or survival.

Under MO4, the higher pool elevations during the winter associated with flood risk management and power generation could result in a colder thermal mass that warms slower in early spring. The subsequent cooler releases would delay in-reservoir and downstream productivity. This would lead to slight reductions in resident fish growth and survival. However, reservoir elevations by late April would be lower than the No Action Alternative and this would increase warming.

Under MO4, Libby Dam discharge at peak flows would be lower than under the No Action Alternative. These flows provide less ability than the No Action Alternative to mobilize or reshape tributary deltas that can prevent bull trout access during the fall (low river flow).

MO4 would have many more days of increasing flows than the No Action Alternative. Under MO4, the median Libby Dam discharge would drop precipitously at the end of August, desiccating benthic productivity between the late-August maximum discharge and the minimum bull trout flow of 6 kcfs. In addition, MO4 is expected to have a substantially larger adverse effect on the productivity of the varial zone of the Kootenai River downstream of Libby Dam due to steadily increasing discharge through August in years when the McNary flow augmentation measure is triggered, which would likely reduce growth and/or survival of juvenile bull trout through an adverse impact on the food web and on fish bioenergetics and metabolism. These effects could potentially be mitigated with real-time operation considerations.

MO4 would have higher discharges than the No Action Alternative, but would provide less weighted usable habitat for juvenile (day and night) and adult bull trout than the No Action Alternative. MO4 would provide the least usable habitat for juvenile (day and night) and adult bull trout for all of the MOs. Given these results, lower usable habitat may result in reduced growth and/or survival of all life stages of bull trout under this alternative.

Kootenai River White Sturgeon

MO4 would provide 11 day less than 20 kcfs discharge compared to the No Action Alternative. This would likely result in a negligible reduction in the number of spawning adult Kootenai River white sturgeon that migrate to spawning habitat upstream of Bonners Ferry.

In addition, MO4 would draft Lake Koocanusa to a lower pool elevation than the No Action Alternative for Dry and Average forecasted years. This would allow the lake to warm slightly faster. This faster warming would initiate earlier onset of spring warming in the river below the dam (via selective withdrawal) and increase summer productivity and fish growth slightly.

<u>Other Fish</u>

While the minimum and maximum elevations at Lake Koocanusa for MO4 would not differ from the No Action Alternative, on average water levels would be lower for the summer growing season. This would result in slightly less insect larvae production and less food available for resident fish species. However, on wet years MO4 would maintain higher pool elevations through the winter and spring than the No Action Alternative. This operation may be more beneficial to benthic insect production during these years.

MO4 would have slightly higher discharges from Libby Dam for the period May 15 to September 30 than the No Action Alternative, but would provide less weighted usable habitat for juvenile and adult redband rainbow trout than the No Action Alternative. Lower usable weighted habitat may result in reduced growth and/or survival of all life stages of rainbow/redband trout. We assumed that these effects would be similar for westslope cutthroat trout.

Mean flows under MO4 as measured at Bonners Ferry between January 1 and April 30 would be slightly higher than the No Action Alternative. These flows would be slightly less likely than the No Action Alternative to provide the low flows needed for successful burbot recruitment.

***Hungry Horse/Flathead/Clark Fork Fish Communities***

<u>Summary of Key Effects</u>

The key effects of MO4 are largely biological responses to changes in Hungry Horse Reservoir elevations and outflows to provide additional water supply and flow augmentation in dry years. Lower elevations through the summer would decrease food supply for fish with minor reductions in plankton production and surface area for summer terrestrial insects in wet and average years and moderate effects in dry years. Benthic insect production important to fish would be appreciably decreased under MO4. Lower surface elevations could also increase issues with predation/exploitation risk as fish migrate into and out of tributaries to fulfill their life cycles, and increased outflows in summer would likely result in increased entrainment of zooplankton and fish out of Hungry Horse Reservoir. Increased flows in the South Fork Flathead River would be attenuated with flows from the mainstem Flathead River but would still result in higher summer flows that would decrease native fish habitat suitability in that reach. MO4 would have negligible effects on Flathead Lake, lower Flathead River, or Clark Fork fish.

<u>Habitat Effects Common to This Fish Community</u>

Wet and average year types under MO4 would be similar to MO1 effects. In dry years, however, the reservoir would be drafted much deeper with higher outflows in the summer months. Modeling shows in wet and average water years the reservoir would still reach near full pool (elevation 3,560 feet) by early July in most average years and mid-July in wet years. However, in these year types the median elevation at the end of September would be 3,546 feet, or about 4 to 5 feet lower than the No Action Alternative. In dry years the reservoir would still approach full pool, miss filling and typically become drawn down much faster in the same pattern as the No Action Alternative, but the dry year elevation would be a median of 10 feet lower than the No Action Alternative dry year. All year types considered, there would be a 60 percent probability of reaching elevation 3,559 feet by July 31, or 15 years more out of 100 that would not reach full compared to the No Action Alternative. In fall and winter months, MO4 would be lower than the No Action Alternative, following the same pattern as MO1 and MO3, but deeper in some years.

Lake elevation in the warm summer months determines the volume of reservoir that would be available to produce plankton (euphotic zone). With lower summer elevations, the euphotic zone would decrease under MO4 in all year types, with the effect being most extreme in dry years. In early June, MO4 and the No Action Alternative are similar in wet and average years, but by July, they begin to diverge with MO4 becoming less than the No Action Alternative. By September, the euphotic zone would be from 32,000 to 37,000 acre-feet smaller than the No Action Alternative in wet and average years, representing a decrease of about 2 percent to 3 percent. In dry years, the median MO4 volume would be about 89,500 af smaller than the No Action Alternative or decreased by about 7 percent. In extreme years, the elevation in dry years would be as much as 16 feet lower elevation at the end of September under MO4, which would reduce euphotic zone by about 158,000 af, or 13 percent compared to the No Action Alternative. Drawdowns any time during the year affect the production of insects that live on the bottom of the reservoir. As reservoir elevations drop, insects that have established in this zone can become dewatered. The insect eggs would have been deposited within the euphotic zone described above. If reservoir levels drop, that zone remains the same thickness and drops with the surface level, but there would be no insects deposited at the lower elevation that would become the euphotic zone. As the elevation drops, the surface for benthic insect production gets smaller. MO4 drops faster than the No Action Alternative in the summer and would be at a median of six to nine feet lower elevation through the following fall and winter. This would result in less area for benthic insect production than the No Action Alternative. In dry years there would be more severe losses, especially with more than one dry year in a row as the reservoir would go into the following water year lower and then be drawn down even further. Some of the larger aquatic insects have long life cycles that require overwintering where they were deposited; lower winter elevations would reduce the survival of these important insects. Using surface area as an index for benthic area, MO4 surface area would decrease in most months of all year types, with the exception of spring/early summer in wet years. Where decreases would be expected, they would range from about 100-over 1,000 acres compared to the No Action Alternative, or about 1 percent to 5 percent. In dry years, the summer months would have surface area 4 percent to 5 percent lower than the No Action Alternative, or a difference of about 730 to 1,030 acres. The large bays at the upper end of the reservoir could experience a proportionally higher rate of dewatering with dropping levels over the summer due to more shallow slopes where an equal drop in elevation would result in a larger dewatered benthic surface area and a considerable loss of aquatic macroinvertebrates that had been established due to desiccation.

Finally, the reservoir elevation determines the surface area available for terrestrial insects to land on the water and be available for fish food, as well as influencing the proximity of the water's edge to terrestrial vegetation and therefor the ability of the two non-flying orders of important insects to be available to fish by passively landing in the water. Under MO4 operations, there would be about 100 to 400 acres (1 percent to 2 percent) less surface area for summer feeding in wet and average year types and 900 to 1000 acres (4 percent to 5 percent) less in dry years.

Zooplankton would continue to be entrained into the South Fork Flathead River from Hungry Horse reservoir. The zooplankton enhances food supply in the South Fork Flathead River and along the near bank of the Flathead River but decreases food supply for fish in Hungry Horse Reservoir. Outflows, and therefore zooplankton entrainment, under MO4 would be at least 8 to 17 percent higher in July and 35 to 37 percent higher in August and September, and 11111 to 12 percent lower in fall through spring. These zooplankton are concentrated in the withdrawal zone in summer so the entrainment effect from increased summer outflows would be disproportionately high.

Outflow patterns from Hungry Horse Reservoir can also affect how fish are entrained into the South Fork Flathead River, and the habitat conditions, such as river elevation (stage), velocities, and temperatures in the river. These effects continue downstream to affect the main Flathead River in the same patterns, but somewhat attenuated by the flows in the mainstem Flathead. Temperatures in summer are regulated with a selective withdrawal structure that is operated to release water of a temperature that favors native fish. A further departure from normative flows due to higher flows would further reduce habitat for native fish in the South Fork Flathead River. Insect production in this reach would also be affected. As modeled, the steep dip in the hydrograph in mid-June of dry years would functionally reset the life cycle of aquatic macroinvertebrates. It would take until August for the biota to recover to become a food source for fish, and by that time, the time period for fish growth would be almost over. This would result in lower growth rates for fish in the South Fork Flathead River.

The temperature control structure would still operate in the summer months as in the No Action Alternative so changes in outflows in this timeframe would not affect summer temperatures downstream.

In the Flathead River down to Flathead Lake, habitat suitability is a key issue in the No Action Alternative due to unnaturally high flows in the summer and winter. Under MO4, mid-July through September flows would be 14 to 22 percent higher than the No Action Alternative summer flows, and winter flows in MO4 would be slightly lower than the No Action Alternative. Spring peaks would also be slightly lower than the No Action Alternative. Winter flows would continue to limit establishment of riparian vegetation important to fish, and spring peaks only slightly lower than the No Action Alternative would continue to occasionally provide flushing of sediments from gravels to maintain habitat.

The winter water temperature warming influence from the contribution of the South Fork Flathead would be slightly less due to slightly lower winter flows out of Hungry Horse. TDG in the Flathead River would be similar to the No Action Alternative, continuing to fluctuate with spill at Hungry Horse dam but, generally speaking, would not exceed 117 percent, which is within a safe zone for fish.

The influence of MO4 changes to Flathead Lake levels would be minimal. Seli'š Ksanka Qlispe' Dam outflows would increase 5 to 12 percent in August and 6 to 7 percent in September and decrease 2 to 5 percent in April through May. Flows would be similar to the No Action Alternative in winter.

Bull Trout

MO4 conditions would be similar to MO1 in wet and average years, with reduced summer production of zooplankton that fuels the food web and surface area available for summer terrestrial insect feeding. In dry years, there would be further reductions to zooplankton. The lower reservoir elevations would result in substantially lower surface area for benthic insect production throughout the year, as well as desiccation of the portion of these insects that have established at elevations that become dewatered. This effect is especially in the bays at the upper ends of the reservoir lobes. Juvenile bull trout moving into the reservoir in the spring rely on the benthic insects in these areas until they transition to eating fish. The prey items that adult bull trout eat also consume these benthic insects and may be in poorer condition or less plentiful in areas. This could result in bull trout being in poorer condition.

Reservoir elevations influence the access to spawning tributaries and the degree of varial zone effects such as predation risk and exposure to angling exploitation that fish experience. Bull trout spawn in the fall. Lower reservoir elevations in the fall as described in the physical habitat section would increase the risk and exposure for upstream migrating bull trout. The sedimentation of tributary deltas currently is not known, but there could potentially be blockages of passage arise with lower elevations as well. These effects would likely be moderate in wet and average years with 3 to 4 feet difference from the No Action Alternative, but dry years could see much lower elevations (up to 16 feet) and more extreme effects in years when the elevations would already be causing access and varial zone issues under the No Action Alternative.

Bull trout entrainment through the dam would increase in MO4 due to increased outflows in late summer. In MO4 these outflows would be 35 to 37 percent higher than the No Action Alternative, and entrainment of bull trout would be expected to increase at least that much. Withdrawals in August and September are generally selected from deep in the water column to release the target temperature, and bull trout have been documented in this stratum at this time of year. The relationship between outflows and entrainment would likely be higher than a direct correlation because of increased risk for bull trout at this time of year. Entrainment rates of bull trout under the No Action Alternative are not known, but a considerable increase expected due to MO4 could rise to population level effects.

The number of individual bull trout in the South Fork Flathead River below Hungry Horse Reservoir may increase with greater entrainment, but these would be lost from their spawning populations. Zooplankton available in the South Fork Flathead River may increase in summer with higher outflows. As in the reservoir, food web relationships are important. The MO4 Alternative would continue to allow for this transitory use by bull trout and other native fish with adequate food. Higher flows may also increase benthic production of food for bull trout prey fish, but increased velocities would result in lower availability of suitable habitat for bull trout due to higher velocities.

Summer flows in the mainstem Flathead River would be higher than the No Action Alternative, further decreasing habitat suitability. Muhlfield et al. (2011) found even moderate increases in flows resulted in substantial decreases in suitable area for bull trout due to velocities, and that nighttime habitat for subadult bull trout was most sensitive. For each increase of 1,765 cfs in Flathead River flows, a decrease of 11 percent habitat would be expected. The median summer flows at Columbia Falls increase under MO4, which is expected to decrease the nighttime habitat for bull trout in this reach of river by about 6 percent. The mainstem Flathead River would be similar to the No Action Alternative in winter and spring, with barely perceptible changes from the No Action Alternative.

Operations of Seli'š Ksanka Qlispe' Dam (Flathead Lake) would also result in increased outflows (6 to 12 percent higher than the No Action Alternative in the late summer months. Entrainment of bull trout would not be an issue because they would not be found near the outlets at that time of year due to warm temperatures.

<u>Other Fish</u>

Hungry Horse Reservoir favors a native fish dominated fish community. Juvenile bull trout and adult whitefish, northern pikeminnow, sculpins, and westslope cutthroat trout feed on zooplankton, aquatic insects, and terrestrial insects, and adult bull trout prey on mountain whitefish, suckers, minnows, etc. The food web effects described above would also apply to all of these species of fish in Hungry Horse Reservoir. Decreases in zooplankton and reduced summertime feeding of terrestrial insects could reduce food supply in summer. Substantial decreases in aquatic macroinvertebrate due to dewatering events and reduced surface area for production would decrease the food supply for many of these fish.

Westslope cutthroat trout and other native fish spawn in the spring (April through June), so effects on adults migrating into tributaries to spawn would differ from bull trout. Spring spawning fish migrate when reservoir levels are lower and tend to experience longer varial zones with increased predation exposure. Under MO4 operations, the median modeled April and May elevations would be five and three feet lower, respectively, than the No Action Alternative. In dry years, the median elevation would remain lower than the No Action Alternative the entire summer. Spring spawning fish such as westslope cutthroat trout would experience greater considerably greater varial zone effects on their way upstream as adults, and could encounter some tributary blockages, but the delta formation of these tributaries is not known. Juveniles typically outmigrate in June. In dry years, especially, juveniles would experience higher predation risk as they outmigrate from the tributaries, through the varial zone without suitable cover, and into the reservoir.

Entrainment from the reservoir of all fish species is known to occur but not quantified. Entrainment would increase under MO4, especially in late summer months with outflows up to 37 percent higher than the No Action Alternative. All fish would experience increased entrainment, but northern pikeminnow and bull trout have been documented at the depths of late summer withdrawal and would be most susceptible to entrainment at rates greater than a direct correlation.

Habitat suitability described for bull trout would be similar for other native fish (Muhlfield et al. 2011) in the South Fork Flathead River and mainstem Flathead River, with higher summer flows in MO4 resulting in appreciably decreased amount of suitable habitat available in summer when flows are higher than the No Action Alternative.

Effects to fish in Flathead Lake would be similar to conditions described in the No Action Alternative. The lower Flathead River would experience increased outflows in summer that would 7 to 12 percent higher than the No Action Alternative. This would further change conditions described in the No Action Alternative flows that tend to favor non-native fish in the lower Flathead River and Clark Fork Rivers.

#### ***Lake Pend Oreille (Albeni Falls Reservoir)/Pend Oreille River***

<u>Summary of Key Effects</u>

Key effects to fish and aquatic resources under MO4 include lower summer pool elevations on dry years that may limit access to tributary habitats and reduce the quantity of important shallow water habitats.

<u>Habitat Effects Common to All Fish</u>

On dry years under MO4 Lake Pend Oreille pool elevations may be as much as 2.5 feet lower June through September compared to the No Action Alternative. This water level may limit access to tributary habitats and would represent a reduction in shallow water weedy habitats in tributary inlets that support warm water fish species.

<u>Bull Trout</u>

Effects to bull trout from MO4 include water level manipulations on drier years. Compared to the No Action Alternative water levels on dry years may be up to 2.5 feet lower under this alternative. On these drier years, access to tributary habitats during summer months may be more limited under MO4 than the No Action Alternative.

<u>Other Fish</u>

On dry years under MO4, Lake Pend Oreille pool elevations may be as much as 2.5 feet lower June through September compared to the No Action Alternative. Under these conditions, there would be a decrease in suitable habitat for warm water fish using weedy shoreline habitats near inlets. Specifically, northern pike, largemouth bass, and smallmouth bass would experience some decrease in summer habitat.

**Region B**

***Lake Roosevelt/Columbia River from U.S.-Canada Border to Chief Joseph Dam***

<u>Summary of Key Effects</u>

Flow, elevations, and water quality affect the quality of habitat for various resident fish species above, in, and downstream of Lake Roosevelt. The Columbia River from the U.S.-Canada border would continue to support a white sturgeon population that spawns successfully but primarily relies on fish manager intervention to survive a recruitment bottleneck; conditions for natural recruitment may be further diminished in a small proportion of years. In Lake Roosevelt, there would be major effects to fish. Retention time is a key metric for most fish species in Lake Roosevelt, driving the food web that supports the fish as well as influencing how many are entrained. It would be considerably lower in late spring and summer in dry years resulting in increased entrainment and decreased food supply. Lower retention times in winter would also increase entrainment risk compared to the No Action Alternative. Lake elevations under MO4 would increase risk of impeded tributary habitat access and egg drying out or stranding for redband rainbow trout, especially in dry years where effects would be major and failure of year classes of some rainbow trout is likely. The portion of kokanee that spawn in tributaries would continue to have access in fall similar to the No Action Alternative in wet and average years but experience higher magnitude of varial zone effects. Reservoir operations would result in increased egg drying out of the burbot spawn and the portion of kokanee that spawn on lake shorelines compared to the No Action Alternative. MO4 would have substantial adverse impacts to native fish species, dependent on the water year. Failures of entire year classes are expected while habitat conditions are expected to improve for predatory non-native warmwater species, further expanding their range. Hatchery raised net-pen fish would be subjected to poorer water quality upon release and would likely be entrained at much higher rates and lost from the Lake Roosevelt populations. Northern pike would likely continue to increase and invade downstream, and the lake elevations could decrease the ability for boat suppression efforts. Entrainment of northern pike juveniles would likely increase and hasten the rate of invasion downstream. Reservoir fluctuation events could increase contaminant uptake by fish as this variability activates mercury into the water. Rufus Woods Lake would continue to provide habitat for fish entrained from Lake Roosevelt and from limited production of shoreline spawning by some species; entrainment could increase in spring and summer months. TDG would be similar or less than the No Action Alternative.

<u>Habitat Effects Common to This Fish Community</u>

The summary hydrograph of Lake Roosevelt water elevations influences many of the fish species in Lake Roosevelt. Refer to Chapter 3.2 for a full description of the changes in reservoir elevations. Operations would have targets to meet the metric of reaching a lake elevation of 1,283 feet by the end of September, which would be met in average and wet years, but the median dry year elevation would be seven feet lower. The winter draft in MO4 would start December 1 compared to February in the No Action Alternative, and reservoir levels run about 7 feet lower through these early winter months, with elevation variations shown in the modeling that would be smoother in real operations. In average and wet years, the spring and summer would be similar to MO1. Initiation of refill would be about May 1 where the levels would rise until reaching a target full pool of about 1,289 feet by early July. In dry years, however, is where MO4 differs substantially from the No Action Alternative and the MOs. The median dry year values have the reservoir failing to refill. In the beginning of May, it still would be drafting to support the McNary Dam Flow Augmentation, and it would not start to refill until June. Peak refill would be more than 20' lower the No Action Alternative as the pool would begin to draft again in July and August for augmentation flows. Median peak outflows follow the same pattern as the No Action Alternative with peaks in early June and another, smaller peak in July. The MO4 flows in early spring through August in wet and average years would be about 2 percent to 5 percent lower than the No Action Alternative. In dry years, however, outflows in May and June would increase by 5 percent to 12 percent, and then would drop to about 3 percent to 15 percent lower than the No Action Alternative flows in August, September, and October. December and January flows would be slightly (-1 percent to 4 percent) higher than the No Action Alternative. These peak outflows can influence the rate of entrainment from Lake Roosevelt into Rufus Woods Lake. TDG in the Grand Coulee tailwater is also a concern for fish in Rufus Woods Lake. Under the MO4 TDG would be lower than the No Action Alternative.

Retention time of water through the reservoir is a driving metric for the food web in Lake Roosevelt and influences the populations of several fish species. In MO4, retention time in December through May is related to winter FRM, Planned Draft Rate, and Upstream Storage Correction.

Generally speaking, under MO4 median retention time would be considerably lower than the No Action Alternative during critical time periods for a number of fish relationships. In dry years, retention time would be much lower in May to August (29 percent, 28 percent, 21 percent, and 11 percent medians in May, June, July, and August, respectively). These reductions of up to 9 days retention time could greatly affect food webs and entrainment of zooplankton and fish in the reservoir. It would be moderately higher in September and October and moderately lower in winter. In average years, retention time under MO4 would be 3 percent to 9 percent lower than the No Action Alternative in the critical spring/summer months, and moderately higher in fall and moderately lower in winter. In wet years, the summer months would be similar or slightly less than the No Action Alternative, higher in October, and moderately lower through the winter. In wet years is when retention time is lowest because more water is moving through the system, and MO4 would reduce retention times even further in these years by up to 9 percent in February and by 3 percent to 9 percent in the entire period of December through May.

Kokanee, redband rainbow trout, juvenile burbot, larval sturgeon, and many prey species rely directly on the food source provided by the zooplankton production and higher-level predators such as bull trout prey on these fish. Zooplankton are more widespread, more plentiful, and larger body size when retention times are higher, and tend to be smaller bodied, swept out of the reservoir faster, and more concentrated near Grand Coulee dam with lower retention time. With lower retention times under MO4 in winter and spring, when retention times are already fairly low, there would be less food available to fish, and they would also tend to follow the food source and crowd down towards the dam, becoming more susceptible to entrainment. The large magnitude of lower retention times in summer months of dry years would be expected to increase entrainment of kokanee, redband rainbow trout, and other native fish as well as increase the invasion of non-native fish such as northern pike downstream.

<u>Bull Trout</u>

Bull trout are temperature sensitive and would continue to use this reach for foraging, migration, and overwintering habitat until temperatures reach stressful levels, which would be the same as the No Action Alternative. Bull trout in Lake Roosevelt could continue to move to cooler locations in the reservoir and these refuges would remain similar to the No Action Alternative. High flow years would continue to influence bull trout distribution through flushing more of them from the river near the U.S.-Canada border down into Lake Roosevelt. Peak flows at the U.S.-Canada border were modeled showing a decrease of about 1 percent to 2 percent under MO4, which would likely be a negligible change to bull trout distribution similar to MO1, MO2, and MO3. Increased outflows in January through May could potentially increase entrainment of bull trout, but this would be negligible because of the scarcity of bull trout in Lake Roosevelt. Bull trout prey base would continue to fluctuate, as the fish they eat are sensitive to changes in productivity and location of zooplankton in Lake Roosevelt that is influenced by the retention time of water in the reservoir, which would be adversely affected by lower retention times in MO4. In dry years, the decrease in retention time in spring and summer would tend to flush zooplankton more quickly and concentrate prey fish that bull trout eat closer to the dam, where they would be more susceptible to entrainment, especially in May when outflows would be 5 percent to 12 percent higher than the No Action Alternative. Bull trout are also sensitive to contaminants that are found in this region and would continue to bioaccumulate contaminants as a top predator. Bigger fluctuations in reservoir levels under MO4 that would increase the exposure of shorelines and the increased fluctuation events could increase methylmercury production, a highly toxic organomercury compound which bioaccumulates in fish (Willacker 2016).

<u>Other Fish</u>

In the Columbia River reach from the U.S.-Canada border to Lake Roosevelt, white sturgeon are typically able to spawn as evidenced by capture of young of the year larvae (Howell and McLellan 2018), but rarely experience successful recruitment from larvae to juvenile sturgeon, and only in extremely high water years. Successful recruitment appears to be dependent on a combination of flows exceeding 200 kcfs and water temperatures of about 14°C for 3 to 4 weeks in late June/early July (Howell and McLellan 2005 Howell and McLellan 2011 and Howell and McLellan 2014). Under MO4, flow over 200 kcfs in June and July would have a slight decrease These slightly reduced flows at the U.S.-Canada border would result in a minor decrease in the recruitment window. The timing of these flows coinciding with lower reservoir levels can also increase recruitment ability with the longer riverine habitat provided by a lower reservoir. MO4 reservoir levels would be similar to MO1 in wet and average years, with slightly lower elevations. In dry years, the reservoir would be considerably lower and provide more riverine habitat length, but flows would not have been high enough for sturgeon to successfully spawn. Other factors that would continue to influence sturgeon include predation by fish that are favored by reservoir conditions if larvae are flushed into the Lake Roosevelt. Slightly lower flows in spring could slightly reduce the risk of larvae entering Lake Roosevelt. The uptake of contaminants such as copper closer to the U.S.-Canada border being flushed downstream into the reservoir by high flows would also be slightly lower. Under MO4, recruitment of white sturgeon would continue to be a rare event supplemented by hatchery propagation, as larval sturgeon are captured and raised in hatcheries until they are past the window where recruitment has been shown to fail at a high rate. Once these juveniles are released back into the reservoir they continue to grow and survive well. The reservoir would continue to provide good conditions for growth and survival of these fish. In dry years there would be more riverine habitat and less lake-like habitat, which could tend to favor white sturgeon juveniles over non-native species.

Wild production of native fish such as burbot, kokanee, and redband rainbow trout would be impaired for populations in Lake Roosevelt. As described in the common habitat effects, these fish are the most sensitive to the effects of changing retention times. Under the No Action Alternative an estimated average of over 400,000 fish annually would be entrained, with 30 to 50 percent of them being kokanee, primarily of wild origin and rainbow trout the second most entrained species. Under MO4 operations, greatly increased entrainment would be expected in spring and summer months of dry years as the outflows increase over the No Action Alternative and retention times are up to 9 days or 30 percent faster. Summer months were found to be the months with the highest rates of entrainment, and in years of high entrainment May, June, and July losses were estimated in the range of about 90,000 to up to 200,000 fish per month (LeCaire 2000) under the No Action Alternative. Increases of 30 percent in these months would likely decrease populations of kokanee and rainbow trout. Wild kokanee would likely be the majority of fish entrained. Entrainment would also be expected to increase in winter in all year types, and December through May in wet years.

The decreased retention time in spring and summer of average and dry years, especially, would also likely adversely affect food sources for fish in Lake Roosevelt to the point of affecting growth of kokanee and other fish. Increased entrainment of zooplankton in winter would decrease food availability that is key to winter survival and growth of several fish species including kokanee, juvenile burbot, and other juvenile fish, though this effect would be somewhat mitigated with increased retention times in September and October that would flush fewer of these zooplankton out in the fall than under the No Action Alternative.

For tributary spawning species such as redband rainbow trout and a portion of the wild production of kokanee, tributary access at the right time of year is important. Reservoir drawdown in the spring creates barren tributary reaches through the varial zone, which directly and indirectly impedes migration to and from tributaries and the reservoir. The operational metric of reaching a lake elevation of 1,283 feet by the end of September would be met under MO4 in average and wet years, but would be about median dry years would be 7 feet lower and levels would be lower than the No Action Alternative in October through December as well.

Lower elevations could impede access and increase predation risk and increase volitional migration time for kokanee. Redband rainbow trout need access tributaries in the spring. Under MO4, reservoir elevations would be slightly lower than the No Action Alternative levels in the critical spawning migration time of April and May in wet and average years, and considerably lower in dry years. This would be most extreme in dry years, with large deviations from the No Action Alternative levels, but also most critical in wet years (20 percent of years) when the median elevation would be 1,217 ft at the lowest point in early May, 5 feet lower than the No Action Alternative. Migratory impacts although not well documented, could be severe for Redband rainbow trout given the timing and extent of drawdowns in MO4. Specific tributaries of concern that redband rainbow trout spawn in Sanpoil, Blue Creek, Alder, Hall Creek, Nez Perce Creek, Onion Creek, Big Sheep Creek, and Deep Creek. These tributaries higher in the basin are more susceptible to elevation changes because a smaller change in lake elevation would result in a larger area of exposure than tributaries closer to the dam. Additionally, increased exposure during migrations to these tributaries would increase the varial zone effect where migrating fish are more exposed to predation and angling due to lack of cover.

Species such as kokanee and burbot that spawn on shorelines in Lake Roosevelt are susceptible to egg desiccation if reservoir levels drop while eggs are still in the gravel. Kokanee spawn on shoreline gravels September 15 to October 15 and eggs incubate through February. Burbot tend to spawn successfully in depths provided by MO4 in the Columbia River and in Lake Roosevelt on shorelines near the Colville River in winter with eggs incubating through the end of March (Bonar et al. 2000). MO4, compared to the No Action Alternative, begins dropping 2 months sooner and would likely strand or dewater burbot and kokanee eggs more than the No Action Alternative. A higher proportion of eggs at all elevations would be affected in all year types due to fluctuations in the modeled elevations, although these could be smoothed out somewhat in real-time operations. MO4 dry year scenarios would strand and desiccate considerably more eggs and larvae than the No Action Alternative in January and February with differences up to ten feet.

Fry sometimes also stay in the gravels and could become stranded as well. The wet years would have steeper and deeper reservoir draft than the No Action Alternative and would result in increased stranding of burbot eggs. Burbot spawn in the Columbia River above Lake Roosevelt and in reservoir towards the upper end; the river spawning fish would not be as susceptible to reservoir fluctuations.

Kokanee are very sensitive to water temperature, and during summer are found at depths below 120 m to find suitably cool water. Similar to the No Action Alternative, Lake Roosevelt is very weakly stratified but does have suitably cool water at this depth along with suitable levels of DO. Lake whitefish and mountain whitefish also likely use this cool water in the summer.

Non-native warmwater gamefish, such as walleye, northern pike, smallmouth bass, sunfish, crappie, and others, as well as the prey fish that they eat (such as shiners, dace, and sculpins) all tolerate a wide range of environmental conditions and would continue to contribute to the fishery community under the No Action Alternative, and continue to adversely impact native species via predation. The invasion downstream by northern pike is of concern, and the Lake Roosevelt Co-Managers are actively suppressing pike populations using gillnets set by boats as soon as they can get on the water in the spring until the boat ramp becomes unusable at elevation of 1,235 feet. Under the No Action Alternative, this occurs on April 15 in wet years and ramps remain useable in dry and average years. Under MO4 in wet years, this would occur up to 6 days sooner, and in dry years the elevation could also drop to this level in May and June, though that is likely after pike would already have spawned. Like MO1, MO4 operations could preclude the ability for the pike suppression efforts for that time period when boat ramps would be inaccessible. For estimation purposes, one crew typically removes about 100 pike per week and they would operate three crews (Colville Tribe unpublished data), so opportunity lost of up to 6 days under MO4 in wet years and potentially some additional time in dry years could result in an estimated 300 or more pike not removed. It should be noted that is only one boat ramp, but the middle of Lake Roosevelt area becomes inaccessible earlier, at lake elevation 1,245' or slightly lower. Additionally, outflows and retention time would continue to influence the entrainment and downstream invasion of non-native gamefish below Chief Joseph Dam where ESA-listed anadromous salmonids would be susceptible to predation by them. During the time when pike juveniles would be most susceptible to entrainment (May to August), retention time under MO4 would be up to 30 percent lower and entrainment risk would be considerably higher than the No Action Alternative. Additionally, as adult pike distribution increases downstream in the reservoir, adults and juveniles both would become more susceptible to entrainment and the higher outflows any time of year would increase entrainment. Overall these effects would likely hasten the invasion of northern pike downstream, which could result in an increased risk of predation to salmon and steelhead.

Once released, the net pen fish that supplement the rainbow trout fishery in Lake Roosevelt would experience similar effects as their native counterparts except for spawning and early rearing effects. In addition, the net pen locations are situated where the water quality can be affected by changes in reservoir elevations; these fish are sensitive to temperature and TDG, and their eventual recruitment to the fishery can be affected by retention time coupled with reservoir elevation at the time of their release (McLellan et al. 2008), which is typically in May. Under the MO4, the water quality at these locations would be similar to the No Action Alternative except for modeled decreases in dissolve oxygen in the Spokane arm. This could decrease habitat suitability for the fish in that location. The operators strive to release these fish to coincide with the initiation of reservoir refill when outflows are reduced, which under MO4 wet and average years would be similar to the No Action Alternative and these fish would continue to be release when water quality conditions would be suitable. In dry years, however, initiation of refill would be delayed by up to four to six weeks later than the No Action Alternative. This delay would result in releasing hatchery fish later where they would likely encounter more stressful rearing conditions with higher temperatures and TDG. If the fish were released at similar time as the No Action Alternative but the refill is delayed, these fish would be subject to much higher risk of entrainment due to low retention times and higher outflows in May and June. Conditions in dry years would already be stressful to fish, and these conditions would be exacerbated by the delay in release.

The fish in Rufus Woods Lake would continue to be supplemented by entrained fish out of Lake Roosevelt to a large extent, with fish mostly entrained during the spring freshet and winter drawdown periods. MO4 operations would likely considerably increase entrainment in spring and summer, boosting fish populations in Rufus Woods Lake, where decreased outflows in August and September likely would decrease entrainment. This lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. High flows during late spring and early summer would continue to flush eggs and larvae from protected rearing areas similar to the No Action Alternative, but at a higher magnitude in dry years. Median peak outflows occur in early June and would be about 3 percent lower than the No Action Alternative in wet and average years but higher in dry years. TDG in the Grand Coulee tailwater is a concern for fish in Rufus Woods Lake; modeling showed TDG would be lower than the No Action Alternative.

***Chief Joseph to McNary Dam***

<u>Summary of Key Effects</u>

Changes in key effects to fish and aquatic resources in this reach of the Columbia River under MO4 relative to the No Action Alternative include slight decreases in flows during May and June and minor increases in water temperatures during June and July similar to effects seen for MO1. In addition, seasonal fluctuations in water levels could occur in the McNary pool.

<u>Habitat Effects Common to All Fish</u>

The main habitat effect common to all fish under MO4 would be the greater degree of McNary pool fluctuation under this alternative. MO4 allows for a drawdown of 1 foot on average years, while on the driest years there may be a drawdown of 3.5 feet. This level of drawdown could adversely impact shallow water rearing and nesting habitats for warm water fish species and shallow water macroinvertebrates.

<u>Bull Trout</u>

Under MO4, there would be slight increase in water temperature in June and July. These higher temperatures may have minor added stress to bull trout and may induce them to leave the mainstem earlier in the year when compared with the No Action Alternative.

<u>Other Fish</u>

Key effects to white sturgeon from MO4 would include slightly lower spring peak flows in most years and slightly higher water temperatures upstream of McNary pool when compared to the No Action Alternative. In low water years there would be higher flows in May and June than the similar type of years in the No Action Alternative. While this may provide a minor survival benefit, sturgeon spawning and recruitment would not be successful in low water years of either alternative. The number of days in the year when water temperature would be over 21°C was used to evaluate temperature effect to white sturgeon. Under the No Action Alternative, there were about 5 days over this threshold while there were over 11 days under MO4. The effect of this change in water temperature would be a minor increase in risk of mortality to white sturgeon under this alternative.

Key effects of MO4 to fish species in this reach of the river that differ from those of the No Action Alternative include a slight increase in survival of juvenile salmon and steelhead that would increase forage for resident predator species, and potential McNary pool water level drawdowns of 1 to 3.5 below current operations that may affect rearing and survival of some warm water fishes. Under MO4 juvenile salmon and steelhead survival would be expected to increase by about 1 percent and provide an increase in forage for walleye, smallmouth bass, and northern pikeminnow. Currently, water levels are held relatively stable at McNary pool. Under MO4, there could be a drawdown during May and June of 1 foot in most years and up to 3.5 feet in dry years. This drawdown could leave smallmouth bass nests and walleye rearing areas dry and reduce egg and fry survival for these and other shallow nesting or rearing species.

**Region C**

***Snake River Basin***

<u>Summary of Key Effects</u>

Changes in key effects to fish and aquatic resources in this reach of the Snake River under MO4 relative to the No Action Alternative include increases in spill and TDG concentrations March through August and a potential to delay upstream dam passage for bull trout or other migratory species.

<u>Habitat Effects Common to All Fish</u>

The habitat effects common to all fish under MO4 would be the greater exposure to elevated TDG concentrations that results from increased spill.

<u>Bull Trout</u>

Effects of MO4 to bull trout in the Snake River that differ from the No Action Alternative include additional spill that may cause delays in bull trout upstream passage at the dams in May and June when the fish are moving out of the system to avoid warming water temperatures.

Elevated TDG levels from spill under MO4 may adversely affect an unknown number of bull trout in the reservoirs by degrading feeding, migrating, and wintering habitat in the mainstem Snake River. Under MO4, a total of 48.3 percent of all modeled days from November through June would have TDG concentrations over 110 percent, which is the highest number of all the MOs and exceeds the No Action Alternative by more than 10 percent. Higher TDG may affect bull trout in May and June when they are leaving the system.

<u>Other Fish</u>

Under MO4, white sturgeon fry would experience an increase in exposure to high TDG from April through July and a major increase in parts of April and May relative to the No Action Alternative. Modeling shows under MO4 TDG levels would be greater than 120 percent for 52.9

percent of that time period, with a high of 136 percent TDG. This is an increase from only 9.8 percent under the No Action Alternative and is also higher than any of the MOs. This would likely have adverse effects on white sturgeon fry.

Other resident fish would be affected by TDG as well. When compared with the other MOs, warm water fish species that rear near the surface would be subject to increased TDG Exposure in their rearing habitat from April through July and major increases in parts of April and Mary when compared with the No Action Alternative.

**Region D**

***Mainstem Columbia River from McNary Dam to the Estuary***

Summary of Key Effects

Bull trout would continue to use the Columbia River in limited numbers and seek thermal refugia available at the mouths of tributaries. White sturgeon could continue to successfully reproduce in years with adequate flow and temperature conditions (sturgeon recruitment failure could continue to occur independent of CRSO operations).

Habitat Effects Common to this Fish Community

Outflows from McNary Reservoir influence some of the fish relationships described in this section. Peak spring flows affect habitat maintenance for some species. Modeled median outflows for MO4 are shown below. The percent change compared to the No Action Alternative is shown in parentheses.

- April: 186000 (-3 percent)
- May: 255800 (-2 percent)
- June: 282700 (-1 percent)
- July: 198500 (no change)

Other flow parameters referred to in this section refer to outflows of McNary Dam, which are indicative of flows on downstream through the other projects.

Bull Trout

Bull trout are known to use the mainstem Columbia River to move between tributaries and have been observed at Bonneville Dam and McNary Dam in the spring and summer (Barrows et al. 2016). Water temperature is the most important habitat factor for bull trout in the mainstem Columbia. Under MO4, bull trout would continue to use the mainstem Columbia for migration between tributaries, as well as tributary mouths for passage and thermal refugia.

Adult bull trout move downstream during fall and overwinter in reservoirs (October to February; Barrows et al. 2016). Although bull trout successfully move between areas on the mainstem, their migration can be delayed at the dams. MO4 includes structural measures for additional spillway passage at McNary and John Day Dams. This measure would be in operation from March 1 through August 31, and could slightly improve bull trout downstream passage, but the majority of adult bull trout would have moved out of the mainstem by the time this surface passage route would be in use.

Passage through turbines can cause injury or mortality. MO4 includes turbine replacement with IFP turbines, which would improve survival (Deng et al. 2019). At John Day, turbine replacement would provide safer passage for any bull trout that move through the dam.

Bull trout would continue to be subject to bird predation under MO4 at similar levels to the No Action Alternative.

<u>Other Fish</u>

Under MO4, spawning and recruitment of white sturgeon would be similar to the No Action Alternative in average and wet years. In years of low flow conditions, water temperatures could increase beyond the suitable range by early June, resulting in little or no recruitment. White sturgeon spawning generally occurs in areas with fast-flowing waters over coarse substrates (Parsley et al. 1993). Minor changes in outflow under MO4 would not be large enough to cause discernable velocity changes that would affect sturgeon spawning habitat. Lack of effective upstream white sturgeon passage for all age classes decreases the connectivity of the population (Parsley et al. 2007). Under MO4, improvements to turbines at John Day Dam could reduce injuries and mortality of sturgeon.

White sturgeon larvae are adversely affected by TDG. Adults are more able to compensate for increased TDG by moving to lower depths, but larvae in shallow water would be more affected. Under MO4, TDG rates would be higher than No Action Alternative. All four dams in this reach would have a prolonged increase of TDG from 120 percent to about 125 percent TDG. This would result in detrimental effects to juveniles and larvae. Changes in a pool or tailrace elevation can affect juvenile white sturgeon through stranding in shallow water. Under MO4, John Day, The Dalles, and Bonneville Dam would all draw down to the minimum operating pool from late March to mid-August. This would be unlikely to result in stranding, since the drawdown would occur before spawning, but it could result in less shallow water habitat being available for juvenile and larval sturgeon.

Under MO4, no changes to other resident fish communities would be expected, though all fish would be subjected to higher TDG levels than the No Action Alternative. As shown above, outflow rates below McNary Dam would be very similar to the No Action Alternative. Water quality and food availability would also be similar to the No Action Alternative.

Conditions that promote lower water temperatures and higher spring flows tend to lower the survival rates of warmwater game fish, potentially lowering populations of predators on salmon and steelhead. MO4 would be expected to continue supporting warmwater game fish at levels similar to current conditions. Increased spill under MO4 could have slight adverse effects on northern pikeminnow.

**MACROINVERTEBRATES**

Below is a discussion of the macroinvertebrates in Regions A, B, C, and D under MO4. For more detailed information on the effects of MO4 on aquatic invertebrates and implications on food web interactions see the Habitat Effects section of these respective fish community analyses in the Resident Fish section under the applicable region.

**Region A**

At Hungry Horse reservoir, the wet and average years operations under MO4 would be similar in operations to MO1 (see the discussion of macroinvertebrates in Section 3.5.2.3). In dry years, the reservoir would be drafted much deeper with higher outflows in the summer months. The varial zone that provides benthic insect production would be appreciably reduced due to steeper drafts in the summer and lower elevations through the winter months, and aquatic insects in this zone would become dewatered faster than under the No Action Alternative. The reservoir would miss filling in 15 more years out of 100 compared to the No Action Alternative, and the elevation at the end of September would be 4 to 5 feet lower than the No Action Alternative in wet and average years, but up to 16 feet lower in dry years. Habitat for aquatic insects would be considerably reduced in these years, and benthic insects would be dewatered in a larger area.

With lower summer elevations, the area available for summer zooplankton production would decrease by up to 89,500 to 158,000 acre-feet, or by about 7 percent to 13 percent. Additionally, zooplankton would be flushed out of the reservoir and downstream at a rate that would be much higher than the No Action Alternative in July, August, and September of all years. Fewer zooplankton would be flushed out of the reservoir, compared to the No Action Alternative, in spring, fall, and winter. These outflow changes would increase zooplankton levels and wetted area for macroinvertebrate production in the South Fork Flathead River but could also flush more out of South Fork Flathead River with higher velocities. This pattern would continue (though at reduced levels) into the mainstem Flathead River.

MO4 operations would result in minimal changes to Flathead Lake, but the lower Flathead River would see 5 to 12 percent higher flows in August and 6 to 7 percent higher in September. These flows would potentially flush macroinvertebrates, including opossum shrimp, out of Flathead Lake, and increase habitat in the lower Flathead River for invertebrate production. The Clark Fork River macroinvertebrate communities would be similar to the No Action Alternative.

The operations of the Albeni Falls Project would be similar to the No Action Alternative in wet and average years, where operations would not result in appreciable changes to Lake Pend Oreille or the Pend Oreille River, nor the macroinvertebrate communities in those habitats. In dry years, however, Lake Pend Oreille would fill to elevation 2059.7 feet, which is about 2.5 feet lower than the No Action Alternative. This would result in a reduction of habitat available for aquatic macroinvertebrates through the summer. However, the No Action Alternative elevation drops about a foot through the month of September where the MO4 elevation would hold steady, so the aquatic macroinvertebrates produced would not experience the dewatering event as in the No Action Alternative. Increased outflows from mid-May through June would flush more zooplankton past the dam, but this would be reduced with lower outflows in September. These higher May-June flows would benefit macroinvertebrates in the Pend Oreille River as the river levels would hold about 10 percent higher for about a six-week period rather than dropping and dewatering habitat as in the No Action Alternative.

In the Kootenai Basin, Lake Koocanusa would not have any days over where the water elevation would be greater than 2,450 feet in average or dry years. In average years, MO4 operations result in a median minimum pool elevation from 4 to 5 feet lower than the No Action Alternative throughout the summer months. The rate of drop through the summer would be similar to the No Action Alternative in average years. In the winter months, the water elevation would drop at a less steep rate than the No Action Alternative. This operation would decrease the overall productivity of zooplankton and macroinvertebrates in the system overall through the warm, productive summer months. In average years, the benthic production would be at a lower level than the No Action Alternative but not subjected to any additional dewatering in summer, and fewer insects would be dewatered in the winter months compared to the No Action Alternative. In dry years, however, the pool level would be similar to the No Action Alternative in early July, but drop at a much steeper rate and end the water year a median of 13 feet lower than the No Action Alternative, exposing more varial zone as the summer goes on and dewatering a large portion of the insect production that would have established in the top thirteen feet of the inundated area.

**Region B**

The Columbia River from Canada to Lake Roosevelt would continue to produce benthic aquatic insects such as stonefly, caddisfly, and mayfly larvae. The river elevation in this reach is influenced by Lake Roosevelt operations and inflows so is somewhat variable, which would constrain benthic production to some degree in a reduced capacity.

MO4 operations would change river elevations at the U.S.-Canada border throughout much of the year and differ by year type. Wet and average years would be somewhat similar to MO1, with lower elevations in the winter (see the discussion of macroinvertebrates in Section 3.5.2.3). MO4 would result in water elevation drops compared to the No Action Alternative, with the stage dropping from the beginning of November through March in all year types, and there would be more fluctuations in stage. Steeper drops in water elevation and more variability would reduce suitable habitat for macroinvertebrate production and cause multiple desiccation events, likely limiting productivity in winter. Additionally, dry years would see river stage elevations a median of about 5 feet lower than the No Action Alternative from late June through October. This would limit habitat for the production of macroinvertebrates in the summer in dry years. Wet and average years would also be lower than the No Action Alternative, but only about 2 to 3 feet. This change in elevation represents the vertical feet; actual habitat dewatered would depend on the slope of the riverbanks at this elevation. As the river flows downstream closer to Lake Roosevelt, the pattern is the same but the additional drop from MO4 in dry years would result in about sixteen feet lower elevation at river mile 720.

This would indicate the magnitude of lost benthic habitat and desiccation would become increasingly severe as the river experiences more influence from Lake Roosevelt fluctuations.

Generally speaking, under MO4 median retention time would be considerably lower than the No Action Alternative during critical time periods for a number of fish relationships. In dry years, retention time would be much lower in May-August (29 percent, 28 percent, 21 percent, and 11 percent medians in May, June, July, and August, respectively). These reductions of up to 9 days retention time could greatly affect production and entrainment of zooplankton in the reservoir. It would be moderately higher in September and October and moderately lower in winter. In average years, retention time under MO4 would be 3 percent to 9 percent lower than the No Action Alternative in the critical spring/summer months, and moderately higher in fall and moderately lower in winter. In wet years, the summer months would be similar or slightly less than the No Action Alternative, higher in October, and moderately lower through the winter. In wet years is when retention time is lowest because more water is moving through the system, and MO4 would reduce retention times even further in these years by up to 9 percent in February and by 3 percent to 9 percent in the entire period of December through May.

The elevations in Lake Roosevelt would follow the same pattern as in the river sections described above, with MO4 elevations dropping further through the winter and being more variable. In dry years, the summer elevation would continue to drop from May to July and would be up to 22 feet lower than the No Action Alternative in this time period. This would result in desiccation of more aquatic macroinvertebrates and overall decreased habitat, likely severely reducing benthic productivity in dry years. Wet and average year types would also see loss of benthic production but less severe. More than one back-to-back dry year would intensify these effects.

Downstream of Grand Coulee Dam, Rufus Woods Lake has more riverine characteristics with steep gradients and narrow canyon walls, making it more like a river than a reservoir, with short retention time and low productivity. Regarding aquatic insect production and desiccation, river stage at RM 594 in Rufus Woods Lake would also experience effects differently by year type. Wet and average years would be similar pattern at slightly lower elevation through the spring and summer, and then in November through March experience steeper drops and swings that are more variable in stage than the No Action Alternative. This would reduce production capability. In dry years, this pattern would be similar except for the months of May through June, when additional flow would be released, raising stage and increasing velocities above the No Action Alternative dry year levels, and then July through August would be lower. This late summer period drop in stage could dewater more aquatic inverts produced in May and June.

**Region C**

Dworshak Reservoir elevations would be the same as the No Action Alternative. Benthic production in the reservoir would continue to be low due to the extensive variation in water surface elevation, near-shore wave action that causes erosion, and the lack of aquatic plants along the shoreline. Likewise, outflows would be the same as the No Action Alternative. Benthic communities in the Clearwater River below Dworshak Reservoir would continue to be limited by unsuitably high flows in summer and late winter.

The macroinvertebrate community of the lower Snake reservoirs and river would continue similar to the No Action Alternative. Siberian prawns and opossum shrimp may continue to increase in the reservoir environments. The reservoirs would continue to provide habitat for clams, mussels, etc., as in the No Action Alternative, and crayfish would find ample suitable habitat in the rock and riprap of reservoirs. Soft substrates of the reservoirs would continue to be dominated by low species diversity, mostly worms. Harder substrates would provide habitat for a relatively poor diversity of aquatic insect larvae.

**Region D**

MO4 would result in only minor changes to flows or temperatures that could affect macroinvertebrate communities in the lower Columbia River. Very little benthic macroinvertebrate information is available for the lower Columbia River. Lake habitats in the impounded reaches would continue to support a low diversity of worms, benthic insects, and mollusks. In MO4, John Day, The Dalles, and Bonneville Dams would all draw down to the minimum operating pool from late March to mid-August. The drawdown period in late March would likely result in stranding and desiccation of considerable numbers of aquatic macroinvertebrates, but there would still be ample habitat to continue production.

**SUMMARY OF EFFECTS**

**Anadromous Fish**

MO4 includes structural and operational measures that were intended to increase adult salmon and steelhead returns through improved juvenile migration and survival. These measures include incremental improvements in powerhouse surface passage routes and improved survival of fish that go through the turbines. Large increases in spill compared to the No Action Alternative, lower river reservoir drawdowns, and additional flow augmentation in dry years would be expected to decrease the travel time of in-river fish and decrease powerhouse encounter rates. With the increased spill volumes, TDG exposure would increase substantially compared to the No Action Alternative. Structural measures such as powerhouse surface collectors did not result in substantial increases in juvenile survival or improvements in adult returns.

The potential benefits of MO4 for salmon and steelhead varies greatly depending on which model is used. The CSS model predicts large increases in Spring Chinook salmon and steelhead to the Snake River. These increases are predicted based on increased spill levels that would increase the number of fish passing via the spillways and avoiding powerhouses, which the CSS models predict would reduce latent mortality associated with CRS passage. Snake River spring Chinook and steelhead SARs are modeled to improve by 70-75 percent relative to the No Action Alternative.

The LCM predicts minor increases in benefits to Upper Columbia spring Chinook and steelhead (two percent relative increases in SARs and downstream survival). However, for Snake River spring Chinook, the model predicts that unless changes in passage through the CRS can increase ocean survival by 10 percent (i.e. latent mortality effects are decreased by 10 percent), the net impact to Snake River Chinook salmon would be adverse (a relative decrease in SARs of 12 percent). This potential decrease in overall adult returns is primarily driven by reductions in transportation rates due to high spill, a relationship that could be similar for Snake River steelhead.

MO4 also includes structural modifications to infrastructure at the dams to benefit passage of adult salmon, steelhead, and Pacific lamprey. The objective to improve resident fish for would not be met in the upper basin due to the deep drafts to the upper basin storage projects. There is also the potential for negative effects to resident fish due to increased prolonged exposure to elevated TDG levels in the lower basin.

Overall, predicted effects from this MO are expected to range from moderate adverse to major beneficial. These effects vary widely by species.

**Resident Fish**

MO4 has effects ranging from minor to major adverse for resident fish. In Region A, decreases in reservoir productivity are expected in all years and would be further exacerbated in wet years. A delay in summer productivity in the Kootenai River below Libby Dam would also adversely affect fish. Conversely, MO4 would have a greater potential for cottonwood establishment and riparian regeneration, a moderate beneficial effect, but flows would provide the least usable habitat for bull trout, redband rainbow trout, and westslope cutthroat trout of all the MOs. At Hungry Horse Reservoir, moderate to major effects from decreased reservoir levels and increased summer outflows in dry years include loss of productivity, diminished tributary access, increased entrainment, and degraded habitat in the Flathead River. In most water years, these effects would be similar to MO1; in dry years, they would be more adverse due to releases to support downstream flow augmentation. In areas such as Lake Pend Oreille, lower reservoir elevations in dry years may limit access to tributary habitats and reduce the quantity of important shallow water habitats. Increased TDG associated with higher levels of spill may have effects on bull trout during months where they are leaving the system. Region B would also see moderate to major effects, particularly in dry years when Lake Roosevelt would be drawn down deeper and summer outflows would increase. Changes in retention time would reduce food availability and increase loss of fish through Grand Coulee dam. This increased entrainment would likely hasten the invasion of northern pike downstream with increased entrainment and reduced suppression capability. Tributary access for wild fish spawning and water quality for net-pen raised fish would both be affected, and more eggs would be affected by dewatering; potentially losing entire year classes of some species of native fish. In Regions C and D, resident fish would be affected by increased TDG.

**Macroinvertebrates**

Lower summer elevations in certain areas would reduce habitat for summer zooplankton production, while higher levels of flows during summer months would flush certain macroinvertebrates in areas such as Flathead Lake, while increasing habitat in areas such as the lower Flathead River for invertebrate production. Elevations at Lake Roosevelt would become more variable, reducing benthic productivity in dry years. In Regions C and D, elevations, flows, and temperatures would be similar to the No Action Alternative and would result in negligible effects. Overall, effects are expected to be minor to moderate.

### 3.5.4 Tribal Interests

Fish are of great cultural importance to tribes in the study area and have fundamental roles in diet, medicine, and cultural identity. For virtually all tribes in the region, fish are part of the history of subsistence and important to public health. The CRS dams are viewed by tribes as an impediment to the aquatic resources that are essential to the tribal way of life. For example, the lower Snake River dams are seen as an adverse impact for tribes that rely on the Snake River aquatic resources.

Each tribe has a personal, cultural, spiritual, and commercial connection with the rivers around them. For instance, the Kootenai Tribe of Idaho and *Yaqan Nukiy*, the main source of subsistence historically was fishing. The Kootenai River itself became part of the Tribe's identity and historically there were a number of camp locations along the River such as at Jennings, Montana.

This fish analysis evaluates how MOs impact survival of adult and juvenile salmon and resident fish in the study area in comparison to the No Action Alternative. In terms of how those MOs would impact Tribal Interests, the co-Lead Agencies assume that if more adult salmon, steelhead lamprey, and other anadromous fish are returning to the Columbia River and its tributaries and resident fish conditions improve, then there would be more fish available for harvest. However, because of the differences in life histories, habitat requirements, and effects across the four regions due to operations, the analysis and results are very complicated and effects to tribes would be based on location and the fish species important to that tribe.

In general, however, the analysis describes the following effects.

#### *3.5.4.1 Salmon and Steelhead*

In comparison to the No Action Alternative, Upper Columbia River salmon and steelhead would generally see similar or minor increases in juvenile and adult returns for MO1, MO3, and MO4 unless ocean survival improves dues to reductions in latent mortality. Tribal members that harvest these populations for subsistence, recreation, or commercial fisheries may see an increase in numbers of fish return, except under MO2. MO2 would result in decreased abundance for these fish.

Snake River salmon and steelhead would see minor improvements under MO1. MO2 would result in decreases in juvenile survival and adult abundance. MO3 would have short-term construction related effects but could lead to long-term increases in adult returns. Fall Chinook spawning habitat would increase. MO4 would increase juvenile survival, but adult survival could decrease. In addition to the differences in impact on tribal members that harvest these fish under each MO, there are also differences in the impacts within the MOs based upon which model has been used.

#### *3.5.4.2 Other Anadromous Fish (coho, chum, eulachon, green sturgeon, lamprey)*

MO1 would have minor decreases for coho and chum with mixed impacts for lamprey. Eulachon and green sturgeon numbers would be similar to the No Action Alternative. There would be decreased juvenile survival for MO2 for these species. Under MO3, there would be minor increases in abundance in the lower and middle Columbia reaches for eulachon and green sturgeon, while coho and chum would be similar to the No Action Alternative. MO4 would have minor benefits for lower and middle Columbia juveniles, but there would be corresponding minor adverse effects for chum and lamprey.

#### *3.5.4.3 Resident Fish*

Region A: MO1 and MO3 would have minor to moderate short-term adverse effects to bull trout, food webs, varial zones (important for migration), and habitat. MO3 would have riparian and sturgeon recruitment effects in the Kootenai River as well. MO2 and MO4 would have moderate to major effects in the same areas. MO4 would also have habitat and access issues in Lake Pend Oreille.

Region B: Effects from MO1, MO2, and MO4 would range from minor to major adverse effects to resident fish in Lake Roosevelt stemming from increased entrainment, varial zone effects (important for migration) and in the river reach, there would be minor reduction in sturgeon recruitment. MO3 would have minor adverse effects due to potentially increased entrainment, but would also have a major beneficial effect due to increased recruitment and connectivity for sturgeon in McNary Reservoir with minor short-term construction-related effects.

Region C: MO1, MO2, and MO4 would have minor to moderate adverse impacts to resident fish due to warmer summer water temperatures, reduced flows, increased entrainment, or increased TDG and GBT. MO3 would result in improved connectivity and increased recruitment for bull trout and white sturgeon and more native fish.

Region D: MO1 would have negligible effects to flows and water temperature; minor adverse potential sturgeon effects. MO2 and MO3 would have negligible effects to flow and water temperature. Under MO4, Negligible effects could be expected to flow and water temperature with minor adverse effects due to increased TDG.

All of these fish have economic, subsistence and culturally significant importance for tribes, and as shown, effects vary across the study area depending on species. Tribal Interests would be affected accordingly.

## 3.6 VEGETATION, WETLANDS, WILDLIFE, AND FLOODPLAINS

This section provides analysis for vegetation communities, wetlands, and wildlife, including special status species, and floodplains. It describes the existing vegetation and wildlife that may be affected by measures contained in the No Action Alternative and Multiple Objective Alternatives (MOs), including changes in operations (hydrology) and structures, or dam breach. Wildlife species are grouped into the following broad categories: birds, mammals, reptiles and amphibians, and invertebrates. Land cover with vegetation was grouped into the following broad categories: upland; wetlands-forested; and scrub-shrub, wetlands-emergent herbaceous. Land cover without vegetation was classified as barren zone. Changes in some key islands were also analyzed (i.e., Blalock Island, Crescent Island). Wildlife and plant species listed under the Endangered Species Act and their critical habitat are described separately below in Section 3.6.2.6. Floodplains are discussed in Section 3.6.2.5, Floodplains.

### 3.6.1 Area of Analysis

The CRS study area, or area of analysis, for vegetation, wetlands, wildlife, and floodplains consists of vegetation communities and habitats of the Columbia River Basin currently influenced by the operations of the 14 Federal projects (the CRS). Affected vegetation communities both downstream from the dams and the associated reservoirs upstream are included. The study area extends from the Flathead River, Clearwater River, and the U.S. portions of the Kootenai River, Pend Oreille River, Clark Fork River, the lower Snake River (inclusive of Ice Harbor, Lower Monumental, Little Goose, and Lower Granite projects), and the mainstem Columbia River to the Pacific Ocean and includes the river channels and affected vegetation and wildlife. A map of the Columbia River Basin is included in Chapter 1 (Figure 1-1). Many factors including river flows, timing, duration, and water level affect the species composition and distribution of riparian and upland vegetation and wetlands habitats within the basin, which in turn influence the wildlife species selected for analysis.

The study area extent is generally based on the extent of the H&H model's study area (Section 3.2 and Appendix B, Part 3, specifically the extents of the hydraulic models used to develop water surface elevation data across the reaches between dams). These models were developed to capture inundated areas resulting from a wide range of potential flooding events.  See Appendix A for more information on the H&H modeling tools. For the Libby, Hungry Horse, Lake Pend Oreille, and Dworshak reservoirs, the study areas were based on reservoir operations and changes to full pool water surface elevations. These extents were chosen because they capture changes in water surface elevations that could influence wildlife populations or their habitats as a result of implementing the operational parameters detailed in each MO. Choosing this extent also provides consistency with other resources analyzed in this EIS and aligns with modeled information for the alternatives.

Individual study areas extend upstream from each project to the furthest extent of the reservoir at its maximum operating water level, or to the U.S.-Canada border. Where project operations have a meaningful effect on habitat conditions downstream from the project, the study area extends downstream to the upstream extend of the next downstream project. For example, for Hungry Horse, the study area includes the Hungry Horse reservoir as well as approximately 120 miles downstream of Hungry Horse Dam. The project area for John Day, a run-of-river dam, extends from John Day Dam upstream to the face of McNary Dam. The Dalles Dam. Figure 3-135 through Figure 3-147 show the projects and their associated study areas. Appendix F, Vegetation and Wildlife, provides more in-depth reach- and study area-specific information for vegetation, wetlands, and wildlife, including maps and a discussion of existing conditions.

For Figure 3-135 through Figure 3-147, much of the area designated as upland in these figures occupies the natural (pre-development) floodplain but is currently protected from flooding by levees and reservoir operations (Section 3.9.3). Portions of the areas that are designated uplands in these figures actually may lie in the active floodplain and wetlands, although these areas are likely to be infrequently flooded.

## 3.6.2 Affected Environment

A diversity of plant communities and wildlife habitats are represented in the basin, including riparian and wetland habitats, sagebrush (*Artemisia* spp.)-dominated shrub-steppe communities, mixed coniferous and deciduous forests, moist coniferous forests, grasslands, and agricultural lands. These vegetation communities are specific to the local topography and climate ranging from the wet Pacific Ocean estuary located a few feet above sea level to the high elevation Rocky Mountains, to rich agricultural valleys, to the arid shrub steppe.

### *3.6.2.1 Vegetation Communities and Habitat Types*

Land cover types and vegetation communities, or habitat types, are used in this study as proxies for wildlife habitat. The diverse habitat types (e.g., wetland, upland forest) found throughout the basin are used by various wildlife species for breeding, nesting, feeding, or sheltering. Habitat types are differentiated from one another by their structure, form, and species composition, are shaped by climate patterns, substrate types, and disturbance regimes, and can be broadly defined by dominant plant species. The habitat types described herein are different from species-specific habitats, which are unique to individual species and may include multiple habitat types (e.g., wetlands, forests, marine systems) necessary to complete their lifecycle.

Two primary geographic datasets were used to identify land cover, vegetation, and wildlife habitat within the CRSO study area: the Northwest Habitat Institute (NWHI) habitat land cover classifications and the U.S. Fish and Wildlife Service (USFWS) National Wetlands Inventory (NWI). These datasets were combined in a geographic information system (GIS) where the digital NWI data provided the source for all wetland habitats in the CRS study area and the NWHI dataset was the source for identifying all other habitat types across the CRS study area. More information on the NWHI and NWI are included in Appendix F, *Vegetation and Wildlife*.

Five habitat types were defined for this study: uplands, water, wetlands, barren zone, and islands. These habitat types, the focus of this analysis, are those that include habitat elements that are sensitive to changes in water surface elevation (WSE) and river flows. The NWI and NWHI datasets do not differentiate or show the barren area around reservoirs, nor do they delineate islands as such. Rather, the datasets display water up to the full pool elevation and vegetation coverage on islands. The proposed alternatives may affect WSE and river flows, potentially resulting in changes in the availability, accessibility, and distribution of these habitats, affecting a wide variety of wildlife species. NWHI habitats and NWI wetlands were combined based on types of ecosystems represented and functional groups. Developed and urban lands were not analyzed in terms of habitat effects as they were considered not to be sensitive to changes in water surface elevation or river flows under the proposed operations. Agricultural lands, on the other hand, can provide significant forage and cover (fawning, calving, nesting, and potential hiding and escape cover) for wildlife. However, they were not delineated as a separate habitat type nor were they analyzed as a stand-alone vegetation community.

**UPLANDS**

Upland areas consist of a wide variety of vegetation and wildlife habitat types. The term "upland" typically refers to lands above an alluvial floodplain or river channel. For this analysis, all lands that are not classified as barren, wetlands (including riparian areas), open water, coastal, or islands are considered uplands. Uplands in the CRSO study area include coniferous and hardwood forests, woodlands, grass and scrublands, shrub-steppe, and pasture or agricultural lands.

At Hungry Horse, Libby, Albeni Falls, Lake Roosevelt (upstream of Grand Coulee Dam), and Dworshak Dams, the upland areas are dominated by coniferous forests including ponderosa pine on the warm, dry exposed slopes and a mix including ponderosa pine, western larch, Douglas-fir, lodgepole pine, western hemlock, and western red cedar on wetter slopes, at lower elevations, and near the water's edge. Deciduous tree species such as black cottonwood, willow, and red alder are also found in areas near water. Understory shrubs include western serviceberry, bitterbrush, ocean spray, mallow-leaf ninebark, and snowberry.

From Grand Coulee Dam down through The Dalles Dam and lower Snake River Projects, upland areas are dominated by shrub-steppe vegetation. The shrub component is dominated by big sagebrush, rabbitbrush, serviceberry, currant, and antelope bitterbrush while Idaho fescue, Indian ricegrass, Sandberg bluegrass, Thurber's needlegrass, needle-and-thread, sand dropseed, bluebunch wheatgrass, and bottlebrush squirrel tail make up the primary native grass species. Common forbs include arrowleaf balsamroot, yarrow, various buckwheats, blanket flower, various parsleys, and lupine species.

Upland habitats in the Lake Bonneville study area are diverse and range between warm, dry shrub-steppe to wet, cool forests near the Cascade Range. Mountain hemlock forests transition to drier ponderosa pine and mixed Douglas fir and grand fir forests and then shift to Oregon white oak woodlands and grasslands at the lowest elevations. Deciduous trees include red alder, big-leaf maple, and smaller canopy trees such as cascara buckthorn. Understory shrubs and forbs in upland habitats may include salal, Oregon grape species, and swordfern.

**WATER**

The water cover type includes rivers and streams, lakes, reservoirs, bays, and estuaries. In the CRS study area, the water cover type (also referred to as open water) is composed primarily of the Columbia River and its major tributaries, and storage project reservoirs. Water is a cover type that is used by terrestrial and aquatic wildlife. Many types of wildlife species use open water as primary foraging habitats, migration corridors, or temporary refuge from predators.

Aquatic vegetation that is submerged for its entire lifecycle provides important food resources and shelter for several classes of vertebrates. The aquatic vegetation species commonly found in the CRSO study area are pondweed, parrotweed, duckweed, the invasive *Elodea*, knotweed, and milfoil. Aquatic stalked diatom known as Didymo has become established at a nuisance/noxious density in the Kootenai River downstream of Libby Dam and in localized areas in the Flathead River below Hungry Horse Dam.

**WETLANDS**

Wetland habitats are important ecological features providing a multitude of benefits to the human environment and a unique variety of fish, wildlife, and plant species that are adapted to survive at least part of their life cycle in aquatic environments. Wetlands can be classified based on a dominant vegetation (e.g., evergreen or deciduous) or exposed substrate type (e.g., cobble, gravel, bedrock). While local hydrologic conditions typically vary over time, plant species and soil characteristics tend to reflect the long-term hydrologic conditions of a site and can help identify wetland types when local hydrology is absent. These habitats are usually a transitional area between upland habitats and aquatic habitats. Because wetlands, including riparian habitats, are dependent on the duration of seasonal inundation, these habitats are sensitive to changes in project operations influenced by river flows and precipitation patterns. For this EIS, two types of wetlands are described below: forested and scrub-shrub, and emergent herbaceous. Newly exposed transitional areas that could develop into vegetated wetlands over time are referred to in this EIS as mudflats and could be composed of silty, clayey, or rock material. The length of time that the sediment is exposed would determine if vegetation would establish in these unvegetated sediments.

Riparian zones are transitional areas between flowing and non-flowing bodies of water and the upland terrestrial habitat. Riparian zones are frequently inundated and can contain wetlands. There is no generally agreed upon classification system for riparian vegetation, although a number of systems have been proposed and are in use by individual Federal, state, and local agencies. For the purposes of this EIS, riparian habitat is incorporated into the Wetlands – Forested and Scrub-Shrub section below.

**Wetlands – Forested and Scrub-Shrub**

Forested and scrub-shrub wetlands (riparian habitat) provide important feeding, sheltering, and breeding or nesting habitat for wildlife. The vegetation stabilizes river and stream channel banks and reduces erosion. Along rivers and streams, this vegetation provides a shade canopy over stream channels to reduce temperatures. In addition, this vegetation slows surface water and filters out sediments to improve water quality. Woody wetlands support a high diversity of wildlife.

Throughout the CRS study area forested and scrub-shrub wetlands adjacent to rivers are dominated by deciduous shrub and deciduous tree cover types with a dense understory of grasses, forbs, and shrubs. Cottonwood, aspen, alders, chokecherry, and willows, with some conifers, are common in the forested and scrub-shrub wetlands. Native shrub and undergrowth species typically include red-osier dogwood, mountain alder, gooseberry, various roses, common snowberry, various willows, and Douglas spirea. Himalayan blackberry, a non-native species, is a common shrub. Herbaceous species may include native forbs, grasses, and sedges, as well as invasive and non-native species such as reed canary grass, Western false indigo, flowering rush, yellow flag iris, purple loosestrife, and salt cedar.

**Wetlands – Emergent Herbaceous**

Emergent wetlands are limited in extent throughout the CRSO study area. They are restricted by the steep shorelines, seasonal drawdowns, and shorter-term fluctuations that also influence other habitat types. The emergent wetlands occur along the shoreline primarily in embayments, the mouths of small streams, and in the confluences of larger tributary streams and rivers.

Common plants present in emergent wetlands include cattails, horsetail, bulrush, and sedges. Invasive species such as common reed, reed canary grass, pondweed, parrotweed, duckweed, invasive *Elodea*, knotweed, milfoil, flowering rush, yellow flag iris, purple loosestrife, salt cedar, Japanese knotweed, and western false indigo become a dominant species in some areas.

**BARREN (BARREN ZONE)**

Within the barren cover type, this study focuses on the barren zone within a project reservoir. This is shoreline habitat surrounding reservoirs, which is characterized by having no permanent vegetation. When reservoirs are full of water, the barren zone is not present, or present only as a minor fringe around the perimeter of the lake. Plants do not generally grow in the barren area, and the areas do not provide good habitat for wildlife. They are discussed herein because barren areas do present challenges and opportunities for wildlife and can influence migration and predation. As projects are operated and reservoirs are drawn down, the land previously underwater surrounding the lake is exposed. Generally, the storage projects such as Hungry Horse, Libby, Albeni Falls, Grand Coulee, and Dworshak have a wider barren zone during drawdown than run-of-river projects.

**ISLANDS**

In the CRS study area, islands occur both in reservoirs and rivers. Individual islands or groups of islands may contain one of the cover types identified above, or may contain a mosaic of these cover types. Depending on their size, elevation, and available habitat types, islands can support a wide variety of plant and wildlife species.

In the CRS study area, there are hundreds of islands found both in reservoirs and downstream of the projects, which provide crucial habitat for wildlife species. For example, the Blalock Islands are low-elevation bedrock islands, which are part of the Umatilla National Wildlife Refuge in Lake Umatilla. The Blalock Islands are notable because they provide breeding habitat for colonial nesting waterbirds like Caspian terns, American white pelicans, and several gull species. Other islands, like Puget, Whites, and Tenasillahe Islands downriver from Bonneville Dam, cover large areas and provide a diverse array of mixed habitat types supporting numerous wildlife species and populations. Tenasillahe Island is notable because it provides complex forested wetlands and oak savannahs, which support the Endangered Species Act (ESA)-listed threatened Columbian white-tailed deer. Other islands support large breeding colonies of waterbirds, including Miller Sands Island and East Sand Island near the mouth of the Columbia River. Several thousand Caspian terns and double-crested cormorants nest at East Sand Island, along with smaller populations of Brandt's cormorant and ring-billed gulls. Several hundred American white pelicans nest at Miller Sands Island and Rice Island in the lower river.

#### ***3.6.2.2 Introduced and Invasive Species***

Non-native and invasive plants are currently damaging biological diversity and ecosystem integrity across the Columbia Basin and within the study area. Invasive plants cause displacement of native plants; reduction of habitat and forage for wildlife; changes to plant composition in sensitive areas such as wetlands; loss of sensitive species; impaired water quality; reduced soil productivity and increased erosion; and changes in the intensity and frequency of fires. Invasive plants spread through the air and water, on vehicles, animals, and humans. All lands are at risk of invasive plants. A few of the most common invasive plants in the study area are cheatgrass (*Bromus tectorum*), flowering rush (*Butomus umbellatus*), reed canary grass (*Phalaris arundinacea*), and Eurasian watermilfoil (*Myriophyllum spicatum*).

Throughout the study area, the co-lead agencies are involved with cooperative weed management efforts, invasive species prevention and eradication, and vegetation treatments. For example, on wildlife mitigation properties funded through Bonneville's F&W Program, project partners are replanting grasslands and other habitats with native species in order to outcompete non-native weeds as well as experimenting with prescriptive livestock grazing and other tools.

Populations of invasive plant species are expected to continue to occur and potentially increase throughout the study area, consistent with current trends. The alternatives proposed herein would not change or impact the co-lead agencies' ability to continue with these efforts or affect their ability to conduct invasive species management efforts at projects or participate in cooperative weed management efforts. Effects from invasive species to vegetation, wetlands, and wildlife are discussed only when alternatives are anticipated to cause a measurable change in the quantity or distribution of invasive species and their subsequent impact on the ecological function of wildlife habitat. The alternatives may impact vegetation communities and increase or expose bare ground. Where this may occur, and where weeds are a concern, impacts are discussed.

Aquatic species are of particular concern, since they spread rapidly and can quickly alter the function of an ecosystem. Quagga mussels (*Dreissena bugensis*) and zebra mussels (*Dreissena polymorpha*) are invasive, fingernail-sized mollusks that are native to fresh waters in Eurasia. They spread by drifting in water currents and attaching to watercraft. They negatively impact ecosystems in many ways causing harm to the environment, the economy, or to human health. They filter out algae that native species need for food and they attach to and incapacitate native mussels. The threat of zebra mussels at hydropower facilities relates to the species ability to quickly colonize underwater infrastructure such as screens, trash racks, and water delivery systems, which has the potential to render fish passage and protection facilities inoperable. The Columbia River Basin is the last river system free of these mussels in the United States (NWER 2015).

Strict boating inspection and widespread educational materials and training are essential to keeping these species out of the system. Idaho, Montana, Oregon, and Washington all have established rapid response plans for these mussels (Western Regional Panel on Aquatic Nuisance Species 2010; Idaho Department of Agriculture 2012; WDFW et al. 2014; Center of Lakes and Reservoirs-Portland State University et al. 2013). The states are also currently in the process of developing a cost-share agreement with the Corps, under Section 104 of the River and Harbor Act of 1958 (as amended), for development of a rapid response plan.

Additional invasive fish species are listed in Section 3.5, *Aquatic Habitat, Aquatic Invertebrates, and Fish*. If these species are present in the CRS study area, they may require control measures. Species that have not yet become established but have the potential to be introduced are the Asian carp, emerald ash borer, European chafer, longhorned beetle, northern snakehead fish, and overbite clam.

#### *3.6.2.3 National Wildlife Refuges and Other Federally Managed Wildlife Lands*

Throughout the CRS study area, there are numerous national wildlife refuges and other federally managed lands for the benefit of wildlife. Of these, the Kootenai, McNary, and Umatilla National Wildlife Refuges (NWRs) and the Corps-managed Habitat Management Units (HMUs) along the lower Snake River may be impacted by one or more of the alternatives presented in this draft EIS, therefore the discussion is limited to these areas.

The Kootenai NWR near the Selkirk Mountains of northern Idaho was established as a migratory waterfowl refuge. The refuge provides habitat for over 220 bird species including bald eagle, mallard, northern pintail, and green-winged teal. Forty-five species of mammals use the refuge habitat, including moose, elk, deer, bear, and otter (USFWS 2017). This refuge contains 2,774 acres of wetlands, meadows, riparian forests, and cultivated agricultural fields, which provides habitat for over 220 bird species and 45 mammal species (USFWS 2017). The seasonal wetlands are drained in spring and summer to promote emergent vegetation for waterfowl.

There are five special wildlife management areas in the Hungry Horse Project study area: the Owen Sowerwine Natural Area, Flathead River Wildlife Habitat Protection Areas, Foys Bend Fisheries Conservation Area, and North Shore Waterfowl Production Area. These areas are mainly restored wetlands and planted riparian areas and are important bird areas that are managed to maintain or improve habitat conditions for fish and wildlife.

McNary NWR covers over 15,000 acres along the left bank of Lake Wallula from the confluence of the Columbia River with the Snake River to the mouth of the Walla Walla River, and downstream into Oregon. The refuge includes sloughs, ponds, streams, islands, forested and herbaceous wetlands, and upland shrub-steppe and cliff-talus habitats. It serves as an anchor for biodiversity in the middle Columbia Basin (Corps 2018).

The Umatilla NWR provides wildlife habitat along both shorelines of Lake Umatilla, where the refuge is composed of a multitude of different habitat types supporting a wide diversity of wildlife. The refuge includes many islands, which provide breeding/nesting/roosting habitat for colonial (mostly fish-eating) nesting birds as well as habitat supporting a variety of waterfowl species.

Within the lower Snake River Projects study area, HMUs were developed as mitigation for effects to wildlife resources during dam construction and operations. A total of 62 HMUs are scattered along the Snake River from Ice Harbor Dam to the upper extent of the Lower Granite Reservoir. There are approximately 107,382 acres of HMUs within the lower Snake River Projects study area. These HMUs include uplands, wetlands—forested and scrub-shrub, wetlands—emergent herbaceous, and islands land cover types.

There are several refuges downstream of Bonneville Dam that span and support multiple habitat types, vegetation communities, and salinity gradients. Pierce, Franz Lake, Steigerwald Lake, and Ridgefield Lake NWR are managed as the Ridgefield Wildlife Complex. This collection of refuges supports a broad mosaic of wetlands, riparian forests, sloughs, wet meadows, and meadows, all of which support a high diversity of plants and wildlife. The Julia Butler Hansen Refuge for Columbian white-tailed deer and the Lewis and Clark NWR are managed as part of the Willapa Complex and also contain a diverse array of habitats and habitat features to support fish and wildlife in the region. The Lewis and Clark NWR encompasses 20 islands and stretches over 27 miles of the Columbia River. Additional information about refuges and refuge complexes are available in Appendix F, Vegetation and Wildlife.

Where impacts are anticipated to these wildlife areas, they are discussed below under the appropriate alternative and region. If an alternative is not anticipated to result in impacts to wildlife refuges or management areas, or there are no refuges or wildlife management areas in a given region that would be affected by an alternative, no narrative is provided in the analysis under Section 3.6.3.

#### *3.6.2.4 Wildlife*

The CRS study area provides important habitat for a diversity of wildlife species. Hundreds of wildlife species use the Columbia River mainstem and tributaries for breeding, nesting, feeding, and sheltering, including amphibians, reptiles, birds, and mammals. Wildlife species common to habitat found throughout the CRS study area are briefly discussed in this section. Species were grouped into the following broad categories: birds, mammals, reptiles and amphibians, and invertebrates. The information in this section was gathered from published and unpublished reports and discussions with local professional wildlife biologists. Additional information regarding wildlife associated with the different reaches can be found in Appendix F, *Vegetation and Wildlife*.

Note that special status species are discussed in a subsection below.

**BIRDS**

The Columbia River and its tributaries provide habitat for many migrating and resident birds. The CRS study area includes several important stopover areas for migrating birds as well as many important bird areas ranging from the north shore of Flathead Lake in Montana to along the Pacific Ocean. The CRS study area is within the Pacific Flyway and a portion of the Central Flyway and thus provides crucial resting and foraging habitat for millions of migrating birds, as well as a variety of primary habitat and niche habitat for resident and breeding birds. Species associated with wetlands, riparian areas, open water, arid lands, and forests are abundant throughout the CRS study area.

In the upper basin reaches of the CRS study area such as Libby, Hungry Horse, Albeni Falls, and Dworshak, forested areas provide habitat for raptors and species such as mountain chickadee, woodpecker, bluebird, crossbill, and pine siskin. The habitats surrounding the Grand Coulee Dam, the lower Snake River Projects, and down to The Dalles provide arid, canyon, sagebrush steppe, and dry forest habitats for sage-grouse, northern harrier, cliff swallow, and horned lark. The lower reaches of the Columbia support American white pelican, tern, great blue heron, plover, and sandpiper. Bald and golden eagles nest throughout the CRS study area. Reservoirs provide feeding areas for these large birds and other raptors. They most commonly nest in large cottonwoods, snags, pine trees, or other evergreen trees or on cliffsides.

Common raptor species include goshawk, Swainson's hawk, Northern harrier, ferruginous hawk, Cooper's hawk, red-tailed hawk, merlin, osprey, American kestrel, prairie falcon, and Peregrine falcon. Barred owl, Western screech owl, flammulated owl, short-eared owl, Northern saw-whet owl, great horned owl, and burrowing owl are found in the CRS study area as well. Owls nest in or on riparian trees and upland forests, snags, hillsides, and open woodlands and hunt small birds and mammals in forested areas, open grasslands, and agricultural lands. Riparian cottonwood areas and nearby evergreen forests are also important nesting habitats for other raptors, including bald eagle, osprey, falcons, and hawks, where birds hunt and forage in wetlands, shallow-water habitats, and the deeper waters of the Columbia River for fish and other prey.

Shorebirds and waterfowl are abundant throughout the CRS study area during all seasons, but particularly during migration periods when hundreds of species can be found at important bird areas, such as the north shore of Flathead Lake and the Columbia, McNary, and Umatilla NWRs. Many large waterbirds, including tern, cormorant, and gull, prey on juvenile fish, including salmonids out-migrating to the ocean. These birds are frequently found nesting and foraging near projects in the middle and lower Columbia River, as well as in the Columbia River Estuary. Shorebirds and other waterbird species also frequent dams and mudflats surrounding reservoirs for foraging and some nesting. Shorebirds and waterbirds commonly found on mudflats include various grebes and gulls, sandpiper, plover, American coot, killdeer, common snipe, greater and lesser yellowlegs, long-billed curlew, American avocet, great blue heron, American white pelican, long-billed dowitcher, greater egret, and American bittern. Over 30 waterfowl species use open water, marshes, deltas, and riparian areas associated with the rivers and reservoirs. Waterfowl nest in marshes and adjacent riparian or upland habitats. Emergent vegetation, submerged vegetation, and shoreline habitats are also important for rearing activities and for food resources. The most numerous and diverse species of waterfowls are migrants, many of which are also year-round residents. Common species include mallard, wood duck, bufflehead, harlequin duck, pintail, American widgeon, teal, gadwall, goldeneye, grebe, scaup, American coot, common merganser, tundra and trumpeter swans, cackling goose, Barrow's goldeneye, and Canada goose. Many of the reaches support large flocks of waterfowl, and serve as major stopovers in the spring and fall for tens of thousands of birds. Some of the highest concentrations of waterfowl in the Pacific Northwest are found in the CRS study area at numerous locations. Wetland habitats, which can be rare in arid areas, provide high-quality forage and cover for overwintering waterfowl. Island habitats provide protected nesting habitats as well.

The CRS study area provides diverse habitat for passerines (also known as perching or songbirds). The upper basin reaches have mixed confer habitats which support species such as the mountain chickadee, swallow, wren, bluebird, finch, flycatcher, red-breasted nuthatch, American robin, hermit thrush, warbling vireo, red-eyed vireo, fox sparrow, pine siskin, and dark-eyed junco. Riparian areas, marshes, and islands provide habitat for warbling vireo, yellow warbler, common yellowthroat, thrush, swallow, bobolink, red-winged blackbird, marsh wren, song sparrow, white-crowned sparrow, and numerous others. Horned lark, western meadowlark, loggerhead shrike, sage thrasher, and sage sparrow are representative passerine species found in sage-steppe upland habitat. Colonies of cliff swallow and bank swallow are found throughout the CRS study area along the Columbia River and tributaries. While not classified as passerines, numerous woodpecker species have been observed in the CRS study area, including Lewis's woodpecker, hairy woodpecker, downy woodpecker, Northern flicker, pileated woodpecker, red-naped sapsucker.

Gallinaceous and Columbine birds, or ground-feeding birds, in the CRS study area include several species of grouse, wild turkey, ring-necked pheasant, Eurasian collared dove, mourning dove, Hungarian partridge, California quail, and band-tailed pigeon. In higher elevations, the ruffed grouse and blue grouse are common in riparian areas, while spruce grouse are common in coniferous forests along valley walls. Agricultural lands near rivers support ring-necked pheasant and mourning dove. Chukar, Hungarian partridge, collared dove, mourning dove, ring-necked pheasant, and California quail eat a variety of seeds, agricultural plants (e.g., wheat, oats, and corn) and insects. Pheasant and quail are found most commonly near agricultural lands and generally do not venture far into shrub-steppe areas. Chukar use a wide variety of habitats including riparian, shrublands, talus areas (accumulated rocks at the base of slopes), and uplands. The breeding and wintering range for Eurasian collared dove has increased westward in recent years as the species rapidly moves into new habitats following introduction into Florida in the 1980s.

**MAMMALS**

Common mammals found within some or all the CRS study area include coyote, fox, mule and white-tailed deer, elk, black bear, mountain goat, raccoon, beaver, rabbit, weasel, skunk, porcupine, chipmunk, squirrel, vole, shrew, bushy-tailed woodrat, kangaroo rat, deer mouse, and the house mouse. The smaller mammals can be found throughout various types of vegetation communities in the CRS study area. In higher elevations, such as near Albeni Falls, Libby, and Hungry Horse projects, less common species are snowshoe hare, marten, Canada lynx, grizzly bear, wolverine, bighorn sheep, fisher, and moose. Mule deer, white-tailed deer, and elk are the most common species managed for hunting in the CRS study area. Herds of big game species are common in all reaches and rely on the diversity of habitats to provide food and cover for their survival and successful reproduction.

Bats are found throughout the CRS study area and likely forage on insects over and near the reservoirs and rivers. Documented species of bats are Townsend's big-eared bat, pallid, fringed myotis, long-eared myotis, long-legged myotis, small-footed myotis, canyon bat, California bat, hoary bat, silver-haired bat, big-brown bat, and Yuma myotis. These bats forage on stream insects such as midges, caddisflies, and mayflies and can roost up to 2 miles from the river and reservoir in various habitat types such as forests, arid grassland, shrubs, trees, and rocky areas. Most of the bat species use a wide range of locations, including caves, mines, trees, buildings, bridges, dams, and rock crevices as roost sites. White-nose syndrome, a disease caused by a fungus that affects hibernating bats, is not currently known in the study area, but it has been detected in Washington State. White-nose syndrome is considered one of the worst wildlife diseases in modern times and has decimated populations in the eastern United States and Canada.

Aquatic mammals in the CRS study area include beaver, muskrat, river otter, and mink, whose population densities are highly variable across the CRS study area. Beaver prefer riparian habitats and marshes with willow, poplar, or other soft wood trees, near permanent water sources. Muskrat, otter, and mink use the rivers, sloughs, lakes, reservoirs and streamside habitats. The barren areas associated with storage reservoirs and rivers limit the habitat availability for these and many other species.

**AMPHIBIANS AND REPTILES**

The variety of aquatic, riparian, and upland habitats supports several species of amphibians and reptiles but in numbers notably less than in warmer regions of the United States. Most amphibian and reptile species depend on shallow-water areas, streambanks, and reservoir edges, and favor submerged or seasonal emergent vegetation. Amphibian and reptile species use these areas during portions of the year because they provide an abundance of food, cover, and water. Amphibians are present in many of the wet habitats, especially wetland and riparian habitats, and include Pacific giant salamander, tiger salamander, long-toed salamander, tree frog, Columbia spotted frog, leopard frog, Pacific chorus frog, tailed frog, Western toad, and the non-native invasive American bullfrog. Bullfrogs are predators for other amphibians and reptiles and can decimate or extirpate local native populations. Many amphibians are closely tied to wet habitats like rivers and sloughs while reptiles can be found from upland coniferous forests to the mats of emergent plant bed in river sloughs. Columbia spotted frog, a Federal ESA candidate species, and Coeur D'Alene salamander, listed as a species of special concern in Idaho and Montana, may be present within the study area. Western toad and Northern leopard frog breed in off-channel pools and forested woodlands along slow-moving rivers in Montana, Idaho, and along the shore of Lake Roosevelt from early May until late June. Tadpoles are general present form late May to early September.

Reptiles include painted turtle, garter snakes (common and western terrestrial), prairie and western rattlesnakes, bull snake, racer, gopher snake, western skink, rubber boa, short-horned lizard, sagebrush lizard, Western fence lizard, and Northern alligator lizard. Reptiles occur in a wide variety of habitats including grasslands and coniferous forests.

#### *3.6.2.5 Floodplains*

Floodplains are the low-lying, relatively flat areas adjoining water bodies that become partially or completely inundated during periods of high flow and rapid surface runoff. Floodplains are generally distinguished from adjacent uplands by a noticeable change in the ground slope. Floodplains include low-elevation areas that are regularly flooded (e.g., every two or three years, on average) and extend to areas at higher elevations that may be rarely flooded. Lower magnitude floods that occur more frequently can be important in the functioning of natural floodplains. Relatively undisturbed floodplains, or those that are restored to a more natural state, can provide a variety of benefits including natural flood and erosion control, water quality maintenance, and groundwater recharge; maintenance of biodiversity, fish and wildlife habitat, and ecosystem services; and societal benefits such as agricultural production, aesthetic values, and recreational opportunities (Federal Emergency Management Agency [FEMA] 1994).

Flood risk management focuses on reducing the effects of high-hazard, low-frequency floods. For the purpose of flood risk management, the floodplain area is defined by its probability of being inundated. The base (100-year) floodplain is the inundated area resulting from a flood with an annual exceedance probability (AEP) of 1 percent. That is, there is a 1 percent chance that the base floodplain will be inundated during any given year. The critical action (500-year) floodplain has a 0.2 percent chance of being inundated during any given year (AEP of 0.2 percent). As described in Section 3.9, *Flood Risk Management*, Columbia River Basin floodplains have been extensively modified during the last century for flood risk management (e.g., levees). These modifications substantially affected the occurrence and functioning of the natural floodplains along the river. In addition, projects supporting navigation, hydropower, and agricultural production have impacted benefits associated with relatively undisturbed floodplains. The effects of past floodplain modifications on other resource areas are discussed elsewhere in this chapter: Section 3.3.2 describes effects on sedimentation and river morphology; Section 3.4.2 describes effects on water quality; and Section 3.5.1 describes effects on fish habitats.

The existing floodplains within the Columbia River Basin occupy the open water and wetland areas shown in the figures in Section 3.6.1, *Area of Analysis*. Much of the area designated as upland in these figures occupies the natural (pre-development) floodplain, but is currently protected from flooding by levees and reservoir operations (Section 3.9.3). Because of the way uplands are defined here, portions of the areas that are designated uplands in the Section 3.6.1 figures actually may lie in the active floodplain and wetlands, although these areas are likely to be infrequently flooded.

#### *3.6.2.6 Special Status Species*

The following list of threatened, endangered, and sensitive species are species that are listed or candidates for listing under the ESA of 1973, as amended, and/or protected under the Marine Mammal Protection Act (MMPA) of 1972, as amended. The list covers species that may occur within the CRS study area or be impacted by any of the alternatives (Table 3-101). The USFWS Environmental Conservation Online System database and USFWS field office websites were accessed to determine if species should be considered given their range and habitat preferences. Appendix F, Vegetation and Wildlife, includes more information regarding migratory bird and marine mammal special status species.

Special Status Species were identified using the USFWS Environmental Conservation Online System (ECOS) database, USFWS field office websites, and previous biological opinions. Species evaluated in previous biological opinions that are outside of the influence of the CRS operations were not considered for further assessment. These include the woodland caribou, Northern Idaho ground squirrel, water howelia, Spalding’s catchfly, White Bluffs bladderpod, gray wolf, and Macfarlane’s four o’clock. The effects to these species will not change as a result of CRS. Additional terrestrial species that are were not carried forward through the assessment include the Canada lynx, pygmy rabbit, red tree vole, marbled murrelet, northern spotted owl, short-tailed albatross, Nelson’s checker mallow, and Oregon spotted frog. These species are evaluated, and CRS was determined to have “no effect” as they are spatially separated from the CRS. For more information on these species, refer to Appendix F.

**Table 3-101. Candidate, Endangered, and Threatened Species in the Vicinity of the Columbia River System Operations Study Area**

| Species, Critical Habitat, and Status | | | | State | | | | Species Carried Forward Through Analysis |

Note: C: candidate; E: endangered; T: threatened; N/A = not applicable.

## GRIZZLY BEAR

The grizzly bear is listed as threatened throughout the conterminous United States, except in the Bitterroot recovery area where it is listed as an experimental population. The current range for grizzly bear overlaps with areas in the CRSO study area in Montana near Libby and Hungry Horse Reservoirs. Habitat use by grizzly bear within the Columbia River Basin varies throughout the year and may include open-canopied upland forests, meadows, riparian and riverine areas, and shrub lands. The Northern Cascades Ecosystem (NCE) in north-central Washington and south-central British Columbia has the most at-risk population in the United States today. The grizzly bear recovery zone within the NCE encompasses 9,800 square miles, includes all of the North Cascades National Park, and most of the Mount Baker-Snoqualmie, Wenatchee, and Okanogan National Forests (Servheen 1997), and extends to the Columbia River. Despite the NCE encompassing, beyond the recovery zone, an additional 3,800 square miles across the U.S.-Canada border and providing rugged, remote habitat, the grizzly bear population in Washington is estimated to be fewer than 20 animals. The population is under review to determine a potential up-listing from threatened to endangered status. The eastern border of the NCE parallels State Route 97 and nearly reaches Chief Joseph Dam.

The Northern Continental Divide Ecosystem (NCDE) in northwestern Montana includes Glacier National Park, and the Bob Marshall Wilderness Complex, including the Flathead, Kootenai, Helena-Lewis and Clark, and Lolo National Forests, contained within 8,900 square miles. The population within this ecosystem is approximately 1,000 animals and continues to grow. This ecosystem encompasses the Hungry Horse Dam study area including the Hungry Horse Reservoir and all forks of the Flathead River.

The Cabinet-Yaak Ecosystem (CYE) is located in northern Idaho and northwest Montana and has an estimated 50 grizzly bears. The Kootenai River, with the Cabinet Mountains to the south and the Yaak River area to the north, bisects the CYE. Most of the 2,600 square miles are within the Kootenai and Panhandle National Forests (USFWS 2017a). This ecosystem encompasses Libby dam study area, northern area of Lake Pend Oreille, and the Kootenai River.

**COLUMBIAN WHITE-TAILED DEER**

The Columbia River Distinct Population Segment (DPS) of the Columbian white-tailed deer has maintained its threatened status since listing on March 11, 1967 (32 FR 4001). The Columbia River population occurs along the lower Columbia River in Oregon and Washington from Wallace Island at River Mile (RM) 50 downstream to Karlson Island at RM 32. There are four main subpopulations (Washington mainland, Tenasillahe Island, Puget Island, Wallace Island–Westport) of Columbian white-tailed deer and one minor one (Karlson Island) that are geographically separated by a main river channel or patches of unfavorable habitat. Julia Butler Hansen National Wildlife Refuge, located in the Columbia River Estuary, was established by USFWS for the recovery and maintenance of the Columbian white-tailed deer.

The islands and bottomlands within an 18-mile stretch of the lower Columbia River contain most of the Columbian white-tailed deer range. The Columbian white-tailed deer are restricted to the flatlands, which have an elevation of about 10 feet above sea level. Vegetation cover preferred by Columbian white-tailed deer includes forested communities with plant heights of at least 2 feet. Studies completed in the 1970s identified the primary plant communities used by Columbian white-tailed deer as park-forest, open canopy forest, sparse rush, and dense thistle (Suring 1974), and some subpopulations used “tidal spruce” communities (Davison 1979).

**STREAKED HORNED LARK**

The streaked horned lark was listed as threatened in October 2013. The streaked horned lark is endemic to the Pacific Northwest and is a subspecies of the wide-ranging horned lark. Streaked horned larks are small, ground-dwelling birds, approximately 6 to 8 inches in length. The combination of small size, dark brown back, and yellow on the underparts distinguishes this subspecies from other horned larks. The current range of the streaked horned lark can be divided into three regions: (1) the Puget lowlands in Washington, (2) the Washington coast and lower Columbia River islands (including dredge spoil deposition sites near the Columbia River in Portland, Oregon), and (3) the Willamette Valley in Oregon (USFWS 2018c).

Streaked horned larks require wide-open spaces with no trees and few or no shrubs. They nest in the ground in sparsely vegetated sites. They use prairies, coastal dunes, sandy beaches, and grasslands. Occupied habitat adjacent to the Columbia River from Corbett, Oregon, west is designated critical habitat.

**WESTERN YELLOW-BILLED CUCKOO**

Western yellow-billed cuckoo was listed as threatened in November 2014. While critical habitat has been proposed by the USFWS, no portion of the CRSO study area was identified for designation. However, suitable habitat for yellow-billed cuckoo occurs throughout the Columbia River Basin where large remnant stands of forested wetland habitat occurs near Flathead Lake in Montana, the Clearwater in Idaho, and along the Columbia and Snake Rivers in Washington State. The yellow-billed cuckoo breeds throughout much of the eastern and central United States, winters almost entirely in South America east of the Andes, and migrates through Central America (USFWS 2018e).

The western yellow-billed cuckoo uses wooded habitat with dense cover and water nearby, including woodlands with low, scrubby vegetation, overgrown orchards, abandoned farmland, and dense thickets along streams and marshes. In the western United States, cuckoo nests are often placed in willows along streams and rivers, with nearby cottonwoods serving as foraging sites (USFWS 2018e).

**UTE LADIES'-TRESSES**

Ute ladies'-tresses was listed as threatened in January 1992. Part of its range includes a small area adjacent to the Columbia River in Chelan, Okanogan, and Douglas Counties, north of Wenatchee, Washington. It is a rare perennial, terrestrial orchid with stems 8 to 20 inches tall. The orchid occurs along riparian edges, gravel bars, old oxbows, and high flow channels, and moist wet meadows along perennial streams (USFWS 2018g).

Potentially suitable habitat occurs on stabilized gravel bars and/or shoreline areas along the Columbia River that are moist throughout the growing season and inundated early into the growing season. While the species has a wide range across the western United States, within the action area, the plan is currently documented in Washington State, occurring along the Rocky Reach Reservoir on gravel bars adjacent to the Columbia River in Chelan County, Washington (Fertig et al. 2005).

Natural flooding cycles are important for creating new alluvial habitat and for reducing cover of competing plant species for Ute ladies'-tresses throughout their range, including along the Columbia River (Fertig et al. 2005). While discharge from Chief Joseph Dam influences downstream flows, the water surface elevation in Rocky Reach reservoir is primarily controlled by the operation of Rocky Reach Dam, which is owned and managed by Chelan County Public Utility District.

**SOUTHERN RESIDENT KILLER WHALE DISTINCT POPULATION SEGMENT**

The Southern Resident killer whale DPS is a single population totaling 78 individuals as of 2016 (Centre for Whale Research 2016). The population ranges from central California to southeast Alaska. During the period from July to September, the DPS inhabits the Salish Sea and the waters near the entrance of the Strait of Juan de Fuca. Winter habitat frequently includes the Washington coast and less often the coastal waters of central California by two of the three pods (K and L) (NMFS 2014). There is no critical habitat designated within the CRSO study area; however, NMFS has proposed critical habitat for the Pacific Ocean marine water along the West Coast between Cape Flattery, Washington, and Point Sur, California, as for the Southern Resident killer whale DPS (84 FR 49214).

The National Marine Fisheries Service (NMFS) has analyzed Chinook salmon stocks based on their estimated importance to the whales and found that the most crucial stocks are those returning to the Fraser River in British Columbia, other rivers draining into Puget Sound and the Salish Sea, and the Columbia, Snake, Klamath, and Sacramento Rivers. The NMFS analysis showed that Puget Sound Chinook salmon stocks are one of the most important salmon stocks for Southern Resident killer whale because the whales have access to them for a greater part of the year than fish from the Columbia, Snake, and Fraser Rivers. Other Chinook salmon stocks from the Columbia River Basin vary in overall importance for the diet of Southern Resident killer whale. For example, Snake River spring-summer Chinook salmon are mainly available to Southern Resident killer whale when the fish gather off the mouth of the Columbia River, whereas Snake River fall Chinook remain closer to the coast and would be available for a longer period before migrating upriver in the fall (NMFS 2014b, 2018; NMFS and WDFW 2018). At times or locations of low Chinook salmon abundance, whales also select other species such as chum salmon, smaller salmonids, or other non-salmonid prey (herring or rockfish).

**STELLER SEA LION**

The Eastern DPS of the Steller sea lion occurs along the West Coast between Washington and California. The Steller sea lion is the largest member of the family Otariidae, the “eared seals.” Steller sea lions are opportunistic predators, foraging and feeding near shore and in open waters on a wide variety of fishes and cephalopods (NMFS 2014a). The Steller sea lion was previously listed under the ESA and the Eastern DPS was delisted in 2014 because it had met its recovery goals (NMFS 2013). In 2010, the NMFS status assessment estimated the population included approximately 70,000 individuals and had maintained a positive growth rate for several years; the Western DPS (Steller sea lions born west of Cape Suckling, Alaska, at 144 degrees west longitude) is still listed as endangered under the ESA (NMFS 2013). The Eastern DPS is still protected under the Marine Mammal Protection Act (MMPA) in all areas where individuals occur.

In the Columbia River, Steller sea lion use the South Jetty on the Oregon shore at the mouth of the Columbia River as a haul out area, but no reproductive activity has been documented there; the Steller sea lion has not been observed using the North Jetty on the Washington shore as a haul out area. The closest breeding rookery to the Columbia River is on the southern Oregon coast at Rogue Reef. Use of the South Jetty by Steller sea lion occurs year round but is heaviest from April through October when as many as 200 to 300 individuals can be present. Steller sea lions typically forage at river mouths and coastal nearshore areas; however, some individuals are regularly observed foraging on white sturgeon and migrating adult salmon as far upstream as Bonneville Dam on the Columbia River and Willamette Falls on the Willamette River. Between 2002 and 2017, the number of Steller sea lions foraging at Bonneville dam has increased from 0 individuals in 2002 to a high of approximately 69 in 2015 (Tidwell et al. 2018).

**CALIFORNIA SEA LION**

Like Steller sea lion, the California sea lion is an eared seal native to the West Coast of North America where they live in coastal waters and on beaches, docks, buoys, and jetties. The California sea lion is distributed from the southern tip of Baja California to southeast Alaska, and they are protected under the MMPA in all areas. The California sea lion breeds in rookeries in southern California and Baja California and individuals move north after the breeding season to forage in productive nearshore areas along the Pacific coast. In 2007, the minimum population for California sea lion was estimated at approximately 150,000 individuals and the population has experienced a positive growth rate since the 1970s (NMFS 2015). The primary diet of California sea lion is a variety of fish and shellfish, including salmon, steelhead, Pacific whiting, herring, mackerel, eulachon, lamprey, codfish, walleye Pollock, spiny dogfish, and squid.

In the Columbia River, California sea lion can be found on the South Jetty, piers, and docks in Astoria, Oregon. Since the mid-1980s, increasing numbers of California sea lion have been observed foraging on white sturgeon and migrating adult salmon at Bonneville Dam, 146 miles from the mouth of the river. Scat samples collected in coastal waters and in the Columbia River estuary indicate that salmon comprise 10 to 30 percent of the animals' diet (ODFW 2017). Between 2002 and 2017, the number of individual California sea lions observed foraging at Bonneville dam has increased from 30 animals in 2002 to a high of 195 in 2015 (Tidwell et al. 2018). Foraging has also been observed at The Dalles Dam.

### 3.6.3 Environmental Consequences

#### *3.6.3.1 Methods and Assumptions*

**METHODS**

Effects to vegetation, wetlands, and wildlife were quantitatively and qualitatively assessed using the best available science and technical methodologies that were accessible for the analysis area. H&H modeling, as described in Section 3.2, was used to estimate water surface elevations and identify the spatial patterns of inundation across the analysis area. The H&H output included seasonal water-level dynamics at discrete locations and inundated area polygons for peak annual water-surface profiles. Potential changes to water surface elevations and the timing and frequency of changes in the reservoir and downstream riverine portions of the Flathead, Kootenai, Pend Oreille, Snake, Clearwater, and Columbia Rivers were used to identify potential effects to habitat, vegetation, floodplains, and wildlife. For the action alternatives, results from the H&H modeling were evaluated on annual, seasonal, monthly, and where relevant, more frequent time-scales to assess change relative to the No Action Alternative and current conditions of the affected environment. H&H model index points were used to assess changes to water surface elevations and effects at potentially sensitive wildlife sites.

Different habitat zones were identified in each reach using USFWS NWI maps, NWHI data, best professional judgment, referenced and local knowledge of the analysis area, and aerial photography. Where possible, the approximate elevations where one habitat type transitioned to another habitat type (for example, the elevation where forested and scrub-shrub wetlands transition to emergent herbaceous wetlands) were identified to assess potential effects. These approximate elevations were calculated using GIS methods in which the NWHI land cover and NWI data layers were overlaid on a 1-meter digital elevation model relief map.

In general, the transition zones from emergent herbaceous wetlands to forested and scrub-shrub wetlands, and forested and scrub-shrub wetlands to upland habitats are dependent upon water surface elevations during the growing season (Figure 3-148). Changes to water surface elevations during the growing season have the potential to impact wildlife phenology and fecundity. A decrease in water surface elevation leads to drier conditions, habitat transition, or plant composition shifts to those more tolerant of dry or drought conditions. An increase in water surface elevation leads to wetter conditions, habitat transition, or plant composition shifts to those more tolerant of wet or inundation conditions.

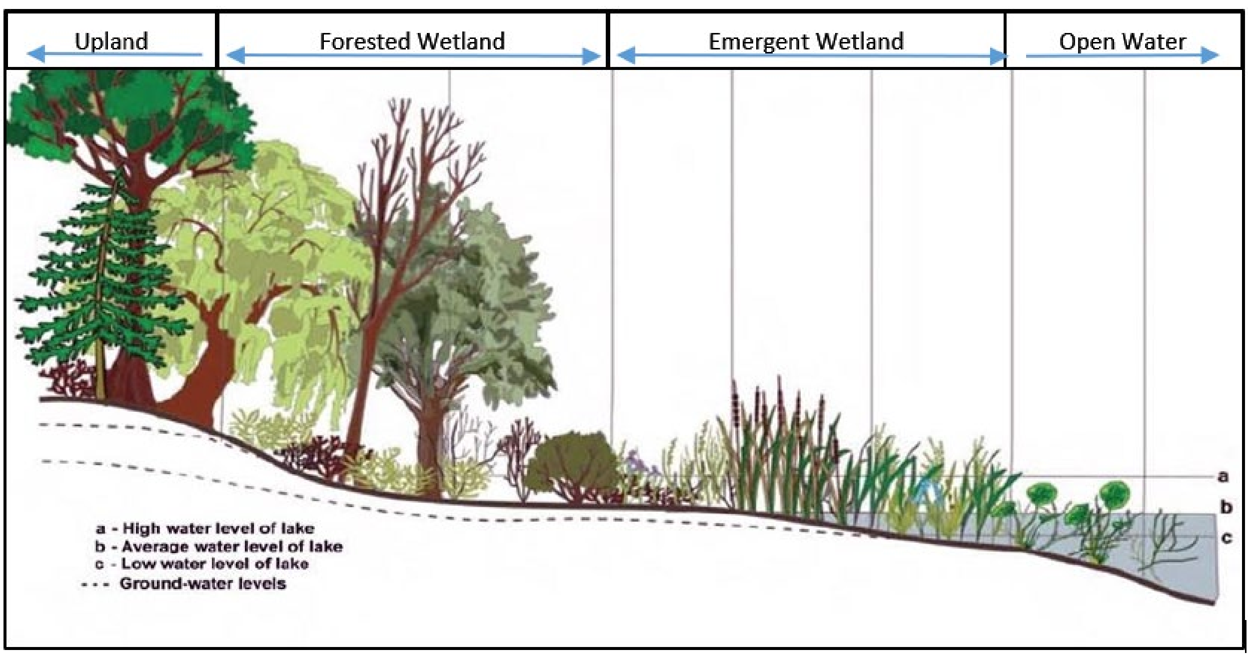

**Figure 3-148. Diagram of Upland and Wetland Transition Zones Typical of Proximity to Water Surface Elevations**

The effects of the alternatives on flood risks to property, structures, and human safety are evaluated in Section 3.9.4. The potential effects of the alternatives on the natural benefits provided by relatively undisturbed or restored floodplains are evaluated in this section. These benefits, described in Section 3.6.2.1, can be affected by changes in the frequency, timing, duration, and inundation area of flooding. The potential effects of the alternatives on the frequency and inundation area of flooding were evaluated by examining the change in flood elevation for a range of flood frequencies, from regularly occurring floods with an AEP of 50 percent (i.e., the flood elevation that occurs once every 2 years, on average) to the base flood with an AEP of 1 percent (the flood elevation with a 1 percent chance of being exceeded in any given year). If an alternative is predicted to cause a minimal change in flood elevations over this range of flood frequencies (AEP from 50 to 1 percent) for a given reach, it is indicative of the probability of inundation remaining unchanged from current conditions for the floodplain adjoining the reach; therefore, the benefits provided by the floodplain would be unchanged from the No Action Alternative. Tables of flood elevation changes for AEP values from 50 to 1 percent were provided by the H&H modeling team. Table 5-6 in Appendix B, *H&H*, shows results for the lower Columbia River below Bonneville Dam. Changes in flood elevations for floods occurring less frequently than the base flood (i.e., the critical action flood) were not evaluated due to uncertainties in the H&H simulation results for floods more rare than the base flood.

In terms of describing severity of effects, the descriptors defined in Section 3.1 are used to describe the anticipated magnitude of effect (No Effect, Negligible Effect, Minor Effect, Moderate Effect, and Major Effect) based on effect level described in Chapter 2.

In addition to the effects of changes in flood frequency and inundation area, the potential effects from changes in the timing and duration of flooding on vegetation, wetlands, and wildlife are discussed below. The potential effects on fish from changes in the timing and duration of flooding are discussed in Section 3.5.2.

**ASSUMPTIONS**

For all alternatives, except MO3, the analysis assumes that all ongoing, scheduled, and routine maintenance activities for the Federal infrastructure and all structural features, including those recently constructed or reasonably foreseeable to be constructed, are included and would be implemented as planned prior to September 30, 2016. For MO3, dam breaching would preclude the need for maintenance at the lower Snake River dams.

For structural changes at dams under MO1, MO2, and MO4, the construction and modification of existing structures would have relatively minor effects on existing habitats and wildlife populations. Typical construction-related effects would include, but are not limited to, temporary and short-term increases in noise, clearing or grading vegetation, erosion control, fish salvage and removal prior to commencing in-water work, and work-area isolation. These actions could result in a temporary displacement of wildlife from preferred or suitable habitat or changes in behavior if animals are near a project during construction. Where new structures are constructed, it is assumed that efforts would be made to avoid effects to wildlife habitat, and where habitat effects could not be avoided, efforts would be made to minimize and possibly mitigate potential effects to habitat and wildlife populations by implementing best management practices (BMPs) to minimize potentially deleterious effects. It is further assumed that construction activities would be detailed and designed at a future date and individual construction actions would undergo additional analysis, if needed when the effects are different from or exceed those anticipated herein. For structural changes under MO3 (e.g., dam breaching), it is assumed there would be major effects on existing habitats and wildlife populations.

BMPs for construction-related activities typically include taking measures to minimize dust, conducting plant and wildlife surveys prior to construction, working outside of the migratory bird nesting times, minimizing ground disturbance or limiting it to areas already disturbed, managing for surface water runoff, and having appropriate containment for fuels and other materials, etc.

Several programs are in place in the lower Columbia River to manage or dissuade pinniped and avian predation on salmonids. All alternatives assume that existing and ongoing predator control programs and other project operations would continue. These plans include the Inland Avian Management Plan (Corps 2018), The Caspian Tern Management to Reduce Predation of Juvenile Salmonids in the Columbia River Estuary (USFWS 2005), and the Double-crested Cormorant Plan to Reduce Predation of Juvenile Salmonids in the Columbia River Inlet (Corps 2015).

Throughout the study area, USFWS, ODFW, Montana Fish, Wildlife, and Parks (MFWP), and Washington Department of Fish and Wildlife (WDFW), and other tribal and governmental entities manage wetland habitats and other wildlife habitat areas to support fish and wildlife. Through its Fish and Wildlife (F&W) Program, Bonneville has implemented wildlife habitat projects to address the impact of the development of the CRS, many of which were permanently acquired for wildlife habitat and provide important benefits for fish. Bonneville also provides operations and maintenance funding for these projects. The alternatives assume that the wildlife area managers would continue to implement management activities consistent with management area and refuge goals and agency policies for the benefit of fish and wildlife.

In the lower Columbia River, below Bonneville Dam, much of the historical floodplain has been levied to protect communities from flooding. Vegetation on levees is managed for structural integrity, limiting potential habitat development immediately adjacent to the river. Routine operations and levee maintenance actions would continue under all alternatives in patterns similar to current practices. In areas where levees are not regularly maintained, some erosion or degradation is evident and these areas would continue degrading consistent with current trends.

Both the Corps and Reclamation engage in cooperative weed management agreements to treat weeds and prevent infestations of invasive species, including aquatic invasive species, throughout the study area. For example, the Corps currently manages flowering rush (*Butomus umbellatus*) and other aquatic invasive species in the McNary Reservoir on submerged Federal lands through the aquatic portion of the Walla Walla District Integrated Pest Management

Program (Corps 2019, NMFS 2019, USFWS 2019). Bonneville also provides funding to decrease the spread of non-native species through its F&W Program, such as weed control actions of wildlife mitigation properties and the removal of non-native fish species that depredate on native fish. Other similar management efforts, where applied, are anticipated to reduce the spread and establishment of invasive species throughout the study area. Invasive species management is expected to continue under all alternatives. Where no management efforts are implemented, invasive plant species are expected to persist and may spread to new areas. In terms of non-native wildlife species in the analysis area, none of the alternatives propose changes in operations that would lead to changes in populations or provide advantages to non-native wildlife over native wildlife. Therefore, they are not discussed further. Efforts currently in place to detect quagga (*Dreissena rostriformis bugensis*) and zebra mussels (*D. polymorpha*) to prevent their spread into the study area would continue and there are no measures that would impact their implementation.

Throughout the study area, cottonwood (*Populus trichocarpa*) galleries (areas with highly fertile soils and water availability) and recruitment are an important habitat feature for wildlife and floodplain development. Cottonwood is a pioneer species adapted to colonize areas disturbed by floodwaters. Cottonwood seed dispersal occurs during high flows as seeds are deposited in the floodplain or above bankfull. Altered flows that do not access floodplains affect the recruitment and survival of saplings and can lead to cottonwood galleries consisting of old, mature trees that eventually die off with no new recruitment. Changes in water elevations and flows influence successful cottonwood germination and establishment. Increasingly dry conditions result in poor germination and reduced survival of cottonwood saplings if soil conditions do not retain sufficient moisture for seed germination in the spring. Subsequent high flows later in the summer or after seed dispersal and before saplings can establish strong root masses can uproot saplings. Winter conditions also influence survival of saplings and the regeneration of cottonwood forests. Ice formation in shallow-water areas, or along reservoir shorelines, can destroy sapling recruitment when water surface levels fluctuate. As water levels decrease, ice moves with the water. As pool elevations increase, ice moving along the shoreline or in shallow-water areas can scour the banks and pull entire generations of saplings out from the shoreline. This can effectively reduce the long-term regeneration of cottonwood galleries when aging forests are lost through natural succession. These relationships between operations and cottonwoods occur to some extent throughout the study area and are analyzed below where effects are particularly important.

When the CRS dams were built and the reservoirs behind them filled, they inundated about 308,996 acres, much of it important fish and wildlife habitat. To calculate the area affected by CRS development in each Region—dam construction and inundation by the reservoirs behind them—Bonneville relied on either the amounts agreed upon in negotiated mitigation agreements with state and tribal entities or the loss assessments prepared by Federal, state, and tribal wildlife managers. To date, Bonneville has implemented wildlife habitat projects on over 689,000 acres to address the impact of the development of the FCRPS, which includes the CRS, many of which were permanently acquired for wildlife habitat. Bonneville also provides operations and maintenance funding for these projects. The loss assessments relating to dam construction and inundation considered all habitat losses up to and including full reservoir pool levels. As such, mitigation for those losses can also serve to address the effects of reservoir operations on wildlife habitat, to the extent that such operational impacts occur below full pool level. These habitats would not change from current conditions in response to continued implementation of the No Action Alternative.[1]

#### *3.6.3.2 No Action Alternative*

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

Vegetation communities adjacent to the study area in Region A are dominated by upland habitat types consisting of agricultural and pasture lands, eastside (interior) grasslands, eastside (interior) mixed conifer forest, and eastside (interior) grasslands. The next most abundant habitat type, besides open water, is freshwater forested and scrub-shrub wetlands and freshwater emergent herbaceous wetlands. Wetlands are located below Libby Dam along the Kootenai River at river mile (RM) 131 through 136, 143 through 144, 184 through 190, and 216 through 219. There are extensive wetlands from Hungry Horse Dam downstream to Flathead Lake, between approximately RM 111 and 140 along the Flathead River. Wetlands within the Albeni Falls Dam study area are located on the Clark Fork River at RM 4 through 8 and 73 through 86.

Throughout Region A, the acreages for the various habitat types would remain relatively unchanged from current conditions (except as described below for riparian and cottonwood habitats below Libby). Wetland habitats would not change under the No Action Alternative because the water surface elevations that influence these habitats would be consistent with current conditions. Operations that benefit wetland habitats by maintaining certain elevations around the reservoirs and downstream would not change under the No Action Alternative. Areas throughout Region A that are recovering from historical operations would continue to recover and areas that are degrading from ongoing operations would continue to degrade if additional mitigation is not implemented.

Factors potentially altering streambank conditions, such as high flows, bankfull flows in the spring, or low-water conditions, would continue under the No Action Alternative. Existing streambank conditions, such as erosion and bank sloughing, influenced by water releases from the Federal projects would continue to occur along the Kootenai River from operations at Libby Dam. Shoreline erosion in Bonner's Ferry, Idaho, caused by frozen banks suddenly drawn down due to reduced flows, would continue to reduce wildlife habitat. The exception is the muddy eastern and northern shoreline of Lake Pend Oreille, where soils are highly erodible and fluctuating water levels from reservoir operations, boat wakes, and wind are expected to maintain erosional processes, contributing to increased undercutting of banks and shoreline

[1] Bonneville funded but did not control the production of wildlife habitat loss assessments by wildlife managers in the mid-1980s and early 1990s. These documents, also called "Brown Books," are on file with Bonneville. The Brown Books generally reflect the acres inundated by the FCRPS as determined by the surface area of the reservoirs created behind each dam. See, e.g., U.S. Fish and Wildlife Service, Wildlife Impact Assessment Bonneville, McNary, The Dalles, and John Day projects (Oct. 1990).

collapse. It is expected that management activities would be implemented to address localized areas of erosion where they pose a risk to public safety.

Operations at all three facilities expose a wide barren zone around the reservoirs during refill and drawdown. For wildlife, the barren zone represents an area that smaller wildlife species, such as rodents or snakes, must navigate to reach water in the reservoir. Crossing wide barren zones with no cover poses a risk of predation for prey species, which is a detriment to them, while conversely providing a benefit to predators (Huokuna et al. 2017). The barren zone width at each facility varies, but the effects on wildlife are similar in terms of predation and would continue unchanged under the No Action Alternative.

In Region A, Bonneville addressed construction and inundation mitigation for Libby and Hungry Horse Dam wildlife using a comprehensive long-term agreement. Under the 1989 Montana Wildlife Mitigation Trust Agreement (Montana Fish, Wildlife, and Parks 2013), Montana has protected or enhanced 272,104 acres (Montana Fish, Wildlife, and Parks 2019) (the Council's program called for a total of 55,837 acres of wildlife mitigation for Libby and Hungry Horse Dams split between 29,171 acres of enhancement and 26,666 acres of protection; NPCC 1987; Montana Fish, Wildlife, and Parks 2009). In the 2018 Albeni Falls Dam Wildlife Mitigation Agreement, Bonneville and the State of Idaho established that 14,087 acres had already been mitigated through the efforts of the state, the Kalispel Tribe of Indians, Kootenai Tribe of Idaho, and Coeur d'Alene Tribe (6,617 acres were impacted as a result of the construction and inundation of Albeni Falls Dam; Northern Idaho MOA 2018). In addition, Bonneville agreed to fund the State of Idaho to protect and enhance 1,279 acres of wetland habitat at the Clark Fork Delta and an additional 99 acres at the Priest River Delta to address the upriver effects of Albeni Falls operations. This is in addition to the 624 acres of wetland protected and enhanced on the Clark Fork Delta by IDFG, which was funded by Bonneville through a letter agreement in 2012.

From May 15 through September 30, operations at Libby Dam maintain higher flows (at or above 6 kcfs) to inundate the channel during the most biologically productive time of the year and exhibit a gradual decline over the summer. While operations at this location are primarily fish focused, wildlife habitats and wildlife populations would continue to benefit from increased water surface in the reservoir and water availability downstream, particularly during the summer months when temperatures are high and water levels inundate wetland habitats. The small wetland fringe in areas where the reservoir converges with small tributaries would continue to be inundated and benefit from operations.

At Libby Dam and downstream along the Kootenai River, because high winter releases scour seedlings, some riparian cottonwood communities could continue to decline in some locations due to altered hydrological conditions.

Through the F&W Program, Bonneville has funded the Kootenai Tribe of Idaho (KTOI) to manage and implement large-scale habitat restoration measures within the Kootenai River. These habitat restoration actions have increased active floodplain and worked to restore riparian forest habitat, including efforts to restore black cottonwood galleries. The efforts to restore black cottonwood galleries within floodplains and along river corridors are being implemented within the upper basin by the Kootenai Tribe of Idaho, (KTOI) the Kalispel Tribe, and the Idaho Department of Fish & Game (IDFG) through Bonneville's F&W Program. The KTOI have been implementing re-planting efforts below Libby Dam within the Idaho portion of the Kootenai River. The Kalispel Tribe has been planting black cottonwoods in Washington and Idaho above and below Albeni Falls Dam, both within floodplain areas and along the Pend Oreille River. IDFG, in their work to restore portions of the Clark Fork Delta, have been conducting revegetation efforts with native black cottonwoods. Mitigation actions like these would continue under the No Action Alternative.

Under the No Action Alternative, cottonwood seed deposition occurs after high flows in June and July moisten the riverbanks, and seeds are dispersed from parent trees in late summer. Winter flows can inundate and scour riverbanks, destroying tree and shrub saplings like cottonwoods and willows (*Salix* spp.) that have not yet developed sufficient root structures to withstand high winter flows or the spring freshet.

The Kootenai Wildlife Refuge contains 2,774 acres of wetlands, meadows, riparian forests, and cultivated agricultural fields, which provide habitat for over 220 bird species and 45 mammal species. The seasonal wetlands are drained in spring and summer to promote emergent vegetation for waterfowl food sources. Current operations of Libby Dam adversely affect wetland management capability, reducing availability of forested and scrub-shrub and emergent herbaceous wetlands (USFWS 2015).

The size and depth of Lake Pend Oreille (approximately 94,600 acres and maximum depth of 1,237 feet) would remain unchanged under the No Action Alternative and the estimated ordinary high water elevation in the summer and fall (2,062.5 feet and 2,051 feet NGVD29, respectively) would remain unchanged throughout the year.

Consistent with current management practices, the Corps would continue to lease approximately 4,000 acres of project lands in the Albeni Falls Dam study area to the State of Idaho for wildlife management. The Pend Oreille Wildlife Management Area (WMA) would be inundated for 4 to 5 months each year, with less than 25 percent of the area above the high-water line. Habitat in the WMAs range from mudflats exposed during reservoir drawdown in the winter to submerged lands with rooted aquatic plants and forested uplands. During the summer months under the No Action Alternative, most of the Pend Oreille WMA is emergent marsh habitat and with an average water depth of 2 to 4 feet surrounded by a narrow zone of sedges, cottonwoods, and willows. Conifers occur further inland.

Amphibians such as the western toad (*Bufo boreas*) and northern leopard frog (*Rana pipiens*) would continue to breed in off-channel pools and forested woodlands along slow-moving rivers in Montana and Idaho from early May until late June. Tadpoles are generally present from late May to early September.

Western grebe (*Aechmophorus occidentalis*) is abundant on portions of the Pend Oreille WMA, particularly in Denton Slough where one of only a few northern Idaho nesting colonies occurs. Nesting occurs from about May through September. Denton Slough is a shallow bay with a large quantity of submerged plants. These plants are used by western grebe to construct their nests, which are composed of piles of floating plant material that are typically hidden among, and may be anchored to, emergent or floating plants (Idaho Department of Fish and Game [IDFG] 1999).

The Canada goose (*Branta canadensis*) ground nests near the Priest Lake portion of the WMA along the shore and on islands (IDFG 1999). Other common nesters include mallard (*Anas platyrhynchos*); American widgeon (*Mareca americana*); gadwall (*M. strepera*); northern shoveler (*Spatula clypeata*); ring-necked duck (*Aythya collaris*); and green-winged, blue-winged, and cinnamon teal (*Anas crecca, Spatula discors,* and *S. cyanoptera*, respectively) (IDFG 1999).

In regard to potential effects in Canada, the effects on vegetation and wildlife resources and their habitats under the No Action Alternative are expected to be similar to the effects described for the United States portion of Region A.

**REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS**

Vegetation communities in Region B are primarily dominated by upland habitats. Upland habitats near the Chief Joseph Dam trend toward agricultural and pasture lands, with some shrub-steppe habitat, while upland habitats near the Grand Coulee Dam are primarily dominated by agricultural and pasture land, ponderosa pine (*Pinus ponderosa*) forests and woodlands, and shrub-steppe habitat. The next most common habitat type in Region B, besides open water, is forested and scrub-shrub wetlands. Emergent herbaceous wetlands, while sparse throughout the region, occur in isolated pockets along the rivers and lake shorelines. Uplands occur above the forested and scrub-shrub wetland habitat in both zones. There are approximately 1,600 acres of urban and mixed-use environment throughout Reach B.

Operations at Grand Coulee expose a wide barren zone around the Lake Roosevelt during refill and drawdown. For wildlife, the barren zone represents an area that smaller wildlife species, such as rodents or snakes, must navigate to reach water in the reservoir. Crossing wide barren zones with no cover poses a risk of predation for prey species, which is a detriment to them, while conversely providing a benefit to predators. The effects on wildlife are similar in terms of predation and would continue unchanged under the No Action Alternative.

Approximately 1,426 acres of forested and scrub-shrub wetlands are located within Region B. These wetlands are composed mainly of cottonwoods and willows.

Habitat types in Region B would not shift or transition to other habitat types, and the spatial extent of existing habitats would not increase or decrease as a function of the No Action Alternative. Water surface elevations, which influence wetland habitats throughout the study area, would continue consistent with current operations and patterns of inundation would continue to support these habitats following expected patterns of seasonal and annual fluctuation. Island habitats and barren areas surrounding the reservoirs would also continue to be present in amounts similar to current conditions. Wildlife use of these habitats would not change in response to implementing operational or structural measures associated with the No Action Alternative.

In this region, project partners like WDFW, Spokane Tribe of Indians (STOI), and Confederated Tribes of the Colville Reservation (CTCR) manage wildlife mitigation properties funded through the Bonneville F&W Program for wildlife mitigation. Under a 2008 agreement between Bonneville and CTCR, CTCR acquired almost 4,000 acres, which are part of the Hellsgate Game Reserve. In addition, CTCR has completed extensive habitat restoration and maintenance actions, such as invasive species and noxious weed control measures and fencing modifications to benefit reintroduced pronghorn antelope. Similar mitigation actions would continue to be implemented in Region B under the No Action Alternative.

Streambank conditions, such as erosion and bank sloughing, and vegetation along the Columbia River are influenced by water releases from Chief Joseph Dam and Grand Coulee Dam. Under the No Action Alternative, conditions affecting shorelines are expected to continue and factors influencing these, such as high flows, or bankfull flows in the spring, would continue consistent with current conditions. Furthermore, areas recovering from historical operations are expected to continue to recover, and areas that generally transition from open water directly to upland, due to the non-existence of established wetland habitats, will remain the same.

The overall wildlife values at Lake Roosevelt are limited because of the lake's storage function and substantial seasonal drawdowns, which adversely affect shorelines and the development of wildlife habitat. Habitats important to wildlife in Region B are generally confined to tributary stream reaches, embayments and backwaters, and islands; conditions are much less favorable on the main reservoir where steep, eroding banks are prevalent. Islands are important in part because only 28 remain of the 114 identified in a pre-construction assessment of the Columbia River in Region B. In general, riparian and wetland habitats exist only as small, isolated habitats around Rufus Woods Lake and Lake Roosevelt.

Winter conditions that influence predator-prey relationships in areas such as Lake Roosevelt, Lake Koocanusa, and Flathead Lake would continue. Shallow-water coves and embayments frequently freeze completely in the winter.

Both mountain lion (*Puma concolor)* and wolf (*Canis lupus*) are known to hunt or pursue prey species such as bighorn sheep (*Ovis canadensis*) and deer (*Odocoileus hemionus*) into barren zones or onto the ice in the winter. The mountain lion is more successful in its capture and kill rates when the water levels are lower in the winter or the reservoir does not refill completely before lake conditions freeze. Under these conditions, mountain lion pursue ungulates such as the bighorn sheep into the barren zone where the surface is predominantly soil instead of rock. When ungulates (i.e., elk, bighorn sheep, deer) are pushed into areas with soft sediments, they have difficulty escaping. The wolf, however, is more successful in its capture and kill rate when the water levels are higher during the winter and areas of the reservoir freeze over. Under these conditions, the wolf hunts and pursues deer and elk (*Cervus canadensis*) onto the ice where the wolf has better traction over snow and ice. Amphibians such as the western toad (*Bufo boreas*) and northern leopard frog (*Rana pipiens*) would continue to breed in off-channel pools and along the fringes of Lake Roosevelt and slow-moving sections of the Columbia River from early May until late June. Tadpoles are generally present from late May to early September.

In regard to potential effects in Canada, the effects on vegetation and wildlife resources and their habitats under the No Action Alternative are expected to be similar to the effects described for the United States portion of Region B.

**REGION C – DWORSHAK, LOWER GRANITE, LITTLE GOOSE, LOWER MONUMENTAL, AND ICE HARBOR DAMS**

Vegetation communities adjacent to and downstream of the Dworshak Dam are dominated by upland habitat types, including eastside interior shrublands, eastside interior mixed conifer forest, ponderosa pine and eastside white oak forest woodlands. At Dworshak, emergent herbaceous wetlands are present generally at the highest water elevation, approximately 1,600 feet, at the confluences of tributaries. Downstream of Dworshak on the Clearwater River, emergent herbaceous and forested and scrub-shrub wetlands occur within 5 feet of water surface elevation.

Dworshak's 80-foot barren zone is caused by the fluctuations of the reservoir between maximum and minimum operating pool. Since the late 1990s, the reservoir has been drawn down to 80 feet annually between July and October to improve passage and survival of endangered salmon in the Clearwater and Snake Rivers. Dworshak Reservoir does not fill until the end of June. During most of the year, large mud flats, sandy banks, and rocky slopes are visible. This has affected the elk populations during the winter months when ice freezes along the reservoir. When ice is present, elk may cross the reservoir to reach their south-facing winter range on the northern end of the reservoir. Migration across the ice occurs frequently when ice and snow conditions permit. In winters when snow accumulates on thin ice, elk and deer may fall through the ice and mortality may occur. Although mortality rates are highly variable, in some years, this can be a major source of mortality.

Wetlands along the Clearwater River are located in areas where sediment accretes at the confluence of the river with its tributaries. Hog Island, located at approximately RM 9, is a large island that includes emergent herbaceous wetlands.

The four lower Snake River projects are primarily dominated by the upland habitat types of agricultural and pasture lands and shrub steppe habitat. There are forested and scrub-shrub wetlands at Lower Granite Reservoir (Reach 9); however, most of the wetlands found at the lower Snake River projects are emergent herbaceous wetlands. There are large wetland areas located at Silcott Island (RM 131), within Lower Granite Reservoir at RM 80, and in Little Goose Reservoir at RM 58 and Lower Monumental Reservoir at RM 17. Wetlands occur approximately 3 feet from maximum operating pool elevation within the lower Snake River projects.

Habitat types in Region C would not shift or transition to other habitat types, and the spatial extent of existing habitats would not increase or decrease as a function of the No Action

Alternative. Water surface elevations, which influence wetland habitats throughout the study area, would continue consistent with current operations and patterns of inundation would continue to support these habitats following expected patterns of seasonal and annual fluctuation. Island habitats and barren areas surrounding the reservoirs would also continue to be present in similar amounts to current conditions. Wildlife use of these habitats would not change in response to implementing operational or structural measures associated with the No Action Alternative.

Streambank conditions, such as erosion and bank sloughing, and vegetation along the Clearwater, Snake, and Columbia Rivers in Region C, are influenced by water releases from Dworshak Dam, Hells Canyon Complex, and the four projects on the lower Snake (Ice Harbor, Lower Monumental, Little Goose, and Lower Granite). Under the No Action Alternative, shoreline conditions would continue and factors influencing these, such as high flows, or bankfull flows in the spring, would continue under the No Action Alternative consistent with current conditions. Furthermore, areas recovering from historical operations would continue to recover.

The Dworshak Dam lands would continue to be managed for elk populations, wildlife habitat, and recreational use.

The 1992 Dworshak wildlife mitigation agreement with the State of Idaho, Nez Perce Tribe, and Bonneville, frequently referred to as the “Dworshak Settlement,” mitigated the impacts to wildlife from developing that dam estimated at 16,970 acres. To determine acreage protected, Bonneville relied on the Dworshak Wildlife Agreement reports from the Nez Perce Tribe. The Tribe’s 2018 annual report indicates it has purchased 7,576 acres and still has over $9.5 million remaining in its mitigation fund established under the agreement (Nez Perce Tribe 2018). The State of Idaho also has a $3 million fund provided by Bonneville to manage the 60,000-acre Peter T. Johnson Unit of the Craig Mountain Wildlife Management Area (formerly known as Craig Mountain), which Bonneville purchased and transferred to Idaho (IDFG 2014). All told, Bonneville has funded approximately 67,576 acres of mitigation for Dworshak Dam. Many of these mitigation sites are located outside of the study area.

Most of the approximate 147 miles of shoreline along the lower Snake River are managed by the Corps as mitigation areas as part of the Lower Snake River Compensatory Mitigation Plan (Corps 1975, 1996). These areas are managed to provide wildlife habitat and recreation areas. Under the No Action Alternative, the wildlife would continue to utilize the habitat types. These species include mule deer, fox, raccoons, bobcat, turkey, and various songbirds as well as otter, beaver, muskrat, and various ducks.

In addition to these areas, Bonneville secured another 61,210 acres of wildlife mitigation through habitat protection and enhancement projects implemented by the Nez Perce Tribe and Burns Paiute Tribe. For example, the Nez Perce Tribe received funding through Bonneville’s F&W Program to acquire the 16,286-acre Precious Lands project near Joseph, Oregon, outside the study area.

**REGION D – MCNARY, JOHN DAY, THE DALLES, AND BONNEVILLE DAMS**

Habitats in Reach D transition from dry, Columbia River Plateau habitat types to wet forests of the Cascade Range and Oregon Coast Range. Upland habitat adjacent to John Day Dam and The Dalles study areas largely consists of shrub-steppe vegetation, mixed grasslands, and agricultural areas farmed for dryland wheat, alfalfa, barley, and vineyards. The distribution and spatial extent (overall acreage) of uplands managed by the Corps would not change under the No Action Alternative. Where upland habitats transition abruptly to the river's edge and no riparian habitat exists, there are few areas where habitat is exposed for prolonged periods of time and shoreline habitat is predominantly bedrock, sand, gravel, and silts with limited or no vegetation. Within the McNary Reservoir, there are extensive wetlands within the McNary Wildlife Area at Burbank Slough (RM 319 to 324) and mudflats at the confluence of the Walla Walla River (RM 313 to 315). The Yakima Delta contains some cottonwood forest habitat (RM 333 to 335).

Within the McNary Reservoir, Crescent Island (RM 316) was managed (fence and willow plantings) to discourage tern nesting, and monitoring of the Island would continue under the No Action Alternative (Corps 2018). The acreage of available habitat for avian predators is dependent on water surface elevation. Under the No Action Alternative, there is approximately 0.25 acre of suitable nesting habitat on Badger Island, depending on river flows, and the island supported 60 breeding pairs of Caspian terns in 2012 (Bird Research Northwest 2013). Wildlife use of these habitats would not change due to operational or structural measures associated with the No Action Alternative. On Crescent Island, approximately 2.4 acres of potential Caspian tern nesting habitat has been covered with passive nest dissuasion materials consisting of fencerows. Open areas on Crescent Island were planted with willow and other native vegetation prior to the 2016 nesting season.

Water surface elevations under current operations, which influence the distribution and maintenance of wetland habitats, would continue and current trends for habitat quality, quantity, and distribution would not deviate from current conditions. The distribution and acreage of wetland habitat in the upper portion of Region D (The Dalles and John Day study areas) is limited due to the close relationship of highways and railroads to the river's shorelines. Forested and scrub-shrub and emergent herbaceous wetlands occur in embayments formed by the location of highways and railroads adjacent to the river at elevations of 14 to 26 feet, above which habitats transition abruptly to upland land cover types. In the lower portion of Region D (downstream of The Dalles Dam), the distribution and acreage of wetland habitats increases, becoming extensive throughout the lower Columbia River, where emergent herbaceous wetlands occur at elevations of 1 to 10 feet. Wildlife use of habitats would not change in response to operations or structural measures associated with the No Action Alternative.

There is very little erosion or bank sloughing in the upper portions of Region D (The Dalles and John Day study areas) due to shorelines consisting almost entirely of bedrock. Under the No Action Alternative, these patterns would not change and factors influencing shoreline conditions, such as high-flow years or low-flow years, would continue. Under the No Action

Alternative, patterns of accretion and erosion in the lower portions of Region D would not change substantively from current conditions, and factors influencing shoreline conditions and erosional patterns, such as high-flow years or low-flow years, would continue similar to current conditions. As a result, due to increasing erosion in the lower portions of Region D, the spatial extent and acreage of sandy shorelines is expected to decline, reducing habitat available for species using these habitats.

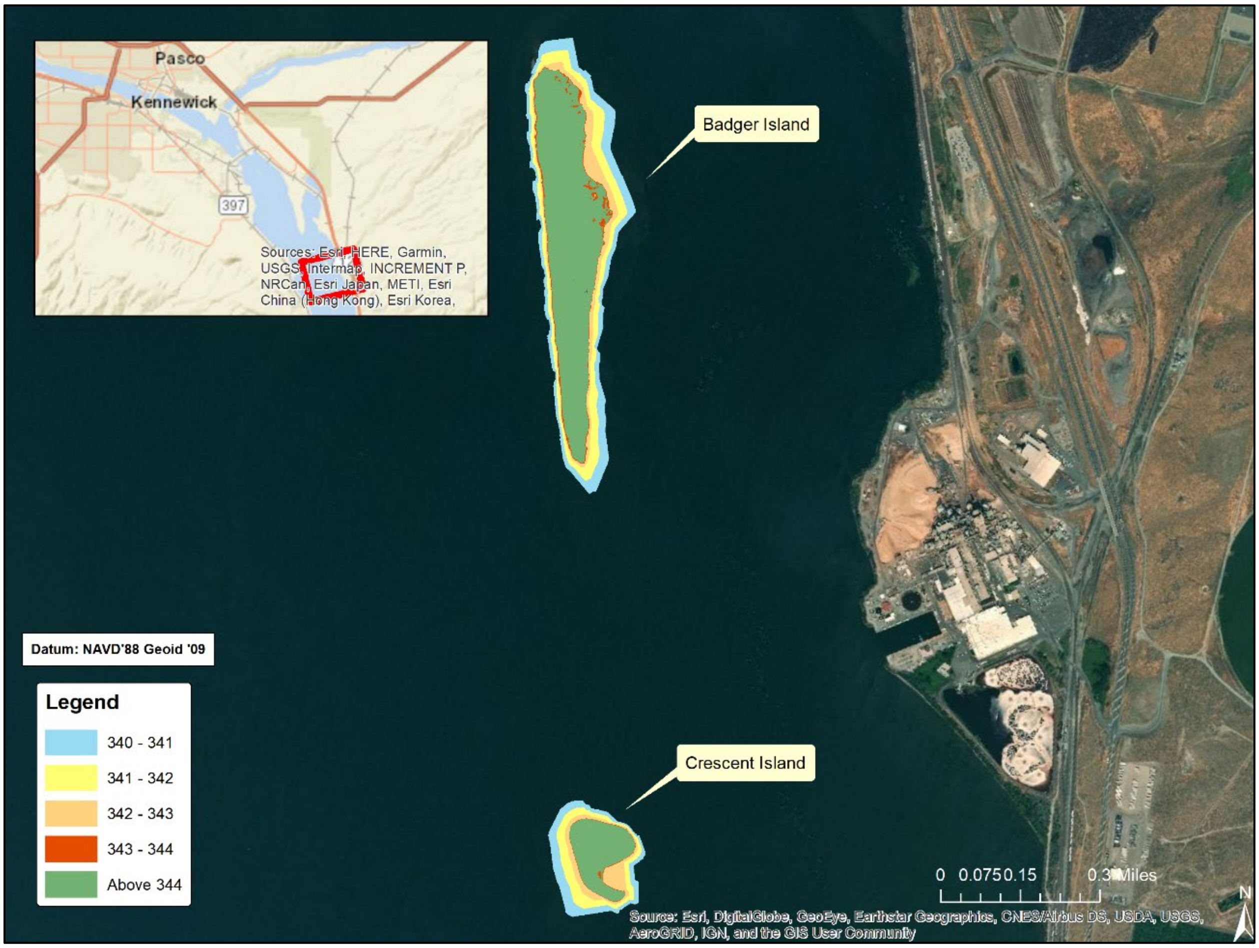

**Figure 3-149. Crescent Island in McNary Reservoir**

Note: Legend units are feet.

Downstream of The Dalles Dam, the ecosystems begin shifting from warmer, drier habitats to cooler, wetter habitats. Upland habitats downriver from Bonneville Dam vary between wet, cool forests west of the Cascade Range to oak savannahs near Vancouver, Washington, and Portland, Oregon, to coastal forests near the ocean. The river banks transition from bedrock shorelines near Bonneville Dam and the Columbia River Gorge to sandy beaches near the coast, with rock- or dirt-fill levees throughout much of the lower river. Habitat conditions associated with the levees would continue under the No Action Alternative. As described above, it is assumed that routine operations and maintenance of levees would continue and in areas that are not regularly maintained, current levels of existing erosion or degradation would continue.

Throughout Region D, USFWS, ODFW, and WDFW manage emergent herbaceous and forested and scrub-shrub wetland habitat to support fish and wildlife habitat. The No Action Alternative assumes USFWS would continue to implement management activities consistent with refuge goals and agency policies for the benefit of fish and wildlife in the lower river. As a result, it is assumed that management activities at McNary, Umatilla, Franz Joseph, Pierce, Steigerwald, Ridgefield, Julia-Butler Hansen, and Lewis and Clark National Wildlife Refuges (NWRs) would maintain habitat conditions similar to current conditions. The Umatilla NWR would continue to support valuable habitat for fish and wildlife under the No Action Alternative, and McCormick Slough on Lake Umatilla would continue to provide valuable habitat for wintering waterfowl in the Umatilla NWR Important Bird Area (IBA) (Figure 3-150). Concentrations of ducks and geese over-wintering in the study area are anticipated to continue in numbers consistent with current trends under the No Action Alternative. The Rock Creek IBA in Washington near The Dalles, Oregon, is anticipated to continue providing valuable shrub-steppe habitat for a multitude of bird species, including ash-throated flycatchers (*Myiarchus cinerascens*) and California scrub jays (*Aphelocoma californica*). Conditions in these habitat areas would remain the same under the No Action Alternative.

Similarly, the Blalock Islands and surrounding low-lying sand and gravel bars, located between RM 272 and 277, are anticipated to continue providing suitable habitat for breeding Caspian terns, gulls, and other waterbirds under the No Action Alternative (Figure 3-151 and Figure 3-152).

Under the No Action Alternative, no management activities would occur to modify or change the suitability of habitats in the Lake Umatilla study area to support or preclude breeding habitat. Currently, John Day Dam is managed to maintain water surface elevations in Lake Umatilla at elevations between 257.0 and 268.0 feet NGVD29 (NAVD88) with normal pool operations changing seasonally. The normal operating range for Lake Umatilla is between 262.5 - 265.0 feet in October, 262.0 - 266.5 feet November through December, 262.0 - 265.0 feet January 1 - March 14, 262.5 – 265.0 feet March 15 – April 9, and between 262.5 and 264.0 feet April 10 – September 30. Slight deviations from these levels could occur occasionally (e.g., to meet navigation requirements, or hydropower needs). John Day Dam operates for flood risk management and Lake Umatilla will draft to as low as 257.0 feet and may fill to a maximum pool of 268.0 feet during flood operations. Under the No Action Alternative operations, approximately 3.6 acres of suitable habitat is available in the Blalock Islands complex during the breeding season for nesting Caspian tern. The total acreage available for nesting terns does not occur as one colony site but is instead fragmented between several low-lying islands with no or very limited vegetation.

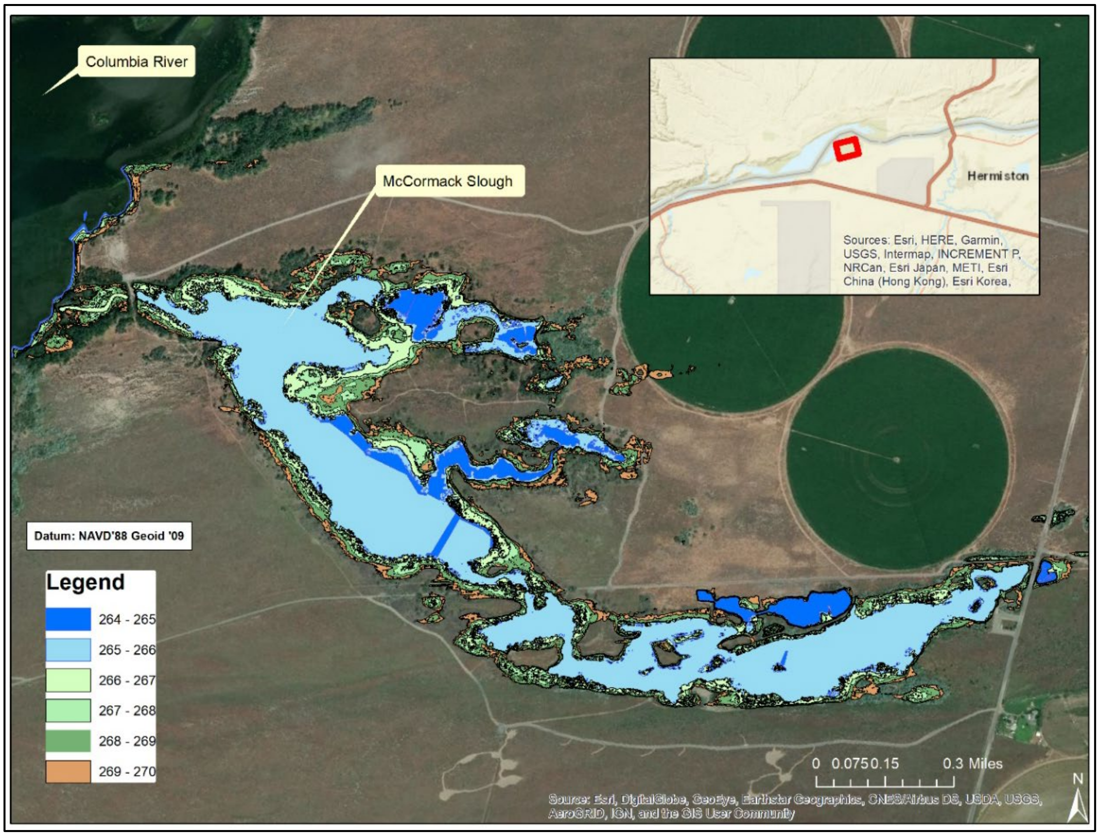

**Figure 3-150. McCormack Slough in the Umatilla National Wildlife Refuge at River Mile 273**

Note: The slough is a shallow water habitat environment that is part of the USFWS-managed Umatilla NWR downstream of McNary Dam. The legend units are feet NAVD88.

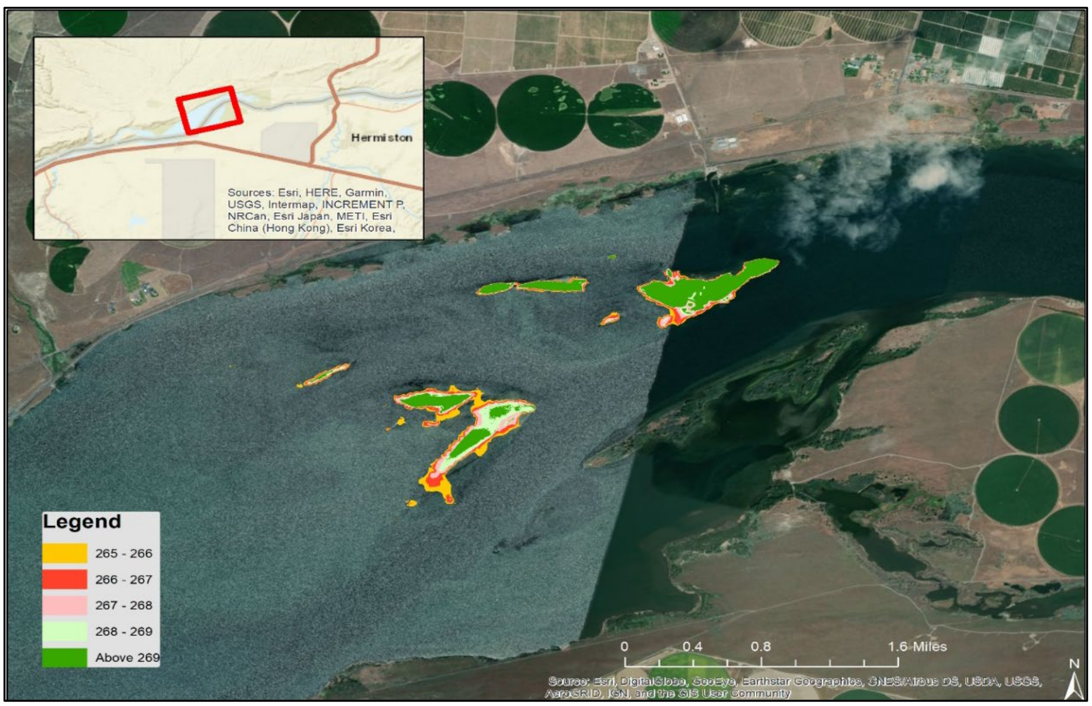

**Figure 3-151. Blalock Islands Complex in the Lake Umatilla at River Mile 273**

Note: The island complex is part of the USFWS-managed Umatilla NWR downstream of McNary Dam.

As mentioned above, operations and maintenance actions at ODFW- or WDFW-managed lands and habitat for the benefit of wildlife are assumed to continue similar to current practices under the No Action Alternative. This includes Klickitat Wildlife Area near RM 180 for western pond turtle (*Actinemys marmorata*) and Sondino Ponds in Washington. As a result of these collective actions, it is assumed that wildlife concentrations and use of habitats in the lower Columbia River would not change from current conditions in response to the No Action Alternative.

The Corps currently implements management activities at and downstream of John Day Dam, The Dalles Dam, and Bonneville Dam to reduce avian predation on juvenile salmonids by gulls and terns. These activities include the maintenance of avian wires spanning the river (effectively bank to bank), in an effort to minimize large concentrations of birds congregating at juvenile bypass outfalls where they can more easily prey upon juveniles exiting the bypass systems. The Corps, with support from USFWS and U.S. Department of Agriculture Animal and Plant Health Inspection Service Wildlife Services, also implement management activities to limit the availability of nesting habitat for Caspian tern and double-crested cormorant (*Phalacrocorax auratus*) at East Sand Island at RM 5.5. These management activities include hazing birds from areas outside of a designated colony area, for example, limiting the availability of habitat for Caspian tern to 1.0 acre through habitat management by removing unwanted vegetation and installing dissuasion materials to delineate a 1.0-acre breeding colony. Under the No Action Alternative, management activities would continue and include coordinating with the USFWS for authorization to haze birds from nesting habitat outside the managed 1 acre, and collect eggs in order to limit nest establishment. These management activities at East Sand Island in the Columbia River estuary, which are outlined in the Caspian Tern Management to Reduce Predation of Juvenile Salmonids in the Columbia River Estuary EIS (Corps 2014) and Double-crested Cormorant Management Plan to Reduce Predation of Juvenile Salmonids in the Columbia River Estuary EIS (Corps 2015), would continue. The effects of these management actions on Caspian terns and Double-crested cormorants are to limit reproductive success, manage population growth, and specific to Terns, relocate some of the nesting population to habitat outside the Columbia River Basin.

In an effort to curb pinniped (seal and sea lion) predation on ESA-listed salmonids, regional fish and wildlife agencies implement management actions to selectively remove (lethally and non-lethally) sea lions observed repeatedly feeding on salmon and steelhead below Bonneville Dam on the Columbia River. Between 2008 and 2016, a total of 144 individual California sea lions were lethally removed (euthanized) from waters below Bonneville Dam, 15 animals were relocated to zoos or aquariums, and 2 died in traps. These actions are expected to continue under the No Action Alternative, with increasing numbers of sea lions lethally removed from the population as capacity in zoos or aquariums declines.

**Figure 3-152. Caspian Tern Nesting Colonies in 2018 at Middle and Long Islands in the Blalock Islands Complex**

Source: Bird Research Northwest (2019)

The Oregon Department of Fish and Wildlife (ODFW) implements management activities for pinnipeds (seal and sea lion) in the Columbia River estuary downstream of Bonneville Dam. In an effort to curb pinniped predation on ESA-listed salmonids, regional fish and wildlife agencies implement management actions to selectively remove (lethally and non-lethally) sea lions observed frequently feeding on salmon and steelhead below Bonneville Dam up to The Dalles Dam. For example, Bonneville's F&W Program has funded a non-lethal sea lion predation deterrence and monitoring project with the Columbia River Inter-Tribal Fish Commission (CRITFC) since 2008. Each year, Bonneville funds CRITFC to conduct boat-based hazing of California and Steller sea lions below Bonneville Dam. The CRITFC project investigates techniques to evaluate the effectiveness of these hazing efforts and also enumerates sea lion abundance and estimates sea lion predation throughout the lower Columbia River. These actions are expected to continue under all alternatives.

In this region, project partners, like WDFW, ODFW, Confederated Tribes and Bands of the Yakama Nation, Confederated Tribes of the Umatilla Indian Reservation, Confederated Tribes of Warm Springs and U.S. Forest Service, manage wildlife mitigation properties funded through the Bonneville F&W Program for wildlife mitigation. For example, the Confederated Tribes of the Umatilla Indian Reservation secured and now manage the 8,768-acre Rainwater project, the 5,937-acre Iskulpa project, and the 2,765-acre Wanaket wildlife area located downstream of

McNary Dam. Further, the 34,000-acre Pine Creek Conservation Area in Wheeler County, Oregon, is owned and managed by the Confederated Tribes of Warm Springs. In total, ongoing Bonneville F&W Program wildlife mitigation projects for Region D dams total over 107,000 acres.

**FLOODPLAINS**

It is assumed here that the current probability of inundation for the existing active floodplains would continue under the No Action Alternative. Therefore, there would be no change in active floodplain benefits under the No Action Alternative.

**SPECIAL STATUS SPECIES**

Table 3-102 provides details about ESA-listed wildlife species that are known or are likely to occur in the study area. Over the 25-year period of analysis, it is assumed that those species federally listed and present in the study area will remain listed and existing regulatory and best management practices would reduce the likelihood that populations would continue declining or go extinct. It is assumed that neither grizzly bear (*Ursus arctos horribilis*) critical habitat nor the whitebark pine (*Pinus albicaulis*) would be listed and their presence and population in or near the study area would remain relatively stable.

**Table 3-102. Sensitive Species that may Occur Within the Analysis Area Boundaries**

| Common Name | Scientific Name | Status of Species and Critical Habitat | Habitat | Potential for Occurrence | Projects Where Species Occurs | Effects of No Action Alternative |
|---|---|---|---|---|---|---|
| **Mammals** | | | | | | |
| Grizzly bear | *Ursus arctos horribilis* | ESA status: T<br>CH: proposed | Relatively undisturbed mountainous, closed and open timber, mixed shrubs (alder/huckleberry), meadows, seeps, and riparian zones.<br>Species has very large home range (50 to 300 square miles for females; 200 to 500 square miles for males), encompassing diverse forests interspersed with moist meadows and grasslands in or near mountains. | Region A: High – there are two grizzly bear populations in the Libby Dam study area: the Cabinet-Yaak and Selkirk Ecosystems.<br>Grizzly bear are also present in areas surrounding Hungry Horse Reservoir and the South Fork Flathead and Flathead Rivers, and are known or expected to occur east of Lake Pend Oreille. Species is unlikely to occur in the study area around Lake Pend Oreille because of the generally developed nature of this area and high degree of habitat fragmentation.<br>Critical habitat is proposed in Albeni Falls study area near Pend Oreille. | Libby<br>Hungry Horse | Operations under No Action Alternative are not expected to adversely impact habitat or individuals using the habitat in the study area. This is based on previous consultations for grizzly bear (USFWS 2000). |
| Columbian white-tailed deer | *Odocoileus virginianus leucurus* | ESA status: T<br>CH: None | Lower Columbia River bottomlands, elevations about 10 feet above sea level, open to forested. | Region D: High – high overlap between this portion of the affected area and species range. | Downstream of Bonneville | Same as existing conditions. |
| California sea lion | *Zalophus californianus* | ESA status: None<br>CH: None | Coastal waters and estuaries of the West Coast. | Region D: High – numerous documented detections at Bonneville Dam and downstream. | Downstream of Bonneville, occasionally to The Dalles Dam. | Same as existing conditions. |
| Steller sea lion | *Eumetopias jubatus* | ESA status: None<br>CH: None | Coastal waters and estuaries of the West Coast. | Region D. High – numerous documented detections at Bonneville Dam and downstream | Downstream of Bonneville | Same as existing conditions. |
| Southern Resident killer whale Distinct Population Segment | *Orcinus orca* | ESA Status: E<br>CH: None | Pacific Ocean between Cape Flattery, Washington, and Point Sur, California. | None – does not occur in the study area but may be affected by changes in prey base (Chinook and chum). | None | Operations under No Action Alternative are not expected to adversely impact habitat or individuals using the habitat in the study area. Same as existing conditions. |
| **Birds** | | | | | | |
| Yellow-billed cuckoo | *Coccyzus americanus* | ESA status: T<br>CH: Proposed | Low elevation, open woodland and deciduous riparian vegetation adjacent to rivers and streams in western United States.<br>Tall cottonwood and willow forests serve as foraging sites. Adjacent suitable, less preferred habitat includes overgrown orchards and abandoned farmland. Species requires relatively large (>49.5 acres) continuous patches of multi-layered riparian habitat for nesting. Also known to nest in early to mid-successional native riparian habitat.<br>Proposed critical habitat does not occur in the Columbia River Basin. | Region A: Low – summering yellow-billed cuckoo range extends into the study area in Montana; however, there are no documented occurrences in the study area.<br>Region B: None – while current range includes the study area below Albeni Falls Dam downstream of Newport, Idaho, there are no known occurrences. However, there may be transient individuals in the study area.<br>Region C: Low – there are no known breeding populations in Oregon (Marshall, Hunter, and Contreras 2003). In Idaho there is reported breeding on the Snake River (Cavallaro 2011) in the area of Twin Falls.<br>Region D: Low – No known breeding populations. Limited to transient individuals. Last recorded observation west of Cascade Range occurred at Sandy River delta in Oregon in 2009, 2010, and 2012 (Withgott 2012; USFWS 2013). | Study area is within the range of yellow-billed cuckoo. | Operations under No Action Alternative are not expected to adversely impact habitat or individuals using the habitat in the study area. |
| Bald eagle and golden eagle | *Haliaeetus leucocephalus*<br>*Aquila chrysaetos* | ESA Status: none<br>CH: none<br>Bald and Golden Eagle Protection Act | Bald eagle roost and nest in large trees adjacent to the river shoreline.<br>Golden eagle roost and nest high on rocky cliffs and talus. | Regions A, B, C, and D. Year-long residents breeding from late January through August with peak activity in March through July. They may also move downslope for wintering or upslope after the breeding season (Polite and Pratt 1999; Technology Associates 2009). | Throughout the study area. | Operations under No Action Alternative are not expected to adversely impact habitat or individuals using the habitat in the study area. |
| Streaked horned lark | *Eremophila alpestris strigata* | ESA status: T<br>CH: Designated | Dredge material disposal sites, open grasslands, dunes, sandy beaches. | Region D: High – high overlap between this portion of the affected area and species range. | Downstream of Bonneville | Same as existing conditions. |

| Common Name | Scientific Name | Status of Species and Critical Habitat | Habitat | Potential for Occurrence | Projects Where Species Occurs | Effects of No Action Alternative |
|---|---|---|---|---|---|---|
| **Plants** | | | | | | |
| Ute ladies'-tresses | *Spiranthes diluvialis* | ESA status: T<br>CH: None | Cobbly sand, shingly sand, gravelly sand, or sandy loam of wet meadows, stream or lake margins, and abandoned stream meanders, riparian sandbars, and sub-irrigated springs and seeps. | Region B: High – they occur at higher elevations, along riverine areas, and do well within disturbed areas. | Grand Coulee<br>Chief Joseph | Operations under No Action Alternative are not expected to adversely impact habitat or individuals using the habitat in the study area. This is based on previous consultations for Ute ladies'-tresses (USFWS 2000). |

Note: C = Candidate for listing; CH = Designated Critical Habitat; E = Endangered; PT = Proposed for listing as Threatened; T = Threatened.

**SUMMARY OF EFFECTS**

Under the No Action Alternative, current mitigation measures, such as juvenile fish transport, salmon and steelhead hatchery production, and avian predation control, would continue, affecting prey availability in the lower Columbia River. Water and sediment quality conditions (water temperatures, thermal conditions, nutrients, and pollutants) and their effects on wildlife would continue under the No Action Alternative. Patterns of erosion and subsequent sediment accumulation behind the Federal dams would continue, trapping potential contamination behind the dams, leading to bioaccumulation in benthic and aquatic organisms. Furthermore, trapping sediments behind the dams disrupts natural sediment transport processes, increasingly resulting in downstream reaches becoming starved of sediment. As a consequence of this, accretion processes in the lower river are diminished, leading to loss of wetlands and mudflats. These patterns are expected to continue under the No Action Alternative. Ongoing actions for impacts to vegetation and wildlife in Regions A, B, C, and D would continue, including protection, mitigation, and enhancement of wildlife habitat as discussed in Section 5.2.1.

As dam operations, and the frequency, timing, depth, and duration of flows throughout the Columbia River Basin, would be similar to existing conditions, the driving ecological and anthropogenic processes that currently influence wildlife habitat and populations would remain largely consistent over the 25-year period of analysis. Because the current probability of inundation for the existing active floodplains would continue under the No Action Alternative, there would be no change in floodplain benefits. Riparian vegetation that is dependent on the natural riverine freshet, such as cottonwoods, would continue to decline in some areas where the hydrology of the floodplains has been altered. Unless otherwise described below, the amount and type of vegetation wildlife habitat and wildlife species present under the No Action Alternative would remain consistent with that described in Section 3.6.2 (Affected Environment).

Under the No Action Alternative, wildlife would continue to be influenced by availability of habitat, natural processes including fire and human-wildlife interaction through recreation, including hunting. Where human disturbance increases, wildlife may experience adverse effects and temporarily or permanently relocate to alternative habitat areas with little or no disturbance. Conversely, wildlife would experience beneficial effects from implementation of habitat restoration actions to meet local, state, and regional habitat objectives. The rich diversity and abundance of wildlife throughout the Columbia River Basin would continue in a manner similar to existing conditions described in Section 3.13.1, as would the seasonal fluctuations in wildlife numbers and diversity resulting from the presence of large numbers of migratory wildlife. Mammals, migratory game birds, reptiles and amphibians, and terrestrial and aquatic invertebrates would remain abundant in the study area. Winter conditions that influence predator/prey relationships are not expected to change from current conditions, and existing patterns of predation would continue.

#### *3.6.3.3 Multiple Objective Alternative 1*

Chapter 2, *Alternatives*, contains a description of how the CRS would be operated under MO1. A full description of the alternative can be found in Section 2.4.3.

**REGION A – LIBBY, HUNGRY HORSE, AND ALBENI FALLS DAMS**

Three operational measures would be implemented at Libby Dam, which differ from current operations as described under the No Action Alternative: the *Modified Draft at Libby*, *December Libby Target Elevation*, and *Sliding Scale at Libby and Hungry Horse* measures. Refer to Chapter 2, *Alternatives*, and Table 2-3 for a description of these measures.

During spring months and the early part of the growing season, water levels under the *Modified Draft at Libby* measure would drop approximately 2.5 feet below average to account for deeper drafts. Changes in a high- or low-water year may have another effect. The increase in annual peak outflow from Libby Dam has a small impact on peak flows downstream in the Kootenai River; however, decreased outflow in May generally translates to a decrease in freshet peaks. Following an increase in water surface elevations in February and March, water surface elevations in the Kootenai River would decrease in April and May by approximately 1 foot in average years from the implementation of the *Modified Draft at Libby* measure under MO1. This change in water surface elevations would potentially alter wetland habitat types throughout the Kootenai River.

By implementing the *December Libby Target Elevation* measure, Libby Dam would be operated to reduce the frequency of overdrafting the reservoir when years are drier than initially forecast by establishing a new end-of-December draft target of 2,420 feet NGVD29 (NAVD88), an increase of 9 feet from the No Action Alternative. This would allow for less variability in pool elevation as opposed to the wider range of December elevations under the No Action Alternative. As a result of this new draft target under the *December Libby Target Elevation* measure, winter water levels in the reservoir would increase, peaking in January when the pool elevation would be 7 feet higher than the No Action Alternative. The primary habitat affected by the new end-of-December water surface elevation would be the barren area, or barren zone.[2] Implementing the *December Libby Target Elevation* measure would reduce the spatial extent of the barren area by approximately 9 (vertical) feet around the reservoir during most years, increasing the wetted area during the winter months. The area of land between 2,411 feet and 2,420 feet would not freeze as in previous years under the No Action Alternative, allowing for potential vegetation establishment in the spring as a result of increased viability of seeds that do not freeze over the winter.

---

[2] A change in the elevation is discussed as a vertical change in elevation and it is recognized that this change does not translate into a 1:1 relationship with the area impacted. For example, an elevation change of 9 feet does not correspond to a horizontal change of 9 feet. Because terrain below the water surface of the reservoir was not available for this analysis, the area impacted by a vertical change in elevation was not calculated and it is therefore unknown how much area would be directly impacted by changing pool elevations. However, the effects of this change can be assessed qualitatively, as described in the narrative above.

The *December Libby Target Elevation* measure would provide additional stability to beaver (*Castor canadensis*) colonies on the lower Kootenai River due to decreased variability in December flows. The beaver is considered an "ecosystem engineer," constructing dams that impound water and increase, diversify, and support wetland vegetation communities (Wright, Jones, and Flecker 2002). The *December Libby Target Elevation* measure would have trickle-down effects immediately benefiting aquatic wildlife and herbivores, such as amphibians and white-tailed deer (not Columbia White-tailed Deer).

Operational changes at Libby Dam under MO1 can be seen throughout the Kootenai River system during most months but are increasingly diluted from tributary inputs downstream of the dam from the Fisher, Yaak, and Moyie Rivers. The largest downstream changes occur in December when outflows decrease by 4 to 5 kcfs, rapidly followed by an increase in outflows in February of up to 3.3 kcfs. Operational changes would cause water levels to fluctuate at the Kootenai Falls Wildlife Management Area (RM 202) from 1.3 feet lower in December (relative to the No Action Alternative) to an increase of 1.2 feet in February and March. Water level fluctuations in March would inundate narrow bands of emergent vegetation along the Kootenai River shoreline adjacent to the wildlife management area at the start of the growing season. However, the wildlife managed at Kootenai Falls Wildlife Refuge are primarily upland species, including mule deer, bighorn sheep, and white-tailed deer (MFWP 2016). Under MO1, changes to wetland vegetation from the proposed operations would not have measurable effects to species in this area.

The *Sliding Scale at Libby and Hungry Horse* measure would increase growth and expand wetlands where they occur at tributary confluences, like the Tobacco River, especially late in the summer months when conditions for wildlife are generally warmer and drier. The biologically rich transition zone between emergent herbaceous, and forested and scrub-shrub wetlands would shift laterally, increasing the overall spatial extent of wetland habitats in the immediate vicinity of Lake Koocanusa relative to the amount of wetland habitats that occur under the No Action Alternative.

Higher water surface elevations within Lake Koocanusa from the *Sliding Scale at Libby and Hungry Horse* measure would also increase the area of open-water habitat and reduce the barren area, and therefore decrease the rates of predation of small wildlife. Higher water levels during summer months (June through September) would increase the inundation levels within adjacent wetlands during the growing season, resulting in a reduction of existing emergent wetland vegetation or a transition in plant communities to species that can tolerate patterns of regular inundation. These changes would impact nesting waterfowl by reducing the amount of woody vegetation along the shoreline available during the breeding season.

With spring and summer, water levels in the Kootenai River are typically several inches lower compared to the No Action Alternative, MO1 operational changes at Libby Dam would likely cause small habitat changes, such as drying of shallow backwater areas. This could affect wildlife such as the western toad by causing immotile amphibian eggs to desiccate.

Aquatic invertebrates, like caddisflies and stoneflies, would experience similar interruptions in life cycle, which could lead to changes in the food web and a corresponding decrease in food availability throughout the area thereby affecting wildlife species that feed on them (See Section 3.5, *Aquatic Habitats, Aquatic Invertebrates, and Fish*).

Under MO1, Hungry Horse reservoir would experience a deeper drawdown during most months that would expose more of the barren area surrounding the reservoir and would create higher predation risk for wildlife. During late fall and winter, the barren area would not be noticeable to wildlife, as the area is typically covered in snow and the reservoir freezes over for many months. During the spring and early fall, when the barren area is exposed and would be larger than that which occurs under the No Action Alternative, wildlife would be at increased risk of predation as they traverse the area to reach the reservoir. This would be a minor effect on wildlife.

The increased barren area would have negligible (if any) impact on birds in the area. The time period when the reservoir would experience the greatest change under MO1 is during the winter months when there is little bird activity at Hungry Horse.

Downstream of Hungry Horse Reservoir, along the South Fork Flathead River, the effects from implementing MO1 would be negligible. The changes in water level are typically less than 0.2 foot (approximately 2.4 inches). This marginal change would not alter floodplain function, wetland habitats, vegetation communities, or wildlife populations in the Hungry Horse study area compared to the No Action Alternative. Current trends associated with plant communities, including willows and cottonwoods, are expected to continue similar to the trends described under the No Action Alternative. While there would be a small increase in water surface elevation in the Flathead River downstream of Hungry Horse Dam in August and September due to increased outflow for water supply through implementation of the *Hungry Horse Additional Water Supply* measure, the effects of this increased water on existing habitats would be negligible In the Flathead River, effects would be even less pronounced and would become increasingly diluted downstream.

Under MO1, no structural changes would be implemented at Albeni Falls Dam or within the Albeni Falls study area. Similarly, no changes would be made to Albeni Falls Dam operations in most water years. Results from H&H modeling and analysis show that higher flow periods in the winter and spring would be slightly lower due to changes at Hungry Horse, resulting in slightly lower water levels compared to the No Action Alternative. The differences in monthly water surface elevations (less than 6 inches) is typically within the expected range of natural variability. Thus, negligible impacts to floodplains are expected from the implementation of this proposed measure. Because the annual average probability of inundation would remain unchanged from current conditions, negligible impacts to floodplains are expected.

In most years, implementation of MO1 would have no effect on vegetation or wildlife in the Albeni Falls study area and conditions would remain unchanged from the No Action Alternative. However, during high-flow conditions, water surface elevations downstream of the dam would decrease by as much as 5 inches in November relative to patterns observed under the No

Action Alternative. Despite lower water surface elevations, implementing the *Hungry Horse Additional Water Supply* measure under MO1 is not expected to alter the type, location, or abundance of vegetation, floodplain function, wildlife habitat, or wildlife populations in the Albeni Falls Dam study area. Because river levels would drop less than 6 inches during high water events outside of the growing season, it is highly unlikely that habitats would functionally change in response to the *Hungry Horse Additional Water Supply* measure. Consequently, no effects to wildlife populations are expected from the implementation of this proposed measure.

The operational changes from implementing MO1 would result in small changes in the Lake Koocanusa study area and would therefore have negligible effects on wildlife populations. Similarly, MO1 is not expected to impact any wildlife populations downstream of Libby, Hungry Horse, or Albeni Falls Dams. Similar to the No Action Alternative, trends of reduced riparian vegetation establishment due to higher winter flows would be expected to continue, as observed in the Flathead River study area. The gradual loss of deciduous woody plant communities and conversion to coniferous uplands and forested and scrub-shrub wetlands would lead to a loss of biodiversity and degraded ecosystem function in the Libby Dam study area (Kootenai Tribe of Idaho [KTOI] 2013). Despite these changes, it is anticipated that habitat conditions in Region A and sections of the Kootenai, Flathead, and Pend Oreille Rivers downstream from dams would stabilize after several years under MO1. Efforts to restore black cottonwood galleries, as described under the No Action Alternative, would continue.

The operational changes at Libby Dam from MO1 would also be evident in downstream reaches of the Columbia River, as discussed in the Regions B and D sections below.

In regard to potential effects in Canada, the effects to vegetation and wildlife resources and their habitats under MO1 are expected to be similar to the effects described for the United States portion of Region A.

**REGION B – GRAND COULEE AND CHIEF JOSEPH DAMS**

At Grand Coulee Dam, there are five operational measures under MO1 that have the potential to impact habitats, floodplains, and wildlife populations in the study area: the *Update System FRM Calculation*, *Planned Draft Rate at Grand Coulee*, *Grand Coulee Maintenance Operations*, *Winter System FRM Space*, and *Lake Roosevelt Additional Water Supply* measures. Collectively, these measures influence water surface elevations in Lake Roosevelt and downstream reaches of the Columbia River, as well as the outflow from Grand Coulee Dam, resulting in changes to the quantity, quality, and distribution of habitats in the study area. Changes to wildlife habitats have a corresponding effect on wildlife populations in the study area.

The *Winter System FRM Space* measure would decrease water surface elevations immediately upstream of the dam in Lake Roosevelt by approximately 5 to 6 feet during the winter months (January through March, with less than a foot difference in April) in most years, when compared to the No Action Alternative. The effects of this decrease would be evident throughout the Lake Roosevelt system all the way to U.S.-Canada border, but decrease to a loss of approximately 3 feet in elevation (or depth) farther upstream. Such a large decrease in water surface elevation across the study area would impact wildlife habitat similar to the changes expected at Libby Dam. The frequency and duration of drying conditions would increase for areas with emergent herbaceous and forested and scrub-shrub wetlands, and these habitats would transition into upland habitats, or plant communities in these habitats would transition to predominantly species more tolerant of dry conditions. This would change plant composition and distribution, or reduce the overall quantity of wetland acreage.

The *Lake Roosevelt Additional Water Supply* measure would increase the exposure time of the barren area around the perimeter of Lake Roosevelt in response to decreased water surface elevations in the winter and spring months. Because the growing season (April through October) overlaps with decreased water surface elevations in Lake Roosevelt, changes to growing conditions and plant communities would result from implementation of this measure.

These changes to habitat are expected to reduce overwintering habitats for wintering waterfowl and diving ducks, as well as wildlife populations supported by wetland habitats in the Grand Coulee Dam study area. The gradual loss of deciduous woody plant communities and potential conversion to upland plant communities would lead to a loss of biodiversity and degraded ecosystem function. However, despite these changes it is anticipated that habitat conditions in Region B and sections of the Columbia River downstream from Chief Joseph Dam would stabilize after several years under MO1.

Under the *Planned Draft Rate at Grand Coulee* and *Winter System FRM Space* measures, lower water levels in Lake Roosevelt would persist longer into the spring months compared to the No Action Alternative. As a result, emergent herbaceous and forested and scrub-shrub wetlands would transition to drier habitat types and the composition of plants would shift to primarily species more tolerant of drier conditions, thereby reducing the overall quantity, distribution, or functional quality of wetland habitats in the study area. As a result, these changes would negatively impact the health and development of forested and scrub-shrub wetlands where gallery forests or tree stands, such as stands of black cottonwood (*Populus trichocarpa*), are the predominant tree species supporting bald eagle nests in the study area. Shallow backwater habitat would become intermittently dry as water surface elevations decrease, causing immotile amphibian eggs, like those of the western toad, to desiccate. Because of the lack of vegetation or other habitat cover in the barren zone, small mammals (i.e., mice, voles, and shrews) would experience increased rates of predation, as they would be more susceptible to predators foraging along the reservoir shoreline. Areas that establish as emergent herbaceous wetlands would provide increased protection for some animals, as well as increased overall biodiversity and productivity along the reservoir.

Changes to water levels or fluctuating water conditions in Lake Roosevelt in response to the *Winter System FRM Space* measure would impact foraging behaviors of diving ducks and other waterfowl by changing the quality and quantity of open-water habitat and shallow-water areas for foraging. The common loon (*Gavia immer*) overwinters in Lake Roosevelt, foraging in open-water habitats and shallow-water areas with emergent or submerged vegetation from October through March. When water surface elevations are lower, the availability of open-water habitat with suitable foraging material would be reduced. When shallow-water areas become exposed, emergent vegetation would no longer be available as forage, decreasing overwintering habitat conditions for wintering waterfowl.

Decreased water surface elevations in Lake Roosevelt associated with MO1 would influence predator populations, as well as ungulate populations in the Grand Coulee Dam study area. Increasing the barren area during winter under lower water surface elevations would impact ungulate populations, such as bighorn sheep. More barren area habitat would provide increased area for mountains lion to hunt and kill prey animals, which could result in higher predation rates on the local ungulate (i.e., elk, deer, and bighorn sheep) population.

Upstream of Grand Coulee Dam, the decreased water surface elevations during the winter and early growing seasons would impact plant communities and wetland habitats adjacent to the shoreline, any changes in those habitats (e.g., changed plant composition or distribution, or reduction in overall quantity of wetlands) would impact foraging and sheltering habitats, resulting in effects to migratory wildlife, such as birds or large mammals, utilizing these areas.

The operational changes at Grand Coulee Dam under MO1 are also evident throughout the Columbia River System, as discussed below in Region D. In regard to potential effects in Canada, the effects to vegetation and wildlife resources and their habitats under MO1 are expected to be similar to the effects described for the United States portion of Region B.
